UL MU-MIMO and spatial reuse are promising technologies customers can look forward to with newer devices and upgraded drivers with Wi-Fi 6e/7 wireless adapters. Common Wi-Fi 6 wireless adapters in notebooks, phones, and tablets have 2x2 MIMO with 80 MHz channel width and a maximum PHY rate of 1200 Mbps with drivers that have enabled DL MU-MIMO and both UL and DL OFDMA. When more than one of these devices uses the wireless network at the same time these multiple user technologies kick in. At close range with high traffic demand from more than one such device downlink frames are MU-MIMO while uplink frames are OFDMA. Further away, under low signal to noise ratio conditions, the downlink and uplink frames are OFDMA. The beamforming feedback in these devices provides the ten angles every fourth subcarrier over the full 80 MHz channel width. DL MU-MIMO provides aggregate throughput that is not possible with SU operation. OFDMA improves the uplink link budget, not at the very channel edge where connectivity is soon lost, but increased PHY rates and aggregate throughput in the upload for signals as low as -86 dBm in an 80 MHz OFDMA channel.

Wireless adapters are readily available for notebook computers and some phones and tablets with a maximum PHY rate of 2400 Mbps. These devices have 160 MHz channel width in the 5 and 6 GHz band with 2x2 MIMO. Getting the full broadband service of 1.2 Gbps or higher is readily delivered in SU mode. With a maximum PHY rate of 2400 Mbps, there is a healthy margin of error to deliver 1.2 Gbps service, the MCS rate can drop to 6 when the channel is unused by neighbors or the PHY rate can be close to the maximum and still deliver 1.2 Gbps while sharing the spectrum with neighbors. These devices take full advantage of DL and UL OFDMA when several devices are active at the same time. These devices also can improve download aggregate throughput with DL MU-MIMO. Download speed from two 2400 Mbps PHY devices with DL MU-MIMO exceeded a throughput of 2.1 Gbps. This is not possible with SU operation. Still, this only worked with both computers in the same room and even then, only occasionally. The beamforming feedback from the 160 MHz channel width devices was not sufficient for robust DL MU-MIMO. Still, with the SU mode able to deliver 1.2 Gbps speeds with plenty of margin and both DL and UL OFDMA working well, this does not seem to be much of a concern for overall user experience. Certainly, customers will always benefit from 160 MHz channel width devices.

Finally, the benefits of DL MU-MIMO and UL OFDMA were illustrated with two television sets streaming video while a phone and a tablet downloaded TCP at maximum throughput. The video streaming works flawlessly with periodic bursts of throughput of about 50 Mbps averaging out at about 10 Mbps. Neither the phone nor the computer is capable of downloading over 1 Gbps since their maximum PHY rate is 1200 Mbps. Yet, the sum of the throughput of all four devices quite often exceeded 1 Gbps thanks to DL MU-MIMO working in tandem with UL OFDMA.

1. Introduction

Network reliability and resilience are usually only as effective as the weakest component in the entire network system. The words ‘reliability’ and ‘resilience’ are used in various industries, and have been used more frequently in recent years. They may have slightly different meanings depending on the context, but with respect to network systems, reliability means “it’s there when we expect it to be”. Resilience is a bit more multi-faceted; it means “how well are we prepared for, and how easily and quickly can we bounce back from extreme or prolonged events”. Both require significant investments.

Another way to think of the relationship is this: reliability is the outcome and resilience is how you achieve that outcome. Reliability can be expressed as an availability key performance indicator (KPI), say 99.999% uptime, while resilience is all the detailed technical planning and design needed to achieve that, and for a critical facility, one of the main components is a good grounding and bonding system.

Knowing that critical facilities are foundational to the network and the delivery of lifeline telecommunications services, it is essential that all of their infrastructure systems are fully functional at all times. Cable operators always focus on maintaining robust and redundant systems, but how often do they overlook the proper grounding and bonding of these infrastructure systems?

A single electrical storm or utility surge can wreak havoc on network equipment in a critical facility, often creating significant performance issues that cost valuable time and money to repair, and can potentially result in a loss of customers. Human error also contributes significantly to these unfortunate, but largely avoidable consequences.

The proper grounding and bonding of electrical systems and network equipment in a critical facility is an indispensable element in the assurance of business continuity in the broadband and telecommunications industry, therefore high priority must be given to the grounding and bonding system from design and installation to commissioning and ongoing maintenance.

ANSI/SCTE 275 2021 brings together the best practices and cable industry expertise and experience, as it endeavors to guide cable operators in the deployment of grounding and bonding systems that will enable them to meet their reliability targets and ensure resilience of the network.

This paper will give an overview of the development and contents of the ANSI/SCTE 275 2021 standard, explain how it can improve network resilience, and provide some guidance on how best to deploy a grounding and bonding system that will ensure just that.

2. Development And Benefits Of The Standard

In early 2018, it was determined that cable operators could greatly benefit from an aggregation of grounding and bonding best practices at the very least, and perhaps even an industry standard in this area. A grounding and bonding task force was formed to explore the opportunities around various aspects of telecommunications grounding and bonding practices.

The task force met over a period of three years, and reviewed nearly 100 existing grounding and bonding standards currently being used by cable operators, as well as those from electrical, fire safety, and telecommunications carrier industries. There were contributions to the standard that eventually became ANSI/SCTE 275, “Electrical Grounding and Bonding for Cable Broadband Network Critical Facilities” from Cox, Comcast, Rogers, Shaw, and Charter.

There were a number of challenges, benefits and opportunities that came to light while this project was ongoing:

- Due to the varying histories, organizational compositions and customer services both common and unique to these cable operators, there were consequent variations in intent and approach, as well as the necessary level of detail, within the existing cable operator grounding and bonding standards. For example, there are inherent differences in the AC power and DC power grounding and bonding systems design, data center and headend design, vendor-driven requirements, and the hodgepodge of practices found in legacy acquisition sites. Additionally, the presence of a telephony switch would necessitate particular practices around isolated grounding specifications that are not present (or needed) in other critical facilities.
- To assist with collecting and aggregating the similarities and differences between cable operator specifications, a ‘matrix’ document comparing the specific practices and requirements (or lack thereof) in each grounding and bonding category (or sub-category) for each cable operator was developed and maintained.
- ANSI/SCTE 275 is the first grounding and bonding standard specifically developed for cable operators in the telecommunications industry. It brings together the best practices from various industry sectors, and outlines minimum standards for ensuring network reliability and continuity of cable operators service delivery to customers.
- Additional benefits of ANSI/SCTE 275 are as follows:
 - It lays the groundwork for safety and reliability, and is a key component to the resilience of critical facilities in all grounding and bonding system lifecycle phases - from the engineering design phase, through installation, then on to commissioning and periodic maintenance. By following this standard, cable operators can help assure business continuity.
 - The standard can be used to ensure vendors are using a standardized approach to grounding and bonding systems through each of the lifecycle phases.
 - A commissioning checklist is included in the appendix, which can assist engineering and operations staff with ensuring the grounding and bonding system is properly installed.
 - Proper grounding and bonding are foundational to personnel safety and network reliability, yet it is often the least understood system in a critical facility. ANSI/SCTE 275 will be able to be used as an educational tool for engineers and technicians, and better enable them to ensure continued reliable operation of all infrastructure systems within the critical facility.

3. Main Purposes Of Grounding And Bonding

The main purposes of grounding and bonding in general, and at a high level, are all about safety of personnel and reliability of network and infrastructure equipment systems. The essential elements or qualities for a good grounding and bonding system are primarily that it has a low impedance, and secondarily that it be dependable throughout the lifetime of the critical facility. This is typically ensured through properly sized grounding and bonding cables, short cable runs without sharp turns, and connections that are resistant to corrosion or loosening over time.

There are five principal objectives for providing a dependable low impedance grounding and bonding system. These include:

- 1) Personal Safety: From a “safety first” perspective, we certainly want to minimize the development of any electrical potential that could create a shock hazard to personnel, within and between metallic frames and structures.
- 2) Equipment Protection: It is critical, and therefore required, that adequate fault current paths be provided so any installed overcurrent devices can disconnect faulted circuits to reduce the possibility of fire and limit damage to the critical equipment. System design and operational procedures for electrostatic protection of equipment is also required.
- 3) Equipment Operation: Proper grounding provides an equalized ground reference to electronic communication circuits connected to the ground plane.
- 4) Electrical Noise Reduction: Proper bonding assists in the reduction of electrical interference by maintaining low impedance paths between ground points throughout the communication system.
- 5) Reliability: Naturally, to protect our investment, we should install a grounding system that resists deterioration, requires minimal maintenance, and ensures network service continuity.

Cable operators must of course meet the basic requirements of applicable national and local electrical and safety codes, and comply with any additional requirements set forth by the local authority having jurisdiction (AHJ).

Telecommunications services providers - including cable operators - recognize that these minimum requirements are often not stringent enough to fulfill the industry-specific protection needs of their modern critical facilities, and so go far beyond the minimum requirements as needed to meet the principal objectives and assure business continuity.

4. Exterior Grounding

Although unwanted electrical disturbances may come from both internal and external sources, the most egregious events come from outside the critical facility. Primarily for that reason, and to provide a commonsense flow to the outline and description of the various elements of a grounding and bonding system, the ANSI/SCTE 275 standard is organized from an “outside-to-inside” perspective. This paper will address the important aspects of grounding and bonding in the ANSI/SCTE 275 in the same fashion.

The exterior grounding system establishes a direct path of known low impedance for all power, communication, and signal systems. The exterior grounding system also provides a path to earth for the discharge of lightning strikes, restricts step and touch potential gradient in the area accessible to persons, and assists in the control of electrical noise in signal and control circuits by minimizing voltage differentials, ensuring network continuity through any of these events. Currents associated with power faults and noise typically use this path to return to their source, whereas currents associated with lightning use this path to equalize the charge established on the earth’s surface during storms.

Any ground system installation, whether commercial, industrial, or residential, requires a certain target resistance-to-earth value be met. The industry standards vary on acceptable and maximum values, and

environmental or geographic conditions will affect the application of some of these grounding systems. In general, the lower resistance the better, and the target for cable operators is typically 5 Ohms or less, and 25 Ohms would be considered a maximum level.

4.1. Soil Resistivity

The first task in the design of a good ground system is to test the resistivity of the soil surrounding the critical facility. The ground system design and associated components can only be determined after we know what we have to work with. For the soil resistivity, as is the case for the ground system resistance, a lower value is better.

The resistivity (typically measured in Ohm-m) of a soil depends largely on the types of materials that are contained in the soil, as would be the case for metals and any other materials commonly considered conductive. Soils can contain various materials including clays, sands, rocks, shale, etc. It is this combination of materials that largely determines how conductive the soil will be to electric current flow. In addition, the resistivity of a specific type of soil will vary seasonally because of its moisture, temperature and chemical content:

- The greater the moisture content, the lower the resistivity.
- The higher the temperature, the lower the resistivity.
- The greater the salt content, the lower the resistivity.

Though there are several acceptable methods for measuring soil resistivity, the one most commonly used is the 4-point method. In this method, four small-sized (typically 18-inch) electrodes are driven into the earth at the same depth, in a straight line and equidistant from each other. A known current from a constant current generator is passed between the outer electrodes. The voltage drop, which is a function of the resistance, is then measured across the two inner electrodes. Greater detail on the application of best practices for measuring soil resistivity are described in the latest IEEE Standard 81, “Guide for Measuring Earth Resistivity, Ground Impedance, and Earth Surface Potentials of a Ground System”.

4.2. The Ground Ring

Once the soil resistivity has been measured, the external ground system can be designed to the specific resistance-to-earth target value. This is accomplished mainly by the ground ring and driven rod electrodes, and depending on the characteristics and limitations of the surrounding earth, may include flat plates, rebar, Ground Enhancement Material (GEM) or chemical ground rods, which are typically hollow copper rods filled with an electrolytic salt mixture.

ANSI/SCTE 275 spells out the best practices and minimum standards for cable operators to go by in specifying an external ground system. The ground ring is typically a 2/0 AWG (minimum #2 AWG) copper conductor buried 30 inches below grade or below the frost line, whichever is greater. The ground rods should be ¾ inch x 10 ft long, buried to the same depth as the ring, spaced 20 feet apart, and exothermically welded to the ground ring. Additionally, there should be several inspection wells or hand holes at key locations around the ring.

The external ground system is typically best designed by engineering companies that specialize in this, and there are quite a few good software programs that are utilized for this purpose; however most electrical engineering firms should be capable of designing an adequate ground system.

Finally, ANSI/SCTE 275 gives direction for the proper grounding of exterior objects like towers, guy wires, satellite dishes, masts, fencing and other metallic objects, all of which should be tied to the external ground ring.

Figure 1 – Exterior Ground Ring Conductor Exothermically Welded To A Ground Rod

5. Interior Grounding

The interior grounding system is the most complex portion of a critical facility grounding and bonding system. It also has the most variations in application between the cable operators, and between the site types (i.e. headend, data center, edge hub site), not to mention the variances introduced by legacy and acquisition sites. While there are good established references there was no detail specific to this industry that could be seen as a standard prior to ANSI/SCTE 275 being released.

Still it was possible to detail minimum standards as well as recommended targets for best practices, knowing that cable operators must weigh costs to upgrade against benefits received. For example, if a legacy site has a #2 AWG ground conductor running along the rows of racks (known as an aisle feeder), and the company specification calls for a 2/0 AWG aisle feeder (the size difference between #2 and 2/0 is not insignificant, but neither is it a ‘show-stopper’; it is a commonly used size – especially in legacy sites, and is acceptable as a minimum size in ANSI/SCTE 275), it may be better to wait until an equipment refresh or new racks are installed to do the upgrade, whereas if there is no aisle feeder at all, it should be rectified more immediately.

5.1. Various Grounding System Methods/Theories/Approaches

Most of us have heard the anecdote involving “ask three experts, and you’ll get four opinions”. In the world of grounding, it is no different. Grounding and bonding - is it art, is it science, is it both? The answer is “Yes”.

When you walk into any cable operator headend, telecommunications carrier central office, commercial or military grade data center or critical facility, you will find a variety of grounding methods, and a mixture of some in the same facility, on purpose or by accident, and there are benefits and drawbacks to each.

The main types are Star and Mesh bonding networks, which may or may not be Isolated. What we are mainly talking about is the bonding of equipment racks to the interior grounding system, which ultimately ties to the Master Ground Bar (MGB). Here is an easy way (I hope) to understand it:

- Star means each item (network equipment rack or cabinet) is independently grounded to a dedicated Frame Ground Bar (FGB) which taps into a conductor that goes to a single “point”, typically an area ground bar. Most cable and telecom critical facilities use this method, primarily, but not exclusively.
- Mesh means multiple items are bonded to each other in a sort of “grid” fashion. This is typically done in a raised floor data center.
- By Isolated we really mean a “single-point ground” connection to a ground bar, or perhaps to a specific section of a ground bar is involved. A Mesh or Star sub-“area” may have a connection of this type.

These types may be mixed together in a critical facility, the proper use of which may be dictated by the specific grounding needs of the types of equipment, whether they are AC or DC powered, whether they have the chassis bonded or isolated from the neutral or grounded conductor, etc.

Figure 2 – Acceptable Interior Grounding Methods - Network Equipment Racks

5.2. Common Grounding And Bonding System Requirements

The ANSI/SCTE 275 goes into great detail about best practices of interior grounding and bonding to racks and cabinets, exterior cable entry points, the utility service entrance connection, DC plants and batteries, and multi-floor building applications.

Regardless of the application within the building, there are a few practices that are required for nearly all of them wherever possible:

- Each grounding or bonding connection should be dedicated if possible; no “daisy-chained” or back-to-back connections are permitted in a critical facility.
- Mechanical connections are not permitted to be used for grounding or bonding in a critical facility. All connections should be made using crimp lug or tap connectors.
- Connection of dissimilar metals is prohibited in critical facilities.
- Two-hole lugs should be used wherever possible to prevent rotation and loosening of the lug during or after installation. For some small ground bars within racks or for equipment chassis that provide only a single-hole lug connection, serrated washers should be used.
- Any paint should be scraped off surfaces and anti-oxidation grease should be used for all grounding and bonding connections.
- Ground cables shall “gracefully” flow in the direction of the MGB, as though downstream, with no sharp bends.
- Ground cables of all sizes shall have a minimum bending radius of 8 inches, and the angle of any bend shall not be less than 90 degrees.
- All ground cables that terminate to a ground bar shall be appropriately labeled at both ends.
- Grounding conductors shall be sized per National Electrical Code (NEC) table 250.122

5.3. The Master Ground Bar

The MGB is the primary element of the critical facility grounding and bonding system - it is the single point connection, or main common interface between all interior and most exterior grounding systems of the critical facility. It will typically have connections to the utility ground, the ground ring (two connections, if possible), building steel, cold water pipe, all building interior network equipment area auxiliary ground bars, the DC plant positive return bus, DC equipment frame ground bar, and finally, any cable entry ground bars.

It is very important for all of the conductors that are terminated to the MGB to be labeled. This is helpful for both administrative documentation, maintenance, and troubleshooting purposes when any ground anomalies are discovered.

Additionally, some cable operators employ what is called a PANI configuration of the conductors terminated to the MGB, in order to arrange them according to surge potentials by specific classifications of the grounding system elements. Each section of the MGB is labeled accordingly, and the PANI classifications are as follows:

P - Surge Producers: Typically conductors coming from Cable Entrance Ground Bars (CEGB), as well as generator, UPS, and transformer enclosures

A - Surge Absorbers: Typically contains connections to building steel, the exterior ground ring, the cold water pipe, and the incoming main AC service ground bar – also called the multi-grounded neutral bond

N - Non-Isolated ground zone equipment grounds: Typically includes Secondary Ground Bars (SGB) which are for equipment room ground conductors that include the cabinet/rack grounds, ladder rack, etc.

I - Isolated ground zone equipment grounds: Typically equipment associated with a digital telephony switch, logic grounds and the DC Plant reference ground

Finally, proper connections and cable sizing of the conductors terminated to the MGB help to achieve network reliability by increasing the resilience of the grounding system to ensure it will protect the operational integrity of the equipment and infrastructure within the critical facility.

Figure 3 – Master Ground Bar With PANI Configuration

6. Surge And Lightning Protection

Surge and lightning protection systems complement each other and represent the most efficient and cost effective way to ensure continuity of the network by preventing or mitigating any deleterious effects from voltage instability and high frequency electromagnetic disturbances which are known to cause the most damage to network equipment and infrastructure.

Lightning strikes and electric utility company switching can cause voltage surges on the incoming AC power feeders. To protect the critical facility from these voltage surges, a surge-protective device (SPD) meeting current UL standards is required to be installed at the main service switchboard (MSS) for each facility. The connecting leads should be kept as short as possible and there should be no severe bends in any of the leads. Additional SPDs may need to be installed on downstream AC panels as required by special circumstances for a specific facility, such as those located in areas with high lightning activity or unstable utility power. Care should be taken when specifying these additional devices to ensure they are properly coordinated with the upstream SPDs according to their permissible energy.

A roof mounted lightning protection system is designed to protect a facility by intercepting lightning flashes and conducting the lightning currents into the earth in a safe and efficient manner. A properly designed lightning protection system should protect the facility from structural damage that can be caused when lightning currents flow through a building's concrete and metallic superstructure. The roof mounted lightning protection system should connect to the facility buried ground ring through down lead conductors spaced in accordance with NFPA 780, "Standard for the Installation of Lightning Protection Systems".

A lightning protection system consists of air terminals, conductors, interconnecting conductors, down leads and all the fittings, brackets and support devices required to complete the system. The final installation should be inspected, and UL certified to indicate that it has been properly installed and is compliant to all national and local standards. All down leads should be tested to verify that they are making a low impedance connection with the buried ground ring.

7. Humidity And Electrostatic Discharge

Static electricity is created by the accumulation of stationary electrical charge on a body or conducting medium. As such it is a common phenomenon created by physical motion. Even circulating air currents can cause a charge build-up, especially during low humidity conditions. This electrostatic charge build-up discharges whenever the charge storing medium meets ground. These static charges can store up to as much as 40,000 Volts during the normal course of a human body walking across a nonconductive floor in a low humidity environment. If exposed to electrical static charges of these magnitudes, the static sensitive electronic components contained in a critical facility can become permanently damaged.

Some of the best practices detailed in ANSI/SCTE 275 are as follows:

- To avoid damage of electrostatic dissipative (ESD) sensitive devices the relative humidity (RH) should be ideally kept within the limits specified by ASHRAE TC9.9 and all manufacturer's requirements.
- Wrist straps and anti-static bags should be used by all personnel handling printed circuit boards and blade server type cards.
- There should be wrist strap test stations at all critical facility sites, and wherever sensitive electronic components are handled.
- ESD-rated grounded conductive floor tiles or mats should be installed near the base of each equipment rack.

By employing these best practices, cable operators will be better able to achieve reliability targets and ensure network continuity.

8. Commissioning And Maintenance

The commissioning of a critical facility's grounding and protection system installation shall be performed to ensure that the final installation meets or exceeds the original design intent so the facility will provide a safe and reliable environment for personnel and sensitive electronic equipment to operate, and help to ensure network resilience and thus meet reliability KPIs.

Commissioning entails the visual inspection of the interior and exterior grounding systems, lightning protection system, and SPD installations to verify that the electrical contractor has built these systems in accordance with the design engineer's drawings and specifications, as well as compliance to all applicable standards.

In addition, current measurements are made in all conductor connections to the MGB to identify any unwanted ground current loops in the system, and impedance measurements are made in the lightning protection down leads to verify they are connected to the buried ground ring.

Grounding system preventive maintenance is required periodically, to protect equipment and facility investments, as well as to ensure continuity of network resilience. Improper grounding and bonding, combined with the inevitability of internal and external power surges are the most likely reasons for network equipment failures from "unknown causes" and are often incorrectly attributed to equipment defects.

Replaced equipment will likely fail repeatedly unless the root cause is determined. Ongoing maintenance of the grounding and bonding systems helps to identify the potential causes for ground and surge protection issues before they happen.

9. Conclusion

As we are all aware, these are unusual times, and regardless of the political, environmental or biological climate that cable operators find themselves having to navigate and make adjustments for, there are certain non-negotiable elements of doing business in an uncertain world. The business bottom line is primary of course, and second to that is the customer, without which there is no bottom line.

The cable operator customer of the third decade of this millennium expects a reliable network, and continuous, seamless delivery of services, whether it be broadband cable, internet, telephony, cellular, wireless, home security, telemedicine, etc.

One primary way that network resilience can be attained, risk to service delivery continuity mitigated, and reliability targets realized is to invest the time and energy and dollars to deploy and maintain a solid grounding and bonding network, and the ANSI/SCTE 275 standard is the best way to achieve that objective.

1. Introduction

DOCSIS[®] 4.0 specifications introduced two important changes beyond DOCSIS 3.1 specifications: extended spectrum, and full duplex transmission. As a result, the assumptions change around the interpretation of proactive network maintenance (PNM) data, how the PNM tests and queries may work, and the sensitivity of some frequencies to certain impairments. As such, PNM tools will likely evolve, and operator use of PNM will need to increase to assure service reliability is met.

This paper outlines expectations around how the network will change, and as a result how network operations may change. It can serve as the foundation for an industry project plan to develop network and service operations solutions to keep pace with new DOCSIS 4.0 technology.

2. PNM Overview

During SCTE's 2008 Cable-Tec Expo in Philadelphia, CableLabs' Alberto Campos, Eduardo Cardona, and Lakshmi Raman presented a paper titled "Pre-equalization Based Pro-Active Network Maintenance Methodology" [1]. The authors proposed using cable modem (CM) upstream transmitter adaptive pre-equalization coefficients to detect and localize plant impairments.

The basic idea involved (1) deriving complex frequency response signatures from pre-equalization coefficients, (2) looking for responses indicative of the presence of linear distortions,¹ and (3) overlaying CM location information from the cable company's customer database on a system topology display of some sort – for instance, digitized outside plant maps.

In 2009 CableLabs formed a PNM working group to implement the ideas presented in the Expo '08 paper. The output of the working group's efforts was a PNM best practices document published by CableLabs in 2010 (updated versions of the best practices document have since been published [2]), followed by a reference implementation.²

Using the CableLabs PNM best practices recommendations and sometimes also the PNM reference implementation, several cable operators and third parties were able to create software-based PNM applications. The PNM applications allowed operators to remotely identify and locate plant and drop impairments using data from CM upstream pre-equalization coefficients.

When the DOCSIS 3.1 specifications were created, a decision was made to incorporate provisions and "hooks" for PNM in those specs. PNM was revamped for DOCSIS 3.1 specifications from the ground up to provide downstream and upstream "test points" in the cable modem termination system (CMTS) and cable modem, allowing operators to characterize and troubleshoot hybrid fiber/coax (HFC) plant and subscriber drops; support remote proactive troubleshooting of plant faults; and improve reliability and maximize throughput in well-maintained plants. As shown in Figure 1, from [3], the cable network can be thought of as a device under test (DUT), and PNM measurements are virtual test equipment. For more information, see Section 9 of the DOCSIS 3.1 PHY Specification [3], which details PNM support and requirements.

¹ Linear distortions in cable networks include micro-reflections, amplitude ripple, and group delay distortion.

² SCTE's Network Operations Subcommittee Working Group 7 (NOS WG7), created in 2017, also handles PNM. The CableLabs and SCTE PNM working groups collaborate on the subject, and each group's efforts complement the other's.

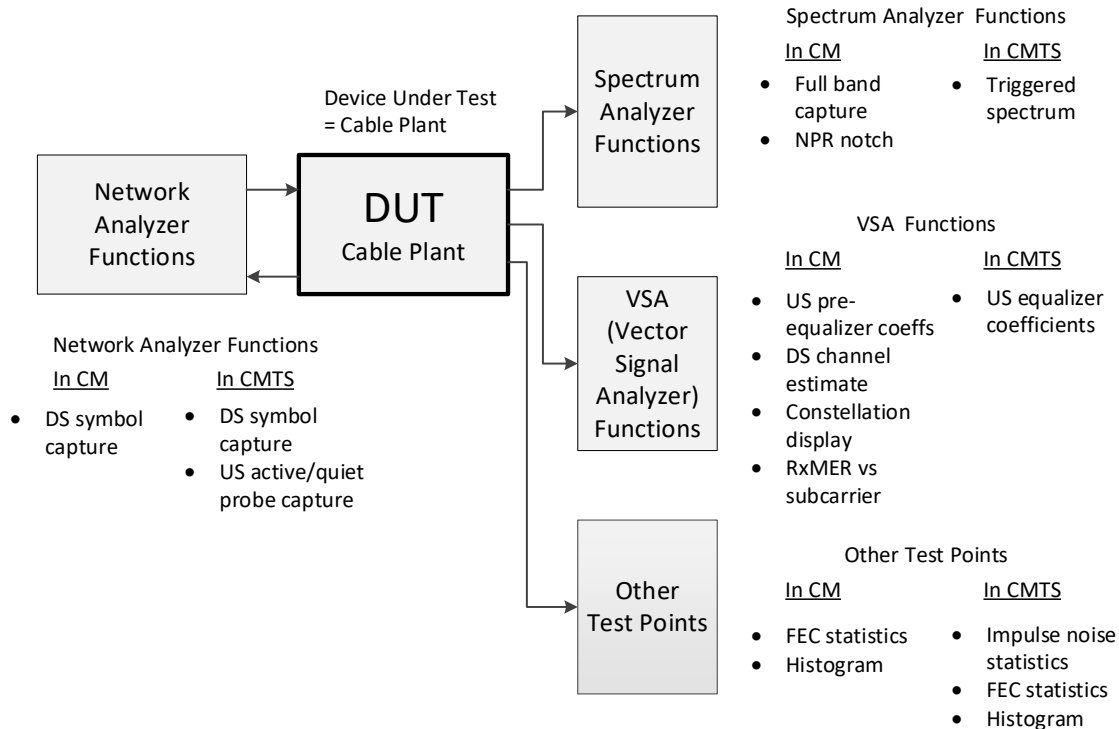

Figure 1 - DOCSIS 3.1 "test points" for an HFC network.

3. What is DOCSIS 4.0?

DOCSIS 4.0 specifications, released in 2019, are the latest in the DOCSIS family. The following description from the introduction in the DOCSIS 4.0 Physical Layer Specification [4] provides an overview:

This generation of the DOCSIS specifications builds upon the previous generations of DOCSIS specifications (commonly referred to as the DOCSIS 3.1 and earlier specifications), leveraging the existing Media Access Control (MAC) and Physical (PHY) layers. It includes backward compatibility for the existing PHY layers in order to enable a seamless migration to the new technology. Further, the DOCSIS 4.0 specifications introduces Full Duplex (FDX) DOCSIS PHY layer technology as an expansion of the OFDM PHY layer introduced in the DOCSIS 3.1 PHY specification to increase upstream capacity without significant loss of downstream capacity versus DOCSIS 3.1. The DOCSIS 4.0 specification also builds upon DOCSIS 3.1 OFDM and OFDMA technology with an extended Frequency Division Duplex (FDD) DOCSIS alternative. DOCSIS 4.0 FDD supports legacy high split and also provides extended splits up to 684 MHz in an operational band plan which is referred to as Ultra-high Split (UHS). DOCSIS 4.0 FDD also introduces expansion of usable downstream spectrum up to 1794 MHz. Both the FDX and FDD DOCSIS 4.0 alternatives are based on OFDM PHY. Many sections refer to basic OFDM sublayer definitions described in [DOCSIS PHYv3.1].

Cable operators have for decades designed their networks to use sub-split band plans. A sub-split band plan is one that has most of the usable radio frequency (RF) bandwidth allocated to downstream signal transmission. A small portion near the lower end of the usable spectrum is allocated to upstream transmission. For example, a common sub-split band plan used in North America and elsewhere has the upstream operating from 5 megahertz (MHz) to 42 MHz, and the downstream operating from about 54 MHz to the highest downstream frequency limit (e.g., 750 MHz). In an effort to increase upstream capacity and data throughput, the industry has been migrating to mid-split and high-split band plans, with the former using 5 MHz to 85 MHz for upstream transmission, and the latter using 5 MHz to 204 MHz for upstream transmission. For more information on band splits and their history, see [5].

Introduced at the 2019 CES, the cable industry's 10G Platform [6], [7] will deliver speeds of 10 gigabits per second (Gbps) with improved reliability, security, and lower latency, using DOCSIS 3.1 and DOCSIS 4.0 technologies, passive optical networks (PON), coherent optics, dual channel Wi-Fi³, and more.

In particular, the 10G Platform will take advantage of DOCSIS 4.0 technology's expanded spectrum usage – to 1794 MHz (aka 1.8 gigahertz, or GHz) or higher – and more efficient use of parts of the RF spectrum with FDX operation.

3.1. Frequency division duplexing

Originally called “extended spectrum DOCSIS” (ESD), the term frequency division duplexing (FDD) is used in the DOCSIS 4.0 specifications. The reason it's called FDD is because, just like DOCSIS 3.1 and earlier technology, downstream signals operate in one frequency range and upstream signals operate in a different frequency range. The DOCSIS 4.0 upstream RF spectrum can operate to as high as 684 MHz, and the downstream to as high as 1.8 GHz or more. Figure 2, from [4], shows the configurable FDD upstream allocated spectrum bandwidths.

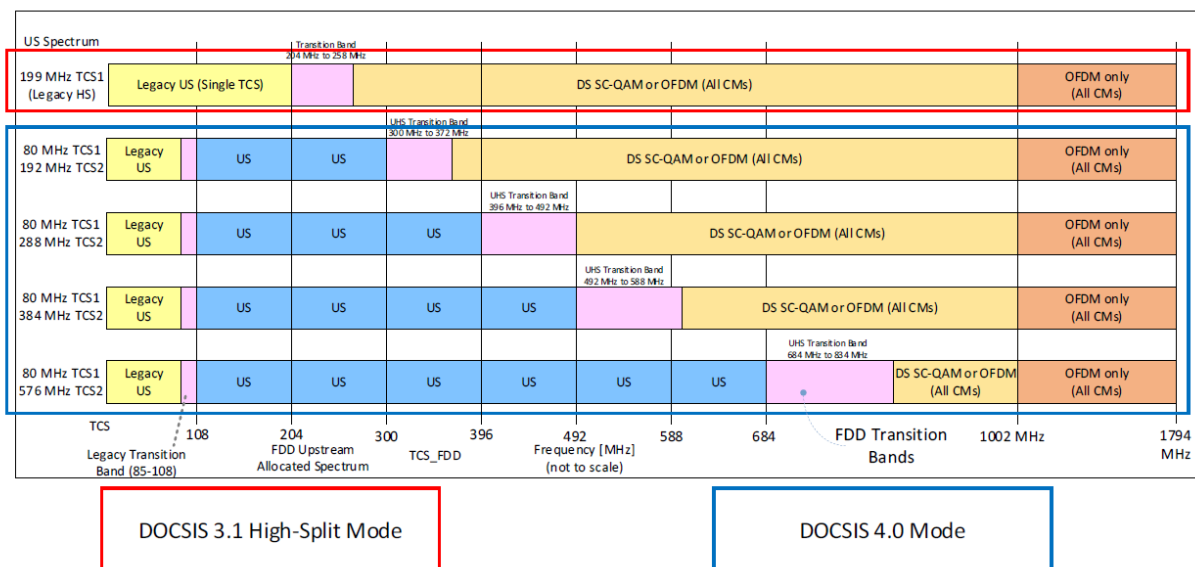

Figure 2. FDD frequency maps.

³ Wi-Fi[®] is a registered trademark of the Wi-Fi Alliance[®]. Wireless local area networks (WLANs) are commonly called Wi-Fi.

3.2. What is full duplex?

FDX – commonly known as “FDX DOCSIS” – was originally introduced as an annex in DOCSIS 3.1 specifications, and is now part of the DOCSIS 4.0 specifications. Through the magic of echo cancellation (EC) and other technologies, FDX allows the carriage of downstream and upstream signals on the same frequencies at the same time. The graphic in Figure 3, from [4], shows configurable FDX allocated spectrum bandwidths, including what is called FDX allocated spectrum. The latter comprises the frequency ranges where downstream and upstream signals can simultaneously occupy the same frequencies, allowing increased data speeds in both directions.

Figure 3. FDX frequency maps.

3.3. PNM in DOCSIS 4.0 networks

As mentioned previously, [3] includes a full section (section 9) covering PNM. “Section 9 PROACTIVE NETWORK MAINTENANCE” in [4] simply says “See [DOCSIS PHYv3.1] section 9.”

While the PNM parameters in [3] are for the most part directly applicable to DOCSIS 4.0 technology deployments, there are some important differences and some new challenges. For example, full band capture (FBC) in cable modems will have to support a higher upper frequency limit in the downstream, to 1.8 GHz in FDD applications. Indeed, all of the downstream PNM parameters described in [3] and referenced in [4] will need to support operation to 1.8 GHz, and the upstream PNM parameters will need to accommodate operation in all of the supported frequency ranges to as high as 684 MHz.

Cable network operation on higher frequencies in both the upstream and downstream will be susceptible to new sources of ingress, as well as services with which signal leakage can interfere. Other challenges include such things as management of total power at active device outputs; isolation requirements for FDX; additional attenuation at higher frequencies; PNM test and query; and more. Developers and users of PNM tools and applications will need to understand these challenges, many of which are discussed in subsequent sections of this paper.

4. Plant Preparation and Transition path

The best proactive network maintenance is that which happens when the network is being prepared for DOCSIS 4.0 technology, well before an impairment occurs.

As networks are being upgraded, consider drop tests as well, to find potential leakage, poor drop performance, and potential sources for non-linear impairments. Passive intermodulation (PIM) distortion is anticipated to be worse in DOCSIS 4.0 networks with higher operating levels. Plant preparation is a convenient opportunity to find and remove any older distribution and drop passives that will not perform well at higher frequencies, find and remove bad or detrimental filters (including in-line equalizers), and find and remove any house amplifiers that will impact service. Degraded and poor performing drops may also have difficulty carrying signals at higher frequencies.

In-depth guidance on plant preparation is beyond the scope of this paper, but the authors acknowledge its importance for PNM. In particular, operators must address plant quality before upgrading to and deploying DOCSIS 4.0 technology.

The next section discusses some of the challenges related to managing impairments, and the potential impacts of those impairments on DOCSIS 4.0 technology deployments. Other potentially impacting topics, such as FDX-capable amplifiers and smart amplifiers, are also discussed.

5. Impairment Management and Other Challenges

5.1. Challenges in legacy plants

Figure 4 shows the results of end-to-end testing of a tapped feeder leg (active device output to last tap) using legacy components designed for a maximum downstream frequency of 1 GHz to perhaps 1.2 GHz. The coaxial cable has a standalone attenuation at 1 GHz of about 24 decibels (dB), typical of just under 1000 feet of 0.500 hardline coax. Looking at the S_{12} and S_{21} traces,⁴ the combined insertion loss (cable plus passives) is about 45 dB at 1 GHz, typical of a span of feeder with taps and other passives. Of particular concern is the sharp frequency response rolloff starting at about 1.3 GHz in the S_{12} and S_{21} traces (circled in red in the figure), indicating that attenuation at higher frequencies is substantial. That rolloff is caused by the passives. The S_{11} trace, from which return loss can be derived, also indicates poor performance above about 1.3 GHz. From this example, operation above 1.3 GHz would be impossible using the legacy passives.

Cable operators contemplating operation to 1.8 GHz will need to evaluate their networks to determine to what extent upgrades or changes will be necessary to support higher downstream frequencies. PNM tools will need to support operation at the higher frequencies, too.

⁴ The S_{11} , S_{12} , S_{21} , and S_{22} parameters in the figure are scattering parameters, or S-parameters. For more on S-parameters, see [13]

5.2. Potential sources of ingress at higher frequencies

Cable operators are already familiar with sources of ingress and over-the-air signals affected by signal leakage in the 5 MHz to 1 GHz frequency range. Most operators have little or no experience with ingress and leakage at frequencies above 1 GHz, though. Figure 5, from [10], shows over-the-air frequency allocations in the United States from about 900 MHz to 1850 MHz (frequency allocations in other countries may be different). This frequency range includes the 902 MHz to 928 MHz industrial, scientific, and medical (ISM) band (shared with amateur radio); the 23 centimeters amateur radio band (1240 MHz to 1300 MHz); six aeronautical radio navigation bands (960 MHz to 1215 MHz, 1300 MHz to 1350 MHz, and four smaller bands from 1559 MHz to 1626.5 MHz); some long term evolution (LTE) bands; among others. GPS frequencies⁵ are in the 1100 MHz to 1600 MHz frequency range, too. Signals on some of the aforementioned frequencies are potential sources of ingress interference to the cable network, and can be interfered with by signal leakage.

PNM's full band capture and receive modulation error ratio (RxMER) will continue to be valuable for identifying and helping to locate potential ingress, especially at the higher frequencies discussed here.

⁵ Global Positioning System (GPS) frequency L1 is 1575.42 MHz (15.345 MHz bandwidth); L2 is 1227.6 MHz (11 MHz bandwidth); and L5 is 1176.45 MHz (12.5 MHz bandwidth). See <https://www.nist.gov/pml/time-and-frequency-division/popular-links/time-frequency-z/time-and-frequency-z-g>

A comprehensive list of plant and drop impairments and their impacts on FDD and FDX operation could easily be the basis for a standalone paper. The following are some of the more important considerations.

- Proper attenuation/insertion loss, frequency response, return loss, port-to-port isolation (where applicable), and other characteristics of network and drop actives, coaxial cable, passives, connectors, etc., across the full operating bandwidth are critical. Out of spec performance for any of the aforementioned could negatively affect FDD and FDX operation.
- Ingress in FDX bands causes errors in channel characterization, and the RF bandwidth of the spectrum affected by noise funneling can be larger in an FDX architecture than in others because of its wider upstream bandwidth. Noise funneling remains a problem because one source impacts all. That is, severe ingress from just one drop can significantly impair a node's upstream performance, regardless of the size of the node's service area or the number of homes passed – decreasing the size of the serving area does not necessarily decrease the noise problem. As well, drop ingress in an FDX band could impair downstream (in the drop) and upstream performance.
- Common path distortion (CPD), originating from inside customers' homes, might be increased by high transmit levels of FDX and FDD CMs.
- An FDX or FDD CM located on unconditioned house wiring, rather than the point of entry, could experience more problems on average. This outcome is due to additional complexity of the inside wiring, presence of drop passives and actives, the number of connectors, etc.

To overcome increased attenuation at higher frequencies in FDD networks, active device output power – including output total composite power (TCP) – will be higher. Figure 6, from [11], illustrates three examples of signal level-versus-frequency in an FDD network. PNM tools can be an important part of the management of active device signal levels and TCP. Section 30.14 and Appendix J of [11] include additional discussion about TCP.

Figure 6. Examples of active device output signal level versus frequency in an FDD network.

5.5. OUDP leakage detection

While signal leakage detection is generally not part of a PNM toolset, ingress detection is, and the two are often related. That is, if leakage exists ingress usually does, too. In high-split and ultra-high-split band plans, the 108 MHz to 137 MHz aeronautical band overlaps part of the cable network's upstream spectrum. Leakage detection and measurement are more challenging, since a continuous downstream leakage test signal cannot easily be transmitted in or near aeronautical band frequencies. One promising method is to use OFDMA upstream data profile (OUDP) for leakage detection and monitoring. This approach is discussed in [12], and recent lab and field test results are encouraging.

5.6. Outside plant amplifiers and impacts on PNM

5.6.1. FDX amplification and PNM

RF amplifiers are an integral part of any HFC network. Their primary purpose is to amplify and condition RF signals so that they may propagate through subsequent spans of coaxial cable. Coaxial cable attenuates RF signals in a non-uniform manner (that is, cable attenuation is greater at higher frequencies than it is at lower frequencies), thus requiring the next RF amplifier to again amplify and condition the RF signals. Rinse and repeat. RF amplifiers and fiber nodes have one or more devices in them called a diplex filter. Two diplex filters are shown in Figure 7(a) and a simulated transition band of the frequency response of a sub-split diplex filter is shown in Figure 7(b). The purpose of the diplex filter is isolate the downstream from the upstream path in the active device, helping to prevent problems such as oscillation.

(a)

(b)

Figure 7: Example diplex filter (a), diplex filter transition band (b).

Diplex filters are not compatible with FDX operation. This is because upstream and downstream signals are present on some frequencies at the same time. The diplex filter prevents this from occurring, so FDX networks require one of two considerations:

- A network design with a fiber node and no active devices after the fiber node (aka Node + 0).
- A design with a fiber node and amplifiers capable of amplifying in both directions without diplex filters, or dedicated FDX-capable amplifiers with echo cancellation.

In the case of FDX amplification and PNM, a Node + 0 network in theory makes for a much simpler network to maintain and troubleshoot. Since it lacks any actives after the fiber node, one only need be concerned with the node (and perhaps power supply), the hardline coax, passive devices, and subscriber drops and their components. When considering troubleshooting using such things as correlation groups and echo cavities, the following are important:

- The number of subscribers available in a correlation group will typically be smaller due to smaller service groups.
- Echo cavities will always be formed between the fiber node and passive devices and/or damaged coax/connectors. Actives after the node will no longer play a role in echo cavities.
- The number of impairments in a given plant segment will decrease because the number of connectors, coax, etc. will be fewer.
- Node + 0 will not fix pre-existing distribution coax and drop issues. RF failure group sizes may be reduced, and some causes of failure eliminated, but the number of overall service issues may or may not be greatly reduced.

While the general maintenance requirements for a Node + 0 network are not substantially expected to go down, the overall performance is expected to improve. This is because RF downstream signals from the fiber node will be nearly equivalent to those in the headend from a quality perspective. Further, upstream signals from the CM will be received and demodulated at the fiber node, assuming a DAA deployment with digital fiber links.

PNM will be a key troubleshooting tool in an FDX deployment to monitor performance, impairments and EC performance. It is assumed that for FDX to be successful some amplification may be required in HFC networks. It will be essential for PNM to have visibility into FDX amplified networks, especially at the amplifier level. See the next section on smart amplifiers.

5.6.2. Smart amplifiers and FDD

FDD is very different than FDX in its requirements for diplex filters and amplification, but there is one commonality discussed this section: smart amplifiers.

FDD will still require diplex filters to separate the downstream from the upstream in actives and certain passives. However, diplex filters in an FDD environment will need to at a minimum be upgradable and ideally programmable (or remotely switchable). Similarly, the RF conditioning circuitry in RF amplifiers should also be programmable. Vendors are producing new amplifiers with diplex filters and conditioning circuitry which can be remotely configured or locally configured with a mobile app.

This leads into the concept of smart amplifiers. Smart amplifiers not only include the ability to eliminate legacy plug-in pads and equalizers, but they are also adding PNM functionally such as full band capture so that one can remotely see the output of the amplifier to configure its padding and conditioning. PNM can take advantage of FBC in the fiber nodes and amplifiers as yet another monitoring point in the field to identify and localize RF impairments. This is useful for both FDD and FDX deployments.

Because the FBC capability in smart amplifiers is built on CM technology, other PNM tests can use the CM in the amplifier. Now the amplifier can be used for all PNM tests supported by the CM chipset. Of

particular importance is that this functionality operates over the extended upstream and downstream RF bandwidths.

6. DOCSIS 4.0 Technology

6.1. Triggered RxMER

As stated in [4], FDX modems can measure RxMER over all subcarriers at the same time. This measurement is triggered by events including time triggers, echo canceller training (ECT) probe triggers, and OUDP sounding triggers.

Time triggers could be the most useful for PNM because they are triggered at a specific time, and that time could be correlated to certain events by the CMTS or converged cable access platform (CCAP). For example, a CM can measure RxMER per subcarrier while a specific test downstream signal is sent, and while another upstream signal is sent by another CM. This could be used to find nonlinear impairments. Also, it could be used to synchronize data collection on multiple CMs at once, or to coordinate with a test device signal or measurement, or to time an external radio signal to potentially look for ingress sources, for example.

ECT RxMER probe triggers measure a modem's receive capabilities during worst case conditions, used for setting bit-loading after echo cancellation training. As such, it could be useful for PNM as an indication of the environment for transmission, and will provide a peek at the bit loading that the CM is capable of achieving.

OUDP sounding triggers allow measurement of the interference between CMs. With a measure and a sounding CM pair, the information could be very useful for PNM, particularly for fault localization. The information may even be useful to verify relative location information.

While these alternate forms of RxMER are described for the DOCSIS 4.0 protocol in both the PHY [4] and MULPI [8] specifications, the OSSI [9] specifications have not yet outlined how the data would be reported for fault management purposes.

6.2. Interference group information

The CMTS or CCAP determines a given FDX modem's participation in an interference group (IG) and transmission group (TG) after modems have performed sounding. This process helps the CMTS to identify which CMs interfere with other CMs on a given HFC plant segment. During sounding one CM is granted time to transmit and surrounding CMs are told to measure the per-subcarrier RxMER for the FDX sub-band being used for the sounding. Future enhancements in the OSSI specifications are planned to address the reporting of which CMs have been placed into specific IGs and TGs. Because CM membership in a given IG or TG is not operator-configured, the CMTS/CCAP is the source of truth for these associations.

Additionally, FDX manages the usage of a given FDX sub-band through the use of what is called a resource block (RB). It is possible to assign a given RB in a given TG as either static (always one direction, usually upstream) or dynamic (scheduled by the CMTS or CCAP, the block operates in both directions in a given sub-band for a specific TG). In the dynamic resource block assignment (RBA) scheduling, RBA switching can happen at an extremely fast rate which makes tracking and reporting of the RBA metrics challenging.

6.3. Echo cancellation in the node

To maintain increased capacity, and to meet 10G goals, greater reliance on echo cancellation is to be expected. When echo cancellers do not perform as needed, RF impairments may impact service.

FDX-capable nodes support simultaneous upstream and downstream communications over each FDX channel. FDX-compliant CMs will operate in FDD mode, where on any FDX channel or sub-band, the CM is either transmitting in the upstream or receiving in the downstream direction. To avoid the risk of co-channel interference (CCI) and adjacent channel interference (ACI) between CMs, the CMTS schedules transmissions and grants such that a CM does not transmit at the same time as other CMs that are susceptible to interference from the transmitting CM. CM to CM interference susceptibility is measured through a sounding process that is defined in the specification. Even with the CMTS determining interference groups, there is still a need to manage the impacts of upstream and downstream signals at the node. The FDX node has to employ echo cancellation methods to help remove the reflection of the downstream transmitted signals that are reflected back from components in the node and in the plant which impact the reception of upstream signaling. This echo cancellation can be done in both the analog and digital domains. In the analog domain, traditional techniques can be utilized that copy the DS carriers and then manipulate phase and magnitude and then apply that as a filter on the receiver path. EC conducted in the digital domain allows for near signal regeneration, depending on the node design. At the node, the DS signals are at their strongest so this method can be effective at cancelling out echoes in the FDX node itself.

From a PNM point of view, more work and definition need to be performed to determine how to measure and report echoes, and the signals after echo cancellation has been performed. As more FDX plant and nodes are deployed, these challenges will be met, and new management objects will be created which will aid in better performance of these plant segments.

A pre-EC RxMER measurement, possible at the node, could provide some information about the signal before EC, which may be partially informative toward gauging the EC effectiveness.

Generally, there are four approaches for providing this information, which could be useful for PNM and operations tools and applications:

- a measure in the specification that is based on what is described here;
- a measure in the specification that is based on some combination of US and DS RxMER and maybe more to describe some equivalent of the effort spent on echo cancellation and how much more could be corrected, without getting into manufacturer-specific intellectual property;
- a best practice based on one of these approaches, doing what is best to use external testing and available measures to provide equivalent information; and
- new requirements to collect and hold the information for future use.

A fiber node typically feeds up to four legs of coax. Management of the FDX spectrum and EC process in nodes with multiple legs can vary among vendors, with potentially different implementations. Actual capabilities and details are beyond the scope of this paper. However, from a PNM perspective there would be value if per-leg EC data were available.

The authors suggest that the DOCSIS specifications teams develop an engineering change to provide management objects that describe the limits and performance of ECs.

6.4. Echo cancellation in the CM

As with the node EC, a couple of parameters should be reported for the FDX CM EC. However, the FDX CM is a lower cost device and may not have the horsepower to provide all the measurements that a node could.

- EC is trained or not trained—In the OSSI and MULPI specifications, a trained EC is sufficiently converged. Reporting on the state of training is important for PNM. For instance, if the EC is not converged, reception of the channel(s) in the sub-band might not be usable, and knowing that the EC is not converged provides valuable information for troubleshooting why the channel/sub-band is not usable.
- Echo before and after cancellation—Operators need a way to express this so they can characterize the plant and find when and where changes happen in the network.
- Margin remaining before EC begins to have problems—Operators need a way to express this parameter. The specifications development organizations could suggest measurement and reporting methods.
- Any indication of why an EC cannot train or is on the margin—For example, if there is a particular echo that is too big, then data on that echo could be used to provide the echo's distance, which would allow an operator to troubleshoot. The industry will need to determine how that information would be communicated and what the data would look like.

7. Telemetry

With increased complexity and the expectation of new service-impacting failure modes being revealed in the network, new telemetry, and more frequent telemetry in some cases, will be needed. PNM fault management requires identification of faults from the telemetry, and then use cases for localizing the fault must follow. Fault identification requires a broad scope covering the entire network, with an initial granularity for the next step of fault management; fault localization requires several different groupings and finer resolution of telemetry. PNM fault management will require ways for operators to manage their operations and maintenance costs, so improvements in tools will follow the improvements in telemetry delivery.

PNM telemetry today consists of queries (polling data that are intermittently collected) and tests (requiring configuration to enable the data collection). In DOCSIS 3.0 networks, Simple Network Management Protocol (SNMP) was the primary method in use. The need for larger data sets occurred with DOCSIS 3.1 technology. Trivial File Transfer Protocol (TFTP) was introduced to enable more optimal data transfer than what is possible with SNMP. TFTP was adopted by CM vendors, but had limited adoption by CMTS vendors.

DOCSIS 4.0 technology brings new possibilities with telemetry from CMTS equipment. With R-PHY architectures, there are new tunneling protocols such as Layer 2 Tunneling Protocol (L2TP) pseudowires presenting a packet streaming protocol (PSP). DOCSIS 4.0 technology brings requirements for more data, more measurements, more often. SNMP will continue to increase our “technical debt” that limits the full capabilities of monitoring platforms. L2TP is one such protocol that is in use by CMTS vendors for transporting large amounts of data fast.

With R-MACPHY, YANG data models describe the methods for acquiring telemetry, delivered through TFTP, HTTP, and other means. Like L2TP, YANG models eliminate limitations with SNMP and bring data aggregation from DOCSIS devices into the 21st century. YANG models are an interesting discussion

topic but are not a requirement for CMTS vendors to support, therefore, similar to TFTP it could be unlikely that CMTS vendors will adopt YANG models.

Vendors have developed proprietary solutions, based on protocols and techniques such as L2TP, CMTS SSH direct READ access, Kafka bus access, and more. Proprietary solutions have proven to be substantially more effective than SNMP and deliver critical data in near-real time. Examples of this are upstream spectrum analysis and OFDMA RxMER per subcarrier data. Vendor implementations of streaming telemetry using proprietary solutions enable upstream spectrum analysis which rival hardware-based spectrum analyzers in terms of trace update response time. Further, OFDMA RxMER data can be obtained on a fully loaded CMTS chassis every 15 minutes for every active CM connected to that CMTS. This can be done simultaneously while running other PNM tests. For cable operators considering upstream profile management application (PMA), this is a game changer. Those familiar with standard PNM tests know that running OFDMA RxMER typically prevents one from running any other PNM test, such as upstream triggered spectrum capture (UTSC).⁶

The advent of smart amplifiers will add a new telemetry opportunity. This paper previously discussed the FBC capability in smart amplifiers, but there is far more to it. DOCSIS 4.0 amplifiers are expected to run hotter, provide more gain, operate at higher frequencies, and contain sophisticated internal electronics. Having an on-board CM enables the ability to monitor the modem's internal temperature sensor(s), voltages, and any other on-board sensor the vendor may choose to include. All this data gets communicated directly back to the CMTS and the monitoring system. Vendors could, for example, give access to mainline power supply monitoring, RF probing, and more. Each amplifier becomes another telemetry point in the network. How the telemetry is retrieved is again up to DOCSIS 4.0 specifications and vendor implementation. Ideally it will not use SNMP.

What does all this mean? There are many solutions being tested on the open market for DOCSIS 4.0 data collection. Further, new solutions are being proposed by CableLabs. It will ultimately be up to the cable operator community to drive which technologies are adopted and implemented. This paper has identified the need that DOCSIS 4.0 technology has for PNM. However, it should be apparent to the reader that a gap exists. That gap is the lack of a clear path between how vendors and operators will align to a consistent PNM implementation and how PNM will function across multiple vendor platforms to meet the expectations of cable operators. It is recommended that operators understand this gap and align to address it.

8. Test and Query

As discussed previously in this paper, DOCSIS 4.0 technology brings new opportunities and challenges from a PNM perspective. New test methods and data analytic queries must be created and optimized for new spectrum changes and new technologies, such as echo cancellation. As data speeds increase, bandwidths expand and complex technologies are introduced, PNM will be increasingly more important to ensure continued quality of experience (QoE) to subscribers. There is no doubt that subscribers will continue to be more dependent on high-speed data, and competition will continue to apply pressure to improve network quality.

⁶ Rather than track per-modem OFDMA RxMER per subcarrier (and preclude the use of UTSC by field personnel), some operators monitor port average RxMER and other data at the upstream input to the CMTS/CCAP. If a problem is detected, then data from individual modems can be looked at more closely.

8.1. Challenges and Opportunities with FDD

In FDD, the upstream band can extend to as high as 684 MHz. In DOCSIS 3.1 technology, the highest upstream frequency is 204 MHz. Higher frequencies mean much more data to aggregate and store in databases from cable modems and CMTSs. Further, large data sets require significantly more CPU (or GPU) processing power from an analytics standpoint when identifying impairments. Today, most modems and CMTSs still rely on SNMP to retrieve data from them. While SNMP has been a great protocol for the cable industry for more than a decade, it is a very slow and outdated protocol. Fortunately, CableLabs specifications are moving towards other methods of obtaining large data sets, such as TFTP and streaming telemetry. It is critical that adoption of these methods by vendors occurs quickly.

The downstream spectrum in FDD will also be increasing from 1.2 GHz to 1.8 GHz with visions of one day supporting up to 3 GHz (or higher!). As in the upstream, this will require cable modems to support FBC up to the highest frequency supported in the network. Currently, DOCSIS 3.1 modems support FBC up to 1.2 GHz while DOCSIS 3.0 modems only support FBC up to 1 GHz. One can see the disparity of a 1.8 GHz network supporting a mixture of DOCSIS 3.0, 3.1 and 4.0 cable modems. As DOCSIS 4.0 modems are initially deployed, one will have limited visibility to impairments in the RF spectrum above 1.2 GHz, assuming significant deployment of DOCSIS 3.1 modems. It is expected that many passive devices, and subscriber drop cables and components, will have various impairments above 1.2 GHz because the 1.2 GHz to 1.8 GHz spectrum has never been widely tested. It may sound trivial when speaking in terms of “GHz,” but this is 600 MHz of largely untested spectrum that PNM will be essential in analyzing and testing. DOCSIS 4.0 modems with FBC capabilities up to 1.8 GHz are essential. Further, a method of quickly obtaining the FBC spectrum from 5 MHz (or lower) to 1.8 GHz will be critical.

Upstream spectrum analysis is a “meat and potatoes” feature of any PNM application. Technicians rely on it every day to identify and resolve return path ingress and other impairments. The state-of-the-art return path upstream spectrum analysis relies on a CableLabs-based specified measurement called UTSC. UTSC enables compatibility across vendors and platforms whether it is integrated CCAP (iCCAP) or distributed access architecture CCAP (dCCAP). CCAP vendors and PNM vendors will need to ensure their platforms support upstream spectrum analysis up to the highest frequencies supported in FDD. Further, vendors must be able to support fast refresh speeds on upstream spectrum analysis over a much wider bandwidth in order to capture transient noise events, many of which may occur at higher frequencies not previously seen. The current state of DOCSIS 3.1 UTSC across the vendor space is non-optimal in that each CCAP vendor has partial adoption of the CableLabs UTSC specification. This state creates challenges for adoption by cable operators, and a lack of feature sets with some vendors means that not all tests are supported. It will be important that vendors fully adopt UTSC in DOCSIS 4.0 networks so that operators are able to troubleshoot more complex problems as frequency expansion will certainly bring unanticipated complexities.

8.2. Challenges and Opportunities with FDX

Like its counterpart FDD, FDX has similar upstream and downstream frequency expansion challenges for PNM. However, FDX adds more technical hurdles which PNM will be critical to help solve. For instance, downstream FBC at the CM may contain upstream and downstream transmissions within the same interference group in the FDX band (108 MHz to 684 MHz). Visualization and troubleshooting of simultaneous upstream and downstream will lead to new challenges for both vendors and technicians.

Having visibility into the level of EC and reserve EC capacity will be essential. As previously discussed, the CMTS and CM have EC functionality. The authors believe that it will be possible to determine some amount of impairment between the CMTS and the CM by utilizing the information provided by the EC operation in the CM and FDX node.

In general, PNM tests for FDX will be more challenging overall than FDD. A general summary of this can be seen later in Table 1.

8.3. DOCSIS 4.0 Impact on Standard PNM Tests

As defined in the DOCSIS 3.1 and 4.0 specifications, there exists a standard set of PNM test and query features designed to enable cable operators and vendors to obtain optimal troubleshooting data from the CMTS and CMs. Those specifications are designed in order to establish consistent interoperability among vendors of CMTS, CM and PNM software. This section provides a brief description of each PNM test followed by table that summarizes the gaps for full support of DOCSIS 4.0 FDD and FDX.

DS Symbol Capture (CM and CCAP)

Description:

- The `DsOfdmSymbolCapture` object provides partial functionality of a network analyzer to analyze the response of the cable plant. A symbol is generated at the CCAP and also captured at the CM, and then the results compared.

DsOfdmNoisePowerRatio (CCAP/Spectrum)

Description:

- The purpose of downstream NPR measurement is to view the noise, interference and intermodulation products underlying a portion of the OFDM signal. As an out-of-service test, the CCAP can define an exclusion band of zero-valued subcarriers which forms a spectral notch in the downstream OFDM signal for all profiles of a given downstream channel. The CM provides its normal spectral capture measurements per [PHYv3.1], or symbol capture per [PHYv3.1], which permit analysis of the notch depth. A possible use case is to observe LTE interference occurring within an OFDM band; another is to observe intermodulation products resulting from signal-level alignment issues. Since the introduction and removal of a notch affects all profiles, causing possible link downtime, this feature is intended for infrequent maintenance.

DS CM Spectrum Analysis Full Band Capture

Description:

- This test allows for the full band capture of the DS RF spectrum that the modem is configured to use.

CmDsOfdmChanEstimateCoef

Description:

- The purpose of this table is for the CM to report its estimate of the downstream channel response. The reciprocals of the channel response coefficients are typically used by the CM as its frequency-domain downstream equalizer coefficients. The channel estimate consists of a single complex value per subcarrier. The channel response coefficients are expressed as 16-

bit two's complement numbers using 2.13 nibble format. The CM samples are scaled such that the average power of the samples is approximately 1, in order to avoid excessive clipping and quantization noise.

- Summary metrics (slope, ripple, and mean) are defined in order to avoid having to send all coefficients on every query. The summary metrics are calculated when the corresponding MIB is queried. A Coefficient filename and trigger are provided to obtain the channel coefficients.
- The CM will report these metrics for each OFDM channel it has been assigned.

CmDsConstDispMeas

Description:

- The downstream constellation display provides received QAM constellation points for display. Equalized soft decisions (I and Q) at the slicer input are collected over time, possibly with subsampling to reduce complexity, and made available for analysis. This measurement is intended for data subcarriers only. Up to 8192 per OFDM channel samples are provided for each query; additional queries can be made to further fill in the plot.

ModulationOrderOffset

Description:

- This attribute specifies an offset from the lowest order modulation for the data subcarriers in any of the profiles in the downstream channel. If the lowest order modulation order that the CM was receiving was 1024-QAM and the ModulationOrderOffset was zero, then the CM would capture the soft decision samples for all of the subcarriers which were using 1024-QAM. If the ModulationOrderOffset was 1, then the CM would capture the soft decision samples for all of the subcarriers using the next highest modulation order in use for the profiles in the downstream channel.

CmDsOfdmRxMer

Description:

- Provides measurements of the RxMER for each subcarrier.

CmDsOfdmMerMargin

Description:

- Provide an estimate of the MER margin available on the downstream data channel with respect to a modulation profile. The profile may be a profile that the modem has already been assigned or a candidate profile. This measurement is similar to the MER Margin reported in the OPT-RSP Message [MULPIv4.0].

CmDsOfdmFecSummary

Description:

- The purpose of this item is to provide a series of codeword error rate measurements on a per profile basis over a set period of time.

CmDsHist

Description:

- The purpose of the downstream histogram is to provide a measurement of nonlinear effects in the channel such as amplifier compression and laser clipping. For example, laser clipping causes one tail of the histogram to be truncated and replaced with a spike. The CM captures the histogram of time domain samples at the wideband front end of the receiver (full downstream).

Upstream Histogram

Description:

- The upstream histogram provides a measurement of nonlinear effects in the channel such as amplifier compression and laser clipping. For example, laser clipping causes one tail of the histogram to be truncated and replaced with a spike. When the upstream histogram enable attribute is set to 'true', the CCAP will begin capturing the histogram of time domain samples at the wideband front end of the receiver (full upstream band). The histogram is two-sided; that is, it encompasses values from far-negative to far-positive values of the samples. The histogram will have a minimum of 255 or 256 equally spaced bins. These bins typically correspond to the 8 MSBs of the wideband analog-to-digital converter (ADC) for the case of 255 or 256 bins. The histogram dwell count, a 32-bit unsigned integer, is the number of samples observed while counting hits for a given bin and may have the same value for all bins. The histogram hit count, a 32-bit unsigned integer, is the number of samples falling in a given bin. The CCAP will report the dwell count per bin and the hit count per bin. When enabled, the CCAP will compute a histogram with a dwell of at least 10 million samples at each bin in 30 seconds or less. The CCAP will continue accumulating histogram samples until it is restarted, disabled or times out. If the highest dwell count approaches its 32-bit overflow value, the CCAP will save the current set of histogram values and reset the histogram, so that in a steady-state condition a complete measurement is always available.

US Impulse Noise

Description:

- The UsImpulseNoise object provides statistics of burst/impulse noise occurring in a selected narrow band. A bandpass filter is positioned in an unoccupied upstream band. A threshold is set, energy exceeding the threshold triggers the measurement of an event, and energy falling below the threshold ends the event. An optional feature allows the threshold to be set to zero, in which case the average power in the band will be measured. The measurement is time-stamped using the DOCSIS 3.0 field of the 64-bit extended timestamp (bits 9-40, where bit 0 is the LSB), which provides a resolution of 98 ns and a range of 7 minutes.
- The CCAP provides the capability to capture the following statistics in a selected band up to 5.12 MHz wide:
 - Timestamp of event
 - Duration of event
 - Average power of event
- The CCAP provides a time history buffer of up to 1024 events. In steady state operation, a ring buffer provides the measurements of the last 1024 events that occurred while the measurement was enabled.

Us OFDMA Active and Quiet Probe

Description:

- The purpose of upstream capture is to measure plant response and view the underlying noise floor, by capturing at least one OFDMA symbol during a scheduled active or quiet probe. An active probe provides the partial functionality of a network analyzer, because the input is known, and the output is captured. This permits full characterization of the linear and nonlinear response of the upstream cable plant. A quiet probe provides an opportunity to view the underlying noise and ingress while no traffic is being transmitted in the OFDMA band being measured.
- When enabled to perform the capture, the CCAP selects a specified transmitting CM, or quiet period when no CMs are transmitting, for the capture. The CCAP sets up the capture as described in [MULPIv3.1], selecting either an active SID corresponding to the specified MAC address or the idle SID, and defining an active or quiet probe. The active probe symbol for this capture normally includes all non-excluded subcarriers across the upstream OFDMA channel, with pre-equalization on or off as specified in the MIB. The quiet probe symbol normally includes all subcarriers, that is, during the quiet probe time there are no transmissions in the given upstream OFDMA channel. For the quiet probe, the CCAP captures samples of at least one full OFDMA symbol including the guard interval. The CCAP begins the capture with the first symbol of the specified probe. The sample rate is the FFT sample rate (102.4 megasamples per second).

Us OFDMA MER per Subcarrier

Description:

- This item provides measurements of the upstream RxMER for each subcarrier. The CCAP measures the RxMER using an upstream probe, which is not subject to symbol errors as data subcarriers would be. The probes used for RxMER measurement are typically distinct from the probes used for pre-equalization adjustment. For the purposes of this measurement, RxMER is defined as the ratio of the average power of the ideal QAM constellation to the average error-vector power. The error vector is the difference between the equalized received probe value and the known correct probe value. If some subcarriers (such as exclusion bands) cannot be measured by the CCAP, the CCAP indicates that condition in the measurement data for those subcarriers.

Us Triggered Spectrum Capture

Description:

- Capture of upstream spectrum through a number of triggering means including free run, time stamp value, mini-slot number, MAC-SID, idle SID, symbol, event trigger, and IUC.
- Note that reliable US triggered spectrum capture is a top priority for PNM in general, as this has not yet been implemented following the specifications.

8.3.1. Summarizing the gaps

With a high-level understanding of each of the PNM test queries, Table 1 provides an overview of the needed support in DOCSIS 4.0 tools for FDD and FDX as of the writing of this paper. As can be seen in Table 1, it is expected that PNM testing on FDD channels will be less impacted than PNM testing on FDX channels due to the intrinsic complexities of FDX. In general, when PNM tests are run on a channel configured in the FDX band, to perform downstream PMN tests like DS Symbol Capture and

NoisePowerRatio, the RBA for the sub-band must be set in the downstream direction, and upstream PNM tests will need the sub-band to be configured in the upstream direction while the test is performed. Cable operators deploying FDD or FDX will experience new challenges. Having proper tools, especially proper PNM tools, will enable cable operators to be better positioned to effectively and quickly troubleshoot complex problems in their HFC networks.

Table 1. Impact of FDD and FDX on DOCSIS 4.0 PNM tests

DOCSIS PNM Test	FDD Impact	FDX Impact
DS Symbol Capture (CM and CCAP)	None	RBA configured for DS, Testing required – investigation required
DsOfdmNoisePowerRatio (CCAP/Spectrum)	None	RBA for sub-band used on target DS – investigation required
Spectrum Analysis Full Band Capture	More bins, more data	Dual direction, more bins, more data, more complexity, filters in modems may differ by vendor – investigation required
CmDsOfdmChanEstimateCoef	None	Only possible when RBA for TG is set in DS direction, other dependencies involved
CmDsConstDispMeas	None	Uncertain. There may be an ability to capture I and Q values in two directions – investigation required
ModulationOrderOffset	None	None expected
CmDsOfdmRxMer	None	None Expected
CmDsOfdmMerMargin	None	None Expected
CmDsOfdmFecSummary	None	Test runs for several minutes which may be impacted based on RBA scheduling – investigation required
CmDsHist	None	Undetermined what happens with this test when in FDX operation – investigation required

Upstream Histogram	None	Uncertain how to measure the FDX band from 108 MHz to 684 MHz and how to account for any co-channel interference and echo cancellation
Us Impulse Noise	None	Recommend that this test does not apply to the FDX band
Us OFDMA Active and Quiet Probe	None	Multiple issues to address such as configuring all RBAs for the TG and configuring active probes – investigation required
Us OFDMA Rx Power	None	None expected
Us OFDMA RxMER per Subcarrier	None	If other transmission groups are operating in a DS direction, the RxMER values for the tested OFDMA channel could be lower – investigation required
Us Triggered Spectrum Capture	Wider spectrum, more bins, more data	Wider spectrum, more bins, more data, in addition, for SID filtering all TGs and channels must be sync'd to same TG to get a valid measurement

8.3.2. What is required?

As shown in Table 1, several PNM tests are impacted when FDX has been configured for operation. The most obvious impact is seen in the FDX allocated spectrum and the need for the test to be performed when the specific sub band that the channel is configured to use is set in the correct direction. As more FDX segments are brought into service over the next 12 to 24 months, these issues will be overcome and the specific impacts, and their workarounds, will be better understood through additional testing and use. FDX also has the concept of sounding, and the usage of that data for PNM related activities has yet to be explored fully and will be studied once enough DOCSIS 4.0 FDX modems and nodes are deployed.

FDD, in contrast, does not have as significant of an impact to the PNM testing because these channels are all in place today; the issue here is that there are more of them and a greater frequency span to cover for tests including FBC in the modem.

Another class of products will be employed for DOCSIS 4.0 deployments: smart amplifiers. These updated components in the plant will be more bi-directional and have capabilities for sampling and some PNM testing as well, which will allow the operator to have another valuable testing point in the network for measurement and troubleshooting analysis.

There will be challenges that will be met during this period. Some of the challenges are outlined as follows, and are expected to serve as the foundation of an industry project plan to resolve these challenges:

- Vendors of PNM tools must adapt some of the testing to accommodate the FDD and FDX impacts and the implementation of smart amplifiers that are added to the plant.
- Cable company operations and back-office teams dealing with the increased amount of data coming from devices in the field.
- Scheduling of testing for FDX channels.
- Compliance of FDD- and FDX-capable CMTSs and CMs with the DOCSIS 4.0 specifications
- Interoperability among vendors' products (CMTSs, nodes, CMs, etc.) with both FDD and FDX
- Clearly defined FDD and FDX PNM test and query specifications from the standards and specifications development organizations
- Adoption of FDD and FDX PNM test and query DOCSIS specifications by vendors
- Standards and specifications development groups exploring further the usage of FDX sounding data for PNM testing; the addition of test capabilities in smart amplifiers and other plant equipment is an area ripe for study and requirements creation that will likely see more activity as more FDX plant and modems become available.

In order to address the challenges identified above and develop the proposed industry project plan, the following groups will need to collaborate as has historically been done in specifications development:

- Chipset vendors
- CMTS vendors
- CM vendors
- PNM tool vendors
- Standards and specifications development organizations
- Cable operators

Input and collaboration from all parties are essential for bridging the gaps identified in this document.

9. Conclusion and Future Outlook

The past several years have seen significant progress in the use of equipment and PNM tests. This has provided a new level of capability for cable operators to offer more services at higher data rates to more subscribers. As the industry looks to the near future with DOCSIS 4.0 technology and FDX and FDD updates to the plant, these well-known tests will continue to provide significant insight into the health and operation of our cable networks. Operators can rest a little easier knowing that the same applications and methods being used today can be extended, with modifications, into the DOCSIS 4.0 networks that will soon be deployed. While there are still areas for continued innovation and standards work, the authors feel optimistic that the groundwork that has already been implemented will continue to provide operators with actionable data that can help to keep our networks healthy.

However, there is an opportunity for improvement. Many PNM tests were defined in the DOCSIS 3.1 specifications and implemented by equipment vendors. Some of those tests have been invaluable, such as downstream RxMER per subcarrier. However, other tests, such as UTSC giving insight into return path noise and upstream RxMER per subcarrier have been inadequately adopted by vendors. In preparation for

deployment of DOCSIS 4.0 technology, this paper has identified gaps in PNM which are needed to support DOCSIS 4.0 deployments. While specifications can include recommendations, it is up to the cable operator community to decide if PNM test functionality, such as return path monitoring (e.g., UTSC) and extended frequency FBC are valuable tools or not. It is incumbent on cable operators to hold discussions with vendors and determine the priorities. Should enhancing PNM be a priority or not? This is a question cable operators must determine and communicate to their vendor partners.

1. Introduction

During the [COVID-19 Pandemic](#), the surge of broadband bandwidth utilization grew 16% for downstream (DS) consumption while upstream (US) increased 33% from March to May 2020. The resiliency of the hybrid fiber-coaxial (HFC) network delivered nationwide service as subscriber demand continued to increase. As demand for broadband connectivity services continues to grow, Charter Communications and other multiple service operators (MSOs) must utilize intelligent automation (IA) driven by artificial intelligence (AI) and machine learning (ML) technology to address HFC network capacity growth and issues.

Plant upgrades such as high-split are underway and, eventually, DOCSIS 4.0. To defer the high costs of future enhancements and improve capacity, MSOs can extract maximum capacity from existing plants. They can also use this same solution and approach to augment bandwidth capacity for new deployments and network upgrades.

The HFC network is complex. Every plant is unique and requires customization to address individual plant conditions. Using Charter's network data-driven platforms, we can determine how to design, build, or evolve our network. For example, in-home modem telemetry is necessary to fix impairments in the plant. Telemetry collected from devices in the plant transmits the device's health and reports the condition of the plant.

In this paper, we'll discuss the techniques used to evaluate plant conditions and how Charter's Autonomia is used to repair them. Autonomia is one of Charter's data platforms used to standardize data and software engineering by delivering Charter's network data needs under one program and making all network data and models available companywide. Profile Management Application (PMA) is a use case running on Autonomia that aims to focus on the entire data life cycle, including:

- Streaming and data acquisition capability;
- The ability to analyze data using data engineering for governed analytics data sets with ML capability;
- An automation platform that focuses on closed-loop implementations for various use cases.

We'll also discuss optimizing spectrum usage on plants with ingress and roll-off impairments on high-split deployments.

¹ Analytics from Charter Data Technologies Group.

2. Analyzing Plant Conditions

Telemetry data determines the state of the network and provides information that's not easily detectable. Often, subscribers may not be aware of network impairments. However, the network operator must be aware of impairments in order to fix issues, ensure subscriber quality of experience, and meet subscriber expectations.

Proactive Network Management (PNM) data contains critical telemetry information for cable operators to proactively manage and mitigate plant issues. Receive modulation error ratio (RxMER) data provides the status of a subscriber's home network and describes the condition of a service group.

2.1. Using data to determine network performance

Figure 1 and **Figure 2** are sample snapshots of media access control (MAC) domains from different cable modem termination systems (CMTSes). Each dot represents a single cable modem that represents the associated median RxMER value and the variance for all subcarriers on the orthogonal frequency division multiplexing (OFDM) channel. This methodology allows operators to see the current condition of the network, which they can trend over time.

Figure 1 – Med Var plot of Mac Domain A

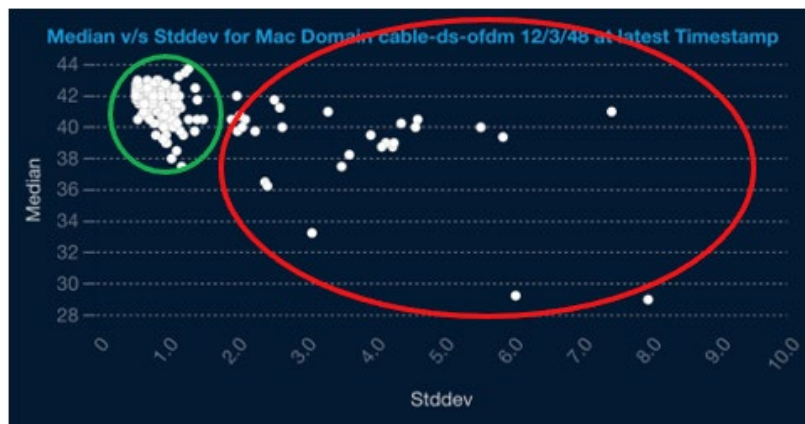

Figure 2 – Med Var plot of Mac Domain B

Using the Med Var plot observations, operators can anticipate a scatter plot pattern to be created from OFDM channels operating in the Long Term Evolution (LTE) frequencies. The OFDM channels shown in the above samples range from approximately 680 MHz to 772 MHz.

Note: This pattern is only identified on plants running on LTE interfered OFDM spectrum and may not apply to other kinds of impairment such as high-split roll-off.

The clusters in the top-left green circles in **Figures 1 and 2** denote healthy cable modems with high median RxMER and low variance. The cable modem on the bottom right denotes unhealthy cable modems that are most likely in partial service.

As the level of variance increases, the severity of impairment increases, as represented by the clusters in the red circles. Our analysis of the RxMER variance for CMs allowed us to classify the modems to a degree of impairment.

Below are our field data observations:

- Standard deviation of <1.0 dB represents cable modems with very consistent RxMER values across the channel. Cable modems lock on the highest-profile signal quality supports.
- Standard deviation of >1.0 dB and <3.0 dB represents cable modems with moderately inconsistent RxMER values across the channel. Cable modems may not be able to lock on the highest profiles.
- Standard deviation of >3.0 dB and <5.0 dB represent cable modems with highly inconsistent RxMER values across the channel. Cable modems may not be able to lock onto more than one profile.
- Standard deviation of >5.0 dB represents cable modems with extremely high inconsistent RxMER values across the channel. Cable modems will not be able to lock onto more than one profile. In many instances, cable modems will exhibit partial-service characteristics.

Most impairments from the data (680 MHz-772 MHz) are LTE-related, as portrayed in **Figure 3**. Using the RxMER data, we correlated the profile posture of cable modems from the Mac Domains. We also collected profile postures for each cable modem CMTSes in **Figures 2 and 3**.

Figure 3 – LTE impaired cable modem

We configured default fixed profiles at 4096 QAM, 1024 QAM, and 256 QAM. Data from live plants indicated the dynamic nature of these profile changes was visible from the hottest to the coolest part of the day, from day to day, season to season.

3. Profile Management Application

Intelligent automation can change the configuration of the CMTS many times a day and should be evaluated to ensure minimal impact on the network. For example, a radio frequency (RF) plant can lose capacity instead of gaining capacity when using PMA profiles without considering Forward Error Correction (FEC).

The PMA software solution optimizes the use of the spectrum by automating the generation of DOCSIS 3.1 profiles and customizing profiles to the condition of the plant. Ultimately, using PMA optimized with FEC data, will enable gains in capacity.

The RxMER and bit-loading thresholds determine the profile a CM runs. The **DS RxMER to QAM Level Mapping** in **Table 1** is specified in the DOCSIS PMA Technical Report, and guides RxMER and bit-loading thresholds.

Table 1 – DS RxMER to QAM Level Mapping

Constellation / Bit loading	CNR / MER (dB)
16 QAM	15.0
64 QAM	21.0
128 QAM	24.0
256 QAM	27.0
512 QAM	30.5
1024 QAM	34.0
2048 QAM	37.0
4096 QAM	41.0
8192 QAM	46.0
1634 QAM	52.0

Using lab tests and data from Charter's network, we concluded that low-density parity check (LDPC) is highly efficient for correcting errors. Moreover, the RxMER thresholds can several dBs below the specification, as shown in Table 1, and continue to work at the highest-available profile (4096 QAM). We performed comprehensive testing in Charter's lab and verified it in production using RxMER readings and the profile posture of those devices in the network.

Figure 6 shows a cable modem with a median of 35.75 dB and a standard deviation of 1.43 dB from the latest RxMER readings. The modem exhibited profile changes from 12 to 10-bit flat profiles during the day, and the other way around in the early morning hours. The graphic also shows that LDPC can correct error packets even if the variance of the signal quality is moderate, with parts of the channel dipping below the 35.0 dB threshold.

Figure 4 – Cable Modem Exhibit 1

The use of FEC to baseline RxMER relative to QAM Level Mapping is critical to maximize the gain, by calculating profiles, as aggressive as FEC can handle. Conservative RxMER to QAM Level Mapping can lead to loss of capacity in plants with relatively clean environments.

The data from CMTSes determine that 70-95% of cable modems operate on the highest bit rate of 4096 QAM at any given time. Varying conditions in the plant from day to day and hour by hour cause a disparity in performance. Unless cable modems can operate at higher bit rates, there's no capacity gain for CMs running on the highest bit-modulation available. However, capacity increases on cable modems not running at the highest bit rate.

This evidence leads us to ask the following questions:

- How many modems can be removed from partial service using customized profiles for each service group?
- How much extra capacity can be gained from cable modems not operating on the highest profile?

3.1. Determining gains and losses

We can determine cable modem speed gains and losses using PMA versus flat-configured profiles. Our configuration includes five 6-MHz, 8 bits-per-hertz, Single Carrier QAM (SCQAM) channels, and one 96 MHz-wide OFDM channel.

We injected noise into the channel spectrum on 12 cable modems, running on 12-bit profiles for our experiment. By injecting noise into the channel, we changed the 12 modems operating 12-bit profiles to three partial-service modems and changed nine modems to run on 8-bit profiles. We hypothesized the best speed gains would impact modems with partial service.

As portrayed in **Table 2**, traffic passed through the modems that used the SCQAM and OFDM channels. The impaired modems passed traffic entirely on the SCQAM channel. The PMA-generated profiles increased speed and capacity for impaired modems and modems running on lower fixed-modulation profiles.

Table 2 – Lab Performance of Cable Modems using Flat-Configured Profiles versus Customized Profiles

Cable Modems	Non-impaired		Impaired		Impaired PMA	
	Profiles **	Speed (Mbps)	Profiles **	Speed (Mbps)	Profiles ***	Speed (Mbps)
CM1	0,1,2,3	907	0,1,(2),(3)	665	0,1,2,3	836
CM2	0,1,2,3	907	(CH)0,1,2,3	175	0,(1),(2),3	655
CM3	0,1,2,3	907	0,1,(2),(3)	665	0,1,2,3	836
CM4	0,1,2,3	907	(CH)0,1,2,3	175	0,(1),(2),3	655
CM5	0,1,2,3	908	0,1,(2),(3)	665	0,1,2,3	836
CM6	0,1,2,3	907	0,1,(2),(3)	665	0,(1),2,3	811
CM7	0,1,2,3	907	0,1,(2),(3)	665	0,(1),2,3	811
CM8	0,1,2,3	903	0,1,(2),(3)	665	0,(1),2,3	811
CM9	0,1,2,3	907	(CH)0,1,2,3	175	0,(1),(2),3	655
CM10	0,1,2,3	907	0,1,(2),(3)	665	0,(1),2,3	811
CM11	0,1,2,3	907	0,1,(2),(3)	665	0,1,2,3	836
CM12	0,1,2,3	906	0,1,(2),(3)	665	0,1,2,3	836

** Flat profiles where 0 = 6 bits, 1 = 8 bits, 2 = 10 bits, 3 = 12 bits, CH = impaired

*** Customized profile where 0 = 6.26 bits, 1 = 10.76 bits, 2 = 10.38 bits, 3 = 7.63 bits

NOTE: PMA profiles generated using FEC-adjusted RxMER and bit-loading thresholds

The data also indicated cable modems removed from partial service gained an average of 7.36 bits per hertz across the OFDM channel, a capacity increase of 480 Mbps for partial-service modems. For modems running on 256 QAM, the capacity increased from 8 bits per hertz to profiles utilizing an average of 10.76 bits per hertz and 10.38 bits per hertz, gaining more than 2 bits per hertz with speeds between 146 Mbps and 171 Mbps. This change represents a significant capacity increase for cable modems operating on low-modulation profiles and partial-service modems, thereby increasing modem speed for those cable modems.

3.2. Potential gain from a live port

Actual field experience works differently from what we simulate in the lab. In the field, a more diverse set of impairments of varying degrees require classification and clustering. Using the Mac Domains in **Figure 2** (above), we calculated the gain loss potential, identified cable modems that are impaired.

The CMTS can run on four profiles with a maximum of four segments. We tested two scenarios, one without FEC and one using FEC, optimizing RxMER bit-loading thresholds.

The results are summarized in **Table 3** as follows:

Table 3 – Potential Gain/Loss comparison using profiles with non-FEC and FEC adjustment

Cable Modems (206 total)					
Flat Profile Configuration		Non FEC PMA Profile Configuration		FEC PMA Profile Configuration	
Bit Load (bits per hertz)	# CM	Bit Load (bits per hertz)	# CM	Bit Load (bits per hertz)	# CM
12	182 (88.3 %)	10.4	182 (88.3 %)	12	182 (88.3 %)
10	14 (6.76%)	10.0	2(0.9%)	11.6	8 (3.8%)
8	5 (2.4%)	7.8	18 (8.7%)	10.4	10 (4.8%)
		5.5	4 (1.9%)	7.1	6 (2.9%)
0	5 (2.4%)	0	0	0	0

When calculating PMA without FEC to adjust RxMER bit load mapping, we discovered:

- Capacity loss by 1.6 bits per hertz for CMs operating on the highest profile;
- General loss of total capacity by 14%;
- Partial-service cable modems are taken out of partial service.

When calculating PMA using FEC to adjust RxMER bit load mapping, we discovered:

- Cable modems running on the highest profiles don't lose capacity;
- Partial-service cable modems are taken out of partial service;
- Increased capacity for cable modems that are not on the highest QAM level.

4. High-split Roll-off

The path to 10G is underway. Using trials, we proved the viability of frequency-division duplexing (FDD) DOCSIS 4.0 by demonstrating the ability to deliver multi-gigabit symmetrical service. Network evolution is complex requiring expensive plant hardware configurations and upgrades, necessitating network operators to take the necessary steps to evolve the network.

4.1. Initial feedback

The **Figure 8 – (Lab) Sample Cable Modem from Cluster A** mimics a live field environment consisting of a node with a cascade of five amplifiers (1.2 GHz), with 32 passive taps (1.0 GHz), with 20 devices on five taps. The most salient pattern is the three distinct clusters (A, B, and C). The cable modem data from the RxMER data indicates the roll-off behavior is different between cable modems and can be completely different within each cluster.

A is the best performing cluster, demonstrating moderate impairment with cable modems located on the second and third amplifiers, with four-seven passive devices.

Figure 7 – (Lab) 1.0-1.2 GHz Spectrum Med Var Plot

Figure 8 is a sample cable modem from *Cluster A* in **Figure 7** and demonstrates a usable spectrum through the entire 192 MHz OFDM channel.

Figure 8 – (Lab) Sample Cable Modem from Cluster A

Cluster B (**Figure 7**) demonstrates extreme impairment with high median RxMER, with cable modems on the fourth amplifier with 11-13 passive devices (shown in **Figure 9**), with usable OFDM spectrum through 1.18 GHz.

Figure 9 – (Lab) Sample Cable Modem from Cluster B

Cluster C (Figure 7) is a single cable modem with extremely low signal quality with extreme impairment as shown in **Figure 10**. The cable modem is on the fifth amplifier with 20 passive devices. Some cable modems deep in the network cannot report OFDM telemetry due to channels in partial service.

Figure 10 – (Lab) Sample Cable Modem from Cluster C

4.2. Utilizing OFDM channel on a high-split deployment

The signal quality in the Med Var charts and RxMER data from cable modems indicates variability for every modem in the service group. The deployment variance is caused by the roll-off, which is caused by the 1.0 GHz taps. This is a unique situation for how an operator can create a profile that works on the channel without sacrificing spectrum and capacity. Using this analysis, we can systematically develop a roadmap for high-split deployments as follows:

- Flat profiles don't work where the roll-off region renders higher parts of the spectrum unusable for most cable modems.
- PMA profiles must operate at 1.0-1.2 GHz to work with the roll-off region.
- Operators can incrementally upgrade plant components such as taps using PMA profiles.

To mitigate the roll-off region entirely for an OFDM channel running on 1.0-1.2 GHz, replacement of taps in the plant will be required. By using PMA we can defer the initial costs of the deployment. Using the data within our lab, we can learn and derive a systematic plan to upgrade a high-split plant. This will give us the ability to postpone upgrades and reduce the initial costs of deployments, simultaneously boosting capacity until upgrades are necessary.

5. Autonoma Platform

As mentioned earlier, PMA is running on Autonoma, that focuses on Data Ops, by building fast and reliable data pipelines, feeding Model Ops, by turning data into action. As the network continues to evolve, data has become prominent in architecting the modern network. The evolution applies to the physical access network architecture and how we design data and software. It isn't practical for large MSOs like Charter to operate approximately 5,000 CMTSes in a 54 million homes-passed footprint using traditional polling such as Simple Network Management Protocol (SNMP) or command-line interface (CLI).

There is cost associated with supplementing and accommodating polling capability and increasing the number of devices. Demand is extensive for data, since various consumers have differing

requirements. It is impossible to control multiple data-polling agents, polling disparate management information bases (MIBs) at disparate frequencies during various times of the day.

5.1. Data Ops

“Growing scale and the increasing use of automation in next-generation enterprise networks require a modern, more efficient approach to network data capture and analytics” – Bo Lane, VP Global Engineering, Kudelsky Security

One of the challenges for operators is how to promptly acquire network data from devices. Two classes of data are required to operate the network:

- **Bulk data:** Telemetry data that is collected at predefined frequencies from all devices on the network;
- **Real-time polling:** Data collected from devices, on an ad-hoc basis, that identifies the devices' conditions at a particular moment.

As the network modernizes, it becomes more complicated to operate, and requires telemetry to operate the network. **Figure 11** is an example of SNMP polling architecture. As the number of devices increase, so does the complexity, and reliability decreases for bulk-data ingestion.

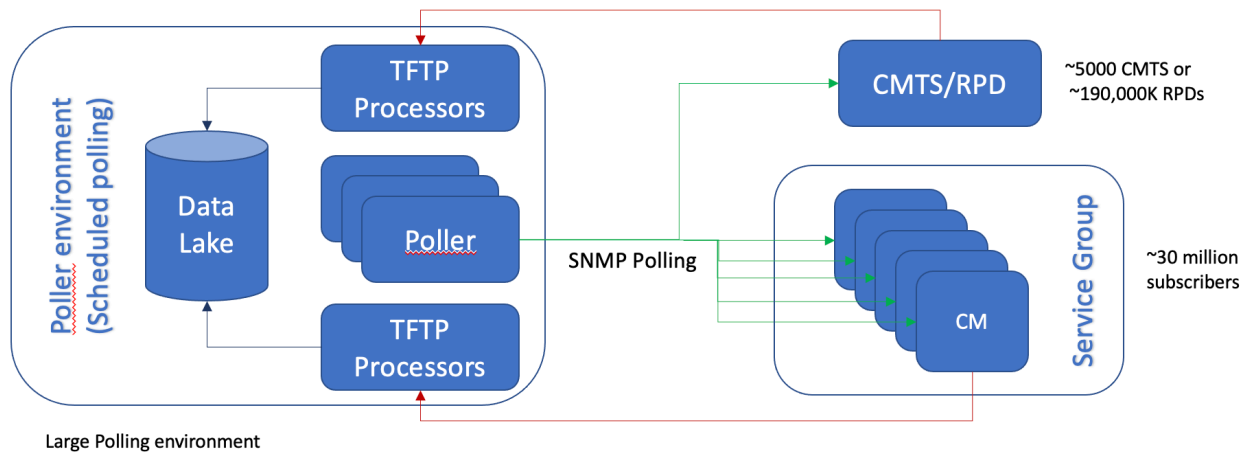

Figure 5 – SNMP Polling Architecture

Alternatives to polling methods like push-based data acquisition are becoming more relevant as real-time data becomes more critical. For example, if the signal quality for a particular channel degrades or experiences latency issues on a specific device, details of the event close to real-time are required. The responsibility to acquire data from remote polling mechanisms shift to the device to provide the telemetry at a granular level.

Figure 12 (below) illustrates a modern data architecture.

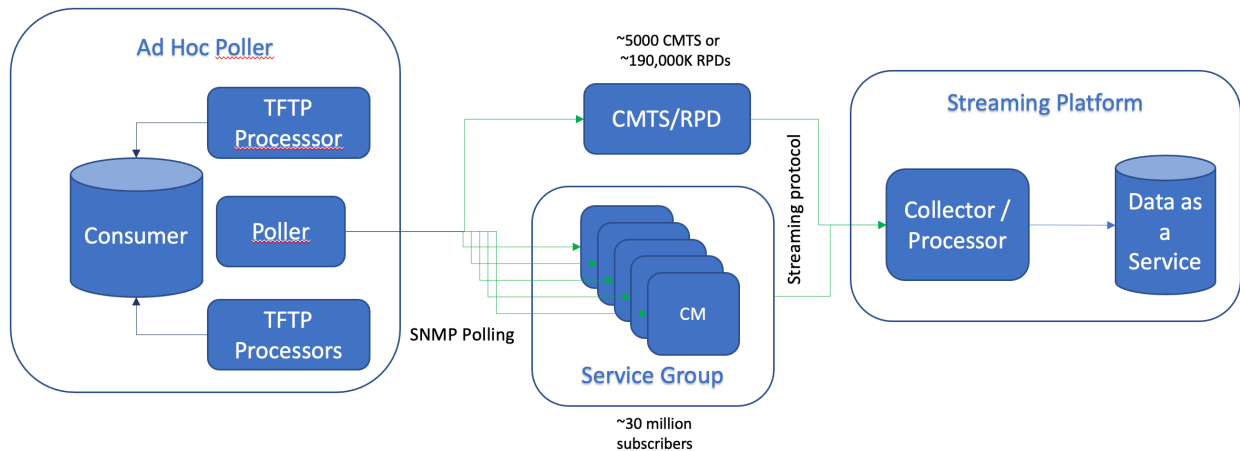

Figure 6 – Modern Streaming Telemetry Data Arthitecture

5.2. Model Ops

The DOCSIS 3.1 PHY specification provides many capabilities to gather telemetry data to conduct PNM. RxMER, a signal-to-noise ratio, is one of the most helpful signals for diagnosing the condition of individual modems on the Charter network. RxMER provides measurements for each subcarrier in the OFDM (downstream) or OFDMA (upstream) channel. We can determine the quality of the signal subscribers receive, including a range of potential impairments that can impact service experience, by analyzing the data's level, shape, and spread.

Some of these impairments, shown in **Figure 13**, include conditions such as:

- **Amplitude Ripple:** Caused by improper network alignment, micro-reflections, or missing end-of-line terminators;
- **Suckout:** Caused by unterminated cable, smashed cable, or repeating divets;
- **LTE Ingress:** Caused by signal leakage (the passage of an outside signal into a coax cable), which can be remediated using Exclusion Bands;
- **Roll-off:** A result of improper balancing, bad amplifiers, or exceeding amplifier specification;
- **Standing Wave:** Can be used to determine the distance to a fault and is the initial premise behind PNM.

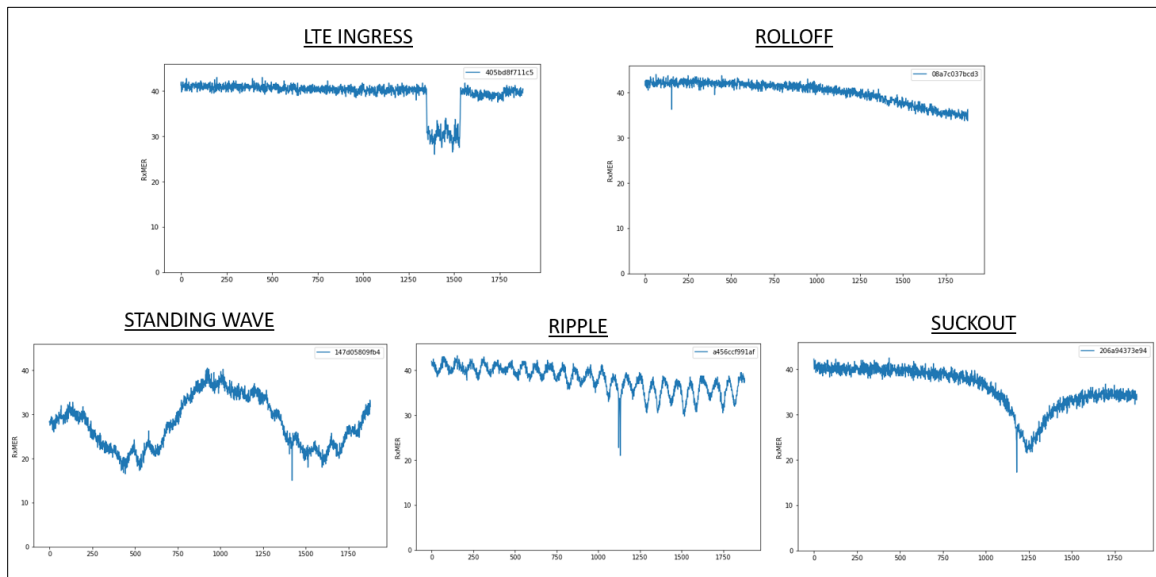

Figure 13 – Impairment Classifications

The classification impairments can identify potential network faults with a known solution. Using the data patterns, we can score and rank-order potential candidates to resolve issues in the field. The challenge is these patterns aren't self-evident, and manually reviewing the available data can be difficult and time-consuming.

We leveraged heuristics and unsupervised learning using AI and ML methods to acquire sufficient sample impairments. Paired with subject-matter-expert consultation, we provided a suitable training set for supervised machine-learning model development.

Using ML, we can monitor data signals 24x7x365, automatically identifying and classifying various impairment types. We can also detect if several modems are displaying the same impairment—a clear indication of an outside plant (OSP) issue—to isolate the impact in homes versus OSPs using clustering and nearest-neighbor modeling, illustrated **Figure 14** (below).

Figure 14 – ML Nearest-neighbor Algorithm Identifying a Cluster of Impairments

6. Conclusion

As the HFC network changes, data is necessary for the evolution of the network. Furthermore, we can use data to determine how and when to make changes to the network.

Software solutions are cost-effective ways to troubleshoot and address impairment issues in the plant. While software solutions may not solve plant issues, they provide time for operators to address issues without immediately sending a technician to a site.

PNM data allows the operator to assess plant conditions in real time by the subscriber, service group, CMTS, and region. We can use various methods to understand a service group. For example, we can learn traits from a collection of devices using clustering. PMA also allows operators to fix impaired cable plants.

We tested plants with LTE Ingress impairments and determined adjustments to the RxMER and QAM-level mappings were required. Our findings are as follows:

- RxMER and QAM-level mappings that are too conservative will result in a capacity loss on the OFDM channel, and FEC is needed to optimize PMA Engine;
- We optimized RxMER and QAM-level mappings for maximum capacity gain;
- Optimizing PMA can gain 30-40% (aggregate capacity) for cable modems not operating on the highest QAM level;
- 3-5% capacity gain for the overall channel;
- We removed cable modems from partial service using PMA;
- Cable modems operated at higher QAM levels when using PMA.

PMA can assist with transitions such as high-split deployments. Our lab-simulated plant indicated a relationship between signal quality, the amplifier, and tap cascades. We based the following assumptions on plants with 1.2 GHz amplifiers working with 1.0 GHz taps, with the cable modem spectrum exhibiting roll-off:

- Fixed modulation profiles don't work on high-split deployments because of spectrum roll-off;
- Dynamic profiles are required to direct spectrum roll-off to utilize a 1.0-1.2 GHz spectrum;
- PMA provides operators the ability to use a 1.0-1.2 GHz spectrum based on the subcarrier RxMER;
- PMA allows operators to strategically execute plant upgrades.

The evolution of modern networks requires ML to process the increasing volume of data and the number of data sets from devices which include:

- Transitioning from pull-based polling methods (e.g., SNMP) for bulk data collection;
- Modernizing bulk data collection using push-based methods, such as gRPC network management interface (gNMI), message queueing telemetry transport (MQTT), Kafka, and other stream-based protocols;
- Only using pull-based polling methods, such as SNMP, for limited, ad-hoc situations.

Machine learning is vital for how networks operate in the future, including:

- Leveraging heuristics and ML to get an adequate number of sample impairments to develop and train models;
- Data-signal monitoring on a 24x7x365 basis to automatically identify and classify various impairment types;
- Clustering classified impairments and using nearest-neighbor modeling to localize impairments.

1. Introduction

A single click of the mouse can cost you your house. A 2021 news article by network solution provider Barracuda measures “bad bots mak[e]ing up nearly 40% of all traffic” (N/A, 2021). It all starts with a single click. Every day, millions of people are asked to click on a link that could cost them everything they own. Malicious links are presented by email, by phishing websites, by dangerous ads on less than reputable websites, by gaming cheats and cracks, and even SMS (Short Message Service) text messaging.

With the exponential growth of the Internet, the threat of these kinds of attacks is supported by a burgeoning underground economy that has only increased the complexity and frequency of their attacks. Tactics are not limited to offering something for nothing. Recent phishing frauds focus on telling the victim something will happen unless they opt out and will often attempt to appeal to their victims at an emotional level. Malicious botnets have different purposes ranging from identity theft to distributed denial-of-service attacks against critical infrastructure. Victims of identity theft based on botnet infections rarely know how they were compromised, leaving the door open for victims to continuously be re-compromised. The end goal of most botnets is monetary gain through identity theft, but the proliferation of botnets also lends itself well to their use as a cyber weapon. The threat vectors vary for users, Internet Service Providers (ISP), retail companies or governments. Though there are legitimate uses of botnets, malicious payloads span a range from questionably legal tactics to blatantly malicious activity. This paper shares ways to identify the initial signs of danger, minimize exposure to these threats and to help bring focus to the recognizable indicators of malicious links.

2. What is a Botnet?

A bot, short for robot, is a software executable application that performs tasks that are automated and repetitive, typically via scripts on the internet. A botnet is a network of bots working together to complete a set of automated tasks that are managed and monitored by a command-and-control system (C2). This C2 is also referred to as a botmaster or botherder. Botnets act like many soldiers being issued orders and reporting back to their general. Botnets are typically used because they can complete tasks quicker and more efficiently than a human.

Botnets have both legitimate and illegitimate purposes. A few examples of both types of botnets are:

- Legitimate botnets
 - o Search engines
 - o Chat bot communications
- Illegitimate botnets
 - o Info-stealers
 - o RAT's (Remote Access Trojan/Tool)
 - o Ransomware
 - o Crypto Miners

Legitimate botnets are essential in enabling the discovery of added content like new websites. This paper focuses on infection methods and payload types of illegitimate botnets. Malicious botnets seek to subvert security controls and to generate revenue at the expense of their victims.

3. History of Botnet Technology

One of the first bots was ELIZA, a chatter bot, that was created at Massachusetts Institute of Technology (MIT) by Joseph Weizenbaum in 1966. According to an eBook Machines Who Think: A Personal Inquiry

into the History and Prospects of Artificial Intelligence, “ELIZA was intended to simulate – or caricature, as Weizenbaum himself suggests – the conversation between Rogerian psychoanalyst and patient, with the machine in the role of the analyst” (McCorduck, 1979). Since then, botnets have evolved drastically in sophistication and purpose.

Botnets use a variety of communication protocols. One of the original protocols is Hypertext Transfer Protocol (HTTP), which was until recently, the most used protocol by many websites. Many of these websites have now moved to Hypertext Transfer Protocol Secure (HTTPS), adding in a security encryption layer. One of the more popular protocols created and still being used is Internet Relay Chat (IRC), which was introduced in 1988 by Jarkko Oikarinen of the University of Oahu. Creators of more advanced botnets added the use of P2P (Peer 2 Peer) in addition to encrypted protocols like The Onion Router (TOR) SOCKS5 proxies and Simple Mail Transfer Protocol (SMTP). Most modern botnets rely on blockchain for a more distributed command and control communication network. Botnet communication keeps pace with all technological evolution.

As the technology of botnets has evolved so has the intent of the botnet. Since 1998, there have been many other malicious botnets that have been unleashed on the internet with names like Melissa, Code Red, Storm Worm, Mirai, and Smominru. A white paper titled The Historical Perspective of Botnet Tools best expresses the growth of botnets from a historical perspective. “As researchers continue to unveil the botnet trend and its mode of propagation within networking platforms the botmaster would continue to create different techniques meant to surpass the earlier botnet tool version used” (Osagie, Enagbonma and Inyang, 2019). These botnets have expanded their targets from attacking computers to cell phones, smart cars, and all types of Internet of Things (IoT) devices.

Overall, malicious botnets continue to evolve in their communication methods, target platforms and intentions over the decades. While botnet technologies have evolved, so have the infections methods.

4. Infection Methods

Today, most malicious bots are installed through several primary channels, email, text messages, malicious advertising and program/game cheats or cracks.

4.1 Phishing

Phishing refers to email sent with malicious links or attachments or fake websites that attempt to appear legitimate. Using social engineering tactics to gain the readers confidence or trust, carefully worded email with malicious attachments or links to malicious or fake websites designed to defraud the victim is one of the most effective cyber-attacks that exist. Attachments such as Adobe PDF (Portable Document Format), Microsoft Excel spreadsheets and even pictures can contain distinct types of malicious payloads as categorized below. Opening any attachment effectively “executes” the code inside that attachment with the associated program. Although anti-virus programs catch some of this malicious code, often the malicious code escapes detection through code obfuscation or encryption. More often, a phishing email contains a link to a malicious or cloned website.

Since most email uses Hypertext Markup Language (HTML), hyperlinks, or links to websites, which allows the text to be different than the underlying link to a website. For example, the text that reads “<http://GoodGuyWebsite.xyz/>” appears to point to GoodGuyWebsite.xyz. However, hovering the mouse reveals the link to the target Uniform Resource Locator (URL) is actually “www.BadGuyWebsite.xyz”. Another way of using formatting to forge URLs of familiar websites is the use of character manipulation. An example might appear to be a link to “www.maybeLegitimate.xyz/” but could be easily confused with

a link to “rnybeLegitimate.xyz” depending on the font. Careful examination reveals that the “M” has been replaced with an “R” and an “N”. Malicious actors often use the original company’s artwork and logos to increase the appearance of the email’s validity and the links to malicious sites. Phishing web sites, using genuine appearing artwork, will ask the victim to login and provide their credentials, which is the goal of this type of attack. A shift in tactics was observed in May 2021 when security firm Proofpoint discovered that a malicious actor set up a fake site that appeared to be a video piracy site called BravoMovies.

Instead of encouraging the victim through reward or fear of missing out, the criminals claimed the victim’s free trial they had signed up for had expired and their credit card was going to be charged, unless they cancelled. According to the Proofpoint article, BazaFlix: BazaLoader Fakes Movie Streaming Service, the email contained only a phone number, where a human operator directed the victim to the malicious website. The cancellation instructions were only available through a downloaded Microsoft Excel Spreadsheet which contained the malicious code. Phishing schemes tend to lose efficacy with each additional victim action, but as Proofpoint pointed out, “...despite being counterintuitive, the techniques used by the threat actors in this, and similar, campaigns help bypass fully automated threat detection systems” (Larson and Mesa, 2021). SMShing, is like phishing in that the actors attempt to persuade the victim to perform an action, however, the risk surface of mobile devices is far greater than a personal computer.

4.2 SMShing

SMShing is the act of enticing victims to click on hyperlinks delivered via SMS messaging on their mobile device or by opening a malicious attachment such as a PDF, Microsoft Excel Spreadsheets, or pictures. Often, malicious actors impersonate large businesses that most people are familiar with. The efficacy of SMShing attacks is often remarkably high, given several varied factors. Gartner Research published the paper called Tap Into the Marketing Power of SMS, which quantified the efficacy of SMS messaging as a sales medium. “Various sources report SMS open and response rates as high as 98% and 45%, respectively — in contrast to corresponding figures of 20% and 6% for email” (Pemberton, 2016). URL shortening services help to create the illusion of legitimacy to links (i.e., the link tinyurl.com/amazon could be redirected to any unknown website), further complicating the ability to identify a SMShing attempt. Compounding the risk level, most mobile devices lack antivirus protection. SMShing is a form of social engineering, which often uses a time-based pretext.

A common technique is to employ a call to action that expires quickly, such as a limited time exclusive offer that expires in one hour. This prompts the targeted user to suspend judgment about risk/reward since there is often a time component that can cloud judgment. The objective is to convince the victim to open an attachment or visit a website that appears legitimate, that either steals the information the victim enters or installs malicious code. Another social engineering technique used is to convince the victim that not responding to the message will have consequences. For instance, a message saying a credit card will be charged if the victim does not act. While SMShing attacks grow in popularity, malvertising has matured significantly.

4.3 Malvertising

Malvertising (Malicious Advertising) is the act of spreading malware through web or application-based advertisements. Advertisements are one of the most profitable areas of online commerce. Criminals monetize on the advertising platforms by distributing malicious payloads through legitimate ad delivery platforms. The threat to online and application users increases in proportion to the reputation quality of the website or application.

Brand protection companies like Trustworthy Accountability Group (TAG) and White Bullet help to combat malicious ads from being placed on reputable websites. This concerted effort to protect specific brands shifts the delivery of malicious ads to websites or in applications that are less reputable. For instance, White Bullet and Digital Citizens Alliance (DCA) published a study in 2021 called Breaking B(ads) measuring the volume of malicious ads in video piracy websites and applications. “White Bullet reviewed 664 billion ad impressions and found that roughly one in three piracy websites and apps have risky advertising that exposes consumers to fraud and malware” (N/A, 2021). The more reputable a company is, the less of a likelihood that malicious ads will be placed on their website or application due to the corporate diligence in brand protection. The advantage of employing malvertising to deliver malicious payloads is that it does not require compromised hosts to spread a malicious payload and the audience reach is limited only by budget.

4.4 Game and Program Cracks and Cheats

Game and application activation cracks and cheats are created to bypass free trial periods on many different applications and games and to add hidden features like in game invincibility and hidden levels. Often packaged together with the trial application files available on torrent sites, the directions for applying the patch or crack explains to disable any antivirus protection to avoid “false” positives. In doing so, the victim purposely shut down their protection long enough to be infected. Game cheats can differ in that the malicious payload is not immediately installed but often lies in wait for the victim to invoke. Game cheats often bypass the antivirus identification by creating in game links to malicious payloads rather than delivering that payload itself.

5. Payload Types

5.1. Info Stealers

The Information Stealer (info stealer) is the most prolific malicious botnet payload type being distributed, often through malvertising, game/application cracks and cheats. Info-stealers focus on stealing the victim's information and exfiltrating it to the C2 servers. The information it extracts can be defined by the person running the campaign but usually includes system and browser information by default. Computer information, which includes operating system and system level information, antivirus's running, IP (Internet Protocol) address, machine name and all installed browsers stored information are usually default targets. The browser information consists of all cached URLs, all stored (or remembered) usernames and passwords, all cached form information and stored (or remembered) credit card information in clear text from all installed browsers. Most stealers (Redline, LokiBot, Dark Crystal RAT etc.) can also be configured to exfiltrate all PDF's, Microsoft Word documents, pictures, or text files in specific folders, like “My Documents,” “Desktop” etc. These payloads can be configured to search for cryptocurrency wallets, social media applications and Multifactor Authentication (MFA) keys as well. Exfiltration of the information takes mere seconds. The explosion in volume of these infections goes completely unnoticed by the victims but can be measured independently.

A 2021 white paper called An Analysis and Investigation of InfoStealers Attacks during COVID'19: A Case Study, attempted to measure the growth of info stealers in the window of the COVID-19 pandemic. “Resultantly, a significant increase in the quantity and variety of cyber-attacks is observed since <the> emergence of COVID-19. Cybercriminals promptly leveraged this pandemic premise to rebrand general attack vectors. These attacks are typically info stealers and vary from attacks of minimal intricacy such as 404 Keylogger to the latest and more frequent attacks such as Lokibot” (Sharma, et al, 2021). The paper explains that the second largest country attacked, “...USA (40%) ...” (Sharma, et al, 2021), is the focus of this case study. The gravity and scope of the impact is multilayered and compounded.

The scope of the credentials is most often extremely broad. Because botnets can extract data from all the victims' browsers, all accounts are compromised, not just one. When a victim realizes their email has been hacked, they may change their password, but if their social media password is different, they may not change all account passwords. To make matters worse, the victim rarely knows their machine is still currently infected. Each time they change the password on the account they know has been compromised and then allows the browser to store that information, the new passwords are captured in an endless loop of re-compromise. Though they are the most predominant payloads deployed, Remote Access Trojans (RAT) serve a diverse set of criminal intentions with equally devastating effects, but the degree impact varies depending on the victim.

5.2. RATs & RESIPs

RATs allow criminal actors to remotely control a victim's computer or mobile device. Unlike info-stealers, RATs allow criminal actors to use the victim's device in any way they would like, exactly as if they were physically using the victim's device. Modern uses of RATs include, but are not limited to, advertising click fraud, credential stuffing, Business Email Compromise (BEC) and Distributed Denial of Service (DDoS) attacks. A paper published in IEEE's (Institute of Electrical and Electronics Engineers) 2020 European Symposium on Security and Privacy Workshops titled Growth and Commoditization of Remote Access Trojans attempts to measure the growth of this type of bot, states "Remote Access Trojans (RAT) are a special type of remote access software commonly used for malicious purposes, where (i) the installation is done without user consent, (ii) the remote control is done secretly, and (iii) the program hides itself in the system to avoid detection" (Valeros and Garcia, 2020). Accurate in the strictest sense, but, due to the profitability of this type of botnet, a new type of RAT has emerged that is offered as a legitimate commercial service. Residential IP Proxy as a Service (RESIP) companies offer the ability to use a consumer's device as a proxy, allowing them to tunnel through the device, assuming its digital identity.

Hola VPN (Virtual Private Network) is a free VPN software/browser that provides users the ability to spoof their location and device type to avoid content access restrictions. The free version comes with a separate software package from Bright Data (formerly Luminati) that hosts the RESIP proxy service on the person's device in lieu of paying for the premium service. Bright Data is one of over a dozen different companies in the RESIP space. The difference between a Remote Access Tool (like Remote Desktop) and a Remote Access Trojan is consent. A white paper called RESIP Host Detection: Identification of Malicious Residential IP Proxy Flows, at the time of its writing in 2021, measured the number of hosts offered by these companies at over 300 million, collectively. "Once a user installs the free HolaVPN, she is recruited as one of Luminati's (Bright Data's) exit nodes" (Tosun et al, 2021). When criminals use these exit nodes for fraud or cybercrimes, the Internet Service Providers (ISP) logs only show that the exit node (the consumer's device) generated the actions of the criminal actor, making it appear the victim is the criminal actor. RATs allow criminals to use other people's digital identities to defraud others. RESIP companies charge by the gigabyte for their victims mobile and home internet usage. Other payloads, such as cryptocurrency miners, have a more direct relationship to the infected victim's device.

5.3. Crypto Jacking

A crypto jacking (cryptocurrency hijacker & miner) solves computational math problems in exchange for cryptocurrency. The explosive increase in value of crypto currency drove the development of malicious deployments of crypto hijacking miners that target high performance computer environments like virtual machines (VM) and cloud computers. A 2017 paper called Mining on Someone Else's Dime: Mitigating Covert Mining Operations in Clouds and Enterprises describes the suitability of crypto miners in

commercial computational environments. “The sheer amount of resources needed for a covert cryptomining operation are readily available in a cloud setting” (Tahir et al, 2017). The costs to the victims are manifested as higher power consumptions, more heat generation as well as the loss of availability of Central Processor Unit (CPU) & Graphics Processor Unit (GPU) resources for legitimate use. Though most profitable in high performance computing environments, crypto jackers are content with exploiting the average consumers devices as well. Often times, crypto jackers run leverage javascript in browsers to launch the covert mining. Ransomware is another botnet payload type that directly impacts the victim's device.

5.4. Ransomware

Ransomware is malicious software which limits or fully prevents a person's access to their infected device (computer, tablet, phone, or other devices) by encrypting the contents of a hard drive. Ransomware also exfiltrates the data it has encrypted to the C2 server. To regain access to the infected device and the information stored on it, the victim is required to pay a ransom. Ransomware is the technologically advanced way to perform traditional crimes like theft or coercion. “In 2013, scareware arrived in the form of Reveton, which locked and prevented access to the infected devices (known as a Locker). After locking the computer (,) the ransomware falsely alleged that the computer (and user) had engaged in unlawful activities and needed to pay a fine to unlock the computer.” (O’Kane, Sezer and Carlins, 2018). The scope and impact of ransomware attacks depends on the victim.

When ransomware infects computer systems in companies, the ransom tends to be much larger and usually based on the company's value. When a botnet detects it is in an enterprise environment, the botnet may try to infect other computers (lateral movement) on the network before activating. Infecting additional computers on the company network allows the ransomware to encrypt and exfiltrate more data. Defending the risks of ransomware in the business environment includes backing up data, limiting access to data, isolating/segmenting systems, anti-malware software, education/training of staff related to malware, phishing tactics, and a dedicated cyber security team monitoring for threats on the network. Ransomware not only encrypts the contents but sends a copy of the files to the ransomware group or actor. Since most businesses use data backup systems, the loss of access to their data is usually limited to the last good backup. This includes information like contracts, emails from high-level executives, market research, intellectual property, and other valuable information. Since most companies have access to their back up data, bad actors shift their tactics to extortion, threatening to publish the information, not just deny access to it. Ransomware has transformed from a platform that denies access to information to an extortion as a service business model. Ransomware is indiscriminate, it impacts individual consumers just as often as large companies, though the impact is quite different.

On personal devices, this equates to the loss of all data like personal pictures and stored documents. The use of reputable anti-virus software is one level of protection against ransomware, another protective measure is to backup data to other locations. This could be one or two hard drives that are used solely for the purpose of data backups that are not connected to the internet. While this will help in recovering some of the information, all usernames, passwords, all credit cards, and all form information (like ship to/bill to addresses) that are retained by browsers are exposed to the criminal actor. All these various payloads are significant threats to all connected devices. Protection should always be applied in layers. In addition to having industry recognized anti-virus protection, there are some obvious signs of the dangers that lie ahead.

6. Indicators of Risk

Whether using a mobile device, personal computer, or web connected television, downloading, and opening any attachments should only be done when the sender is known and trusted. Malicious actors

depend on the victim's curiosity being piqued or reaction to being threatened in some way. Though filters in email and antivirus programs identify some malicious attachments, often many variants make it through with the victim's assistance. Fake URLs and links that make it through automated protection can often be identified with a closer examination.

A URL starts with a protocol, like HTTP or HTTPS. As the name indicates, entering any information into a website without the “S” is unsecured and readable to an attacker. The “S” should also be accompanied by a locked padlock symbol in the address bar. Following the protocol and the forward slashes, the domains are defined. Consider the example “https://subdomain.domain.top level domain (TLD)”. Most legitimate websites are in the .com, .org and .gov TLD’s. Unrecognized TLD’s should always bear scrutiny. The domain, along with the TLD are the most important part of the URL. Any typos, missing letters or characters, or unfamiliar variations of domain names should also inspire closer scrutiny. The subdomain is malleable and should be considered informative but not authoritative. For instance, Google.com is vastly different than Google.hackexample.com. Protecting devices and systems requires both behavioral effort as well as reputable automated solutions.

Antivirus programs are not foolproof but, as the adage goes, you get what you pay for. Free antivirus programs are often viruses in disguise. All companies monetize their products, the RESIP example demonstrates the unseen price a victim pays for a free product. Applying the same level of protection across all devices, like mobile and tablets that connect to the internet, especially those that are used to access secure websites ensures having a baseline level of automated protection of those devices. Anti-virus, anti-malware and automated solutions can provide some protection, but exercising prudence minimizes the reliance on automated solutions. Before downloading an attachment or clicking a link, be certain the source is someone or some company that is known and trusted. Double check the spelling of the sending email address and the contents of the email. Often, foreign malicious actors use broken English. Hover over links in email to examine underlying hyperlinks. Free products are often paid for in ways that are unknown. Game and application cracks and cheats often contain info stealer payloads. Protect mobile devices with antivirus programs as diligently as a personal computer. Use of MFA, passwordless authentication and password managers minimize account password exposures. Never allow web browsers to store passwords or credit card information. Info stealers can extract them all at once. Never reply to an unknown sender of unsolicited SMS messages. Phishing attacks often use the pretext of an offer that is limited time only, time is critical. They also use previous data breaches and open-source intelligence to gather information on the victim. Never share SMS text codes with anyone else.

7. Conclusions

The rise of the volume of botnets is only dwarfed when compared to the risks that the botnet payloads create. The persistent exposure of all account and credit card data stored or saved in browsers that info stealers access ensures continual re-compromise until the infection is eradicated. RATs can impersonate a victims’ network identity and be wielded as a massive network attack weapon. Ransomware has evolved to include extortion, not just denying access to the victims’ data but publishing it as well. Crypto jackers exploit computer resources rather than information so the cost to the victim often goes unnoticed. Free products come with costs that are not as direct as paying with money. In a digital world, every character is important. Reputable automated protection solutions are only one layer, applied prudence and critical assessment of all digital communications and transactions is still the primary line of defense.

1. Introduction

Environmental, Social and Governance (ESG) is a framework within the umbrella of sustainability. It is used to describe and measure an entity's behavior with respect to environmental issues, which includes greenhouse gas emissions and impact on natural resources, its engagement with and impact on society – both local and global, and the strength of its governance and the ethics behind its decision and policy making.

Companies around the world are being pressed to provide more transparency around their ESG risks and meaningful progress toward the mitigation of those risks.

ESG matters for a number of reasons, not least because the criteria are a set of standards that potential investors use to screen and evaluate companies. When a company's ESG "score" (a measure of a company's exposure to long-term environmental, social, and governance risks) goes up, its capital costs are reduced, and the company valuation improves. It is like a sustainability credit rating.

A good sustainability program drives business growth and enhances the brand, while cutting costs and reducing risk.

The most important reasons for focusing on ESG, however, are the long-term impacts on society and the planet.

Energy use is a key component of the Environmental element of ESG. For Cable Operators energy use for critical facilities operation represents one of, if not the largest operating expense. Heating, Ventilation and Air Conditioning (HVAC) systems typically account for 35% to 45% of the cable facility energy use. The Information Technology Equipment (ITE) heat loads represent approximately 45% to 50% and miscellaneous lighting is +/- 5%. By achieving reductions in energy use, related Greenhouse Gas (GHG) emissions can be reduced resulting in an improved ESG score.

The Environmental part of ESG is categorized in three scopes.

- Scope 1 - direct GHG emissions occurring from sources that are controlled by an organization - eg emissions associated with furnaces or vehicles
- Scope 2 – indirect GHG emissions are due to the organizations use of electricity
- Scope 3 – are indirect emissions occurring in the supply chain.

This paper will explore how legacy sites with older cooling systems can achieve significant energy and carbon footprint reduction and will also step into new technologies that will lead to further energy efficiency improvements.

Scope 2 emissions will be the primary focus of this paper and more specifically emissions related to cooling in legacy facilities. Reducing GHG is best done within a management lifecycle process and must include a focus on all three emissions scopes. Meaningful measurement needs to be performed, where baselines and targets are set, and progress is tracked.

Due to variations between operators' approach to preventive maintenance (ie. internal or external business partners) and operators not having readily available emissions data for purchased goods, Scopes 1 & 3 impacts are not considered in this paper. See also Note 1.¹

¹ Note 1: This paper represents the opinions of the authors and is the product of professional research. It is not meant to represent the position or opinions of Rogers Communications, and Rogers Communications does not accept any responsibility or liability for the accuracy, content, completeness, legality, or reliability of the information contained in this paper. The information contained in this paper is not intended to be relied upon for any specific application without independent verification and assessment of suitability.

2. Cooling Technology and GHG

Guidance in collecting and managing data to determine GHG and carbon footprint is found in SCTE 208 2021 – Cable Operator Greenhouse Gas Emissions Data Collection Recommended Practices.

As can be seen from Figure 1- Footprint of a Typical Cable Operator (from SCTE 208 2021) Cooling Technology consists of *Scope 1 (Direct Emissions)*, Refrigerants, 4.2%, and *Scope 2 (Indirect Electricity Emissions)*, Cable Critical Facilities Electricity of 22.2%.

Figure 1- Footprint of a Typical Cable Operator (from SCTE 208 2021)

2.1. Refrigerants

For Refrigerants, *Scope 1 (Direct Emissions)*, the Environmental Protection Agency (EPA) provides a method to estimate emissions from: Installation, Operation and Disposal to determine total emissions in this category. This is covered in detail by the EPA in: *Greenhouse Gas Inventory Guidance: Direct Fugitive Emissions from Refrigeration, Air Conditioning, Fire Suppression, and Industrial Gases*.

Refrigerants used in HVAC systems affects their efficiency and therefore can have an effect on *Scope 2 (Indirect Electricity Emissions)*.

2.2. Cable Critical Facilities Electricity – Cooling Systems

Cable Operators Critical sites commonly consist of a combination of older and newer cooling systems.

Cooling systems that are over 10 years old are generally considered “Legacy” Cooling Systems with higher electrical consumption hence higher emissions.

Legacy Cooling Systems have a number of limitations which result in contributing significantly to the Scope 2 reported emissions of 22.2%.

2.3. Legacy Cooling Systems

Legacy HVAC systems operate at a fixed capacity, or at best in a rudimentary step function to provide some variable capacity, and therefore have a high mechanical Power Usage Effectiveness (PUE) for a

given heat load. Energy saving features such as: Free Air Cooling; Pumped Refrigerant, were not available.

If more than one unit is used to cool a given heat load, quite often they operate independently which means they may not share the heat load causing one unit to operate at a much higher cooling level than another. In some cases, networking, sequencing and ‘teamworking’ the units to operate together, if applied properly, can improve their combined efficiency.

The fans in the evaporator and condenser are fixed speed and so have a fixed energy consumption, regardless of heat load.

Monitoring capability is rudimentary and does not provide any significant data on “real time” energy consumption to enable effective energy management.

Air cooled HVAC installed in Critical Facilities prior to 2010 used the refrigerant R-22. Although the GHG (Measured by Global Warming Potential (GWP)) of R-22 was similar to refrigerants used today, for example R-407C or R410A, they are not chlorinated substances which are classified as an Ozone Depleting Substance (ODP). That makes R-22, a chlorinated refrigerant, a much less desirable refrigerant. New R-22 refrigerant is no longer available which means cooling systems using R-22 are reliant on recycled refrigerant if top ups are required. The supply of R-22 will diminish over the next few years resulting in higher costs and will eventually not be available.

2.4. Cooling Systems Today

HVAC systems in use today have variable cooling capacity, using scroll type compressors or the equivalent to gain over 2000 points to adjust the evaporator. Evaporators have a higher capacity and Electronically Commutated (EC) capability enable variable speed fans to be used on evaporators and condenser. Pumped Refrigerant, or direct free air cooling are also available to reduce energy consumption. This has allowed a significant energy reduction for a given heat load.

Controls and monitoring are much more sophisticated but represent a training challenge for operations teams. There is room for significant improvement both in the operation of units and in right sizing for a given heat load.

Air Cooled units now use more environmentally friendly refrigerants such as R407C or R410A which have zero ODP and a reasonable GHG/GWP.

3. Improvements to Reduce Energy Consumption in Legacy/Existing Facilities and Cooling Systems

Older critical facilities suffer from poor cooling efficiency due to older cooling systems being used and because the sites were not designed for the heat load levels being experienced today. As a result, the racks and cooling designs were not well laid out for effective heat removal. This resulted in poor air flow management requiring excess cooling and air flow to meet the growing heat load demands.

The SCTE Facilities Cooling Technology Optimization Working Group has addressed methods to improve and optimize cooling in legacy facilities in the papers highlighted below.

- Improving air flow management – resulting in less air flow required and higher return air temps – SCTE Journal SCTE-EM-V5N1 – Rightsizing Network Cooling – Getting Ready for 10G
- Increase in set points – SCTE 253 2019 Cable Technical Facility Climate Optimization Operational Practice: Understanding Set Point Values, Part 1
- Air containment – SCTE 274 2021 Cable Operator Critical Facility Air Containment Operational Practice
- Control Systems and Networking cooling units Reference SCTE 184 SCTE Energy Management Design, Construction and Operational Practices for Cable Facilities
- Operational Practice to improve air flow and climate conditions in Critical Facilities – SCTE 219 2021 – Technical Facility Climate Optimization Methodology

Pilots and research trials by multiple Cable Operators have measured and verified the possible energy savings potential of the listed Energy Conservation Measures (ECMs) as shown in Figure 2 - ECM Estimated Savings. The scalability and magnitude of these measures will be unique to the site and providers as they identify, through assessments, where their baselines are, and what would have the most impact to their sites.

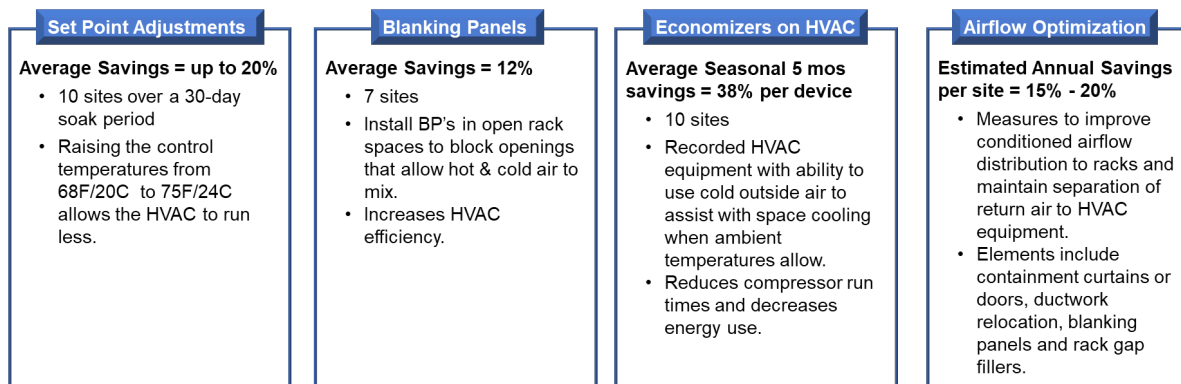

Figure 2 - ECM Estimated Savings

As the savings above indicate, several low-cost implementations can result in measurable energy reductions. Additionally, the replacement of existing aged HVAC units can result in immediate efficiency gains resulting in improvement of Scope 2 by 20% to 30%.

3.1. Floating Head CRAC Retrofit

Floating head retrofit is applicable to Computer Room Air Conditioning (CRAC) units that are Direct Expansion (DX) based and that are 5 years or older. This retrofit will improve energy efficiency and reduce carbon footprint. The mechanical expansion valves in these older units are replaced with electronic expansion valves, enabling the unit to adapt to ambient temperatures and regulate condensing temperatures accordingly.

Traditional fixed head pressure systems run at a condensing temperature of 40°C (105°F). The energy savings for retrofitted low condensing systems begins to accrue whenever the ambient temperature is

below 24°C (75°F). Figure 3 below shows the percentage of time the respective area is below 24°C (75°F) geographically.

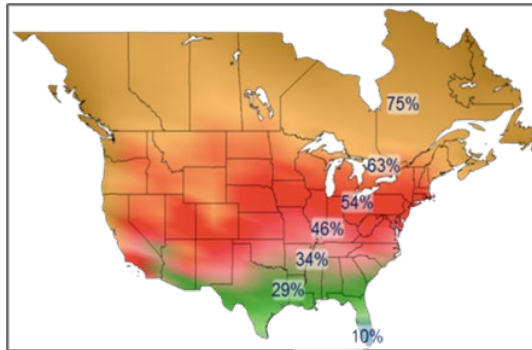

Figure 3 – Map of Temperatures for selecting Floating Head as an ECM

(SCTE Journal of Energy Management 2016 VINI, New A/C System Architecture Promises Significant ROI in Data Centers, Floating Head Pressure Technology Reduces Energy Costs and Consumption)

Temperatures below 10°C (50°F) ambient represents the level at which the maximum energy savings from low condensing operation can be achieved as the compressor wattage decreases. A small increase in cooling capacity also occurs.

Energy consumption can be reduced by up to 45%, and the life expectancy of the unit will be extended as there is less wear on the main components.

A floating head retrofit won't make the legacy unit as energy efficient as the newest economizer models. However, comparing the cost and short payback, typically 2 years or less, of this retrofit, with the capital cost and operational disruption caused by replacing a cooling unit with an economizer system this option is very attractive. The retrofits do qualify for energy incentives if available.

In addition to energy savings two other benefits are captured with the retrofit. If the unit is using R22 refrigerant, that is units produced before 2010, this can be replaced and upgraded to R407C. The second significant benefit is less refrigerant is required for the retrofitted unit. Approximately 35% of the refrigerant is removed. The amount of refrigerant removed is dependent on the cooling capacity of the unit and the physical layout, distance from condenser.

The table below shows a case of retrofitting two Liebert DH-290's and one Liebert DS105. In this example the R22 refrigerant in the DH-290's was removed and appropriately disposed and replaced with R-407C. CO₂ equivalence was calculated using the EPA Greenhouse Gas Equivalencies Calculator.

Table 1 - Floating Head CO₂ Reduction

Floating Head Retrofit - example			
Cooling Units	2 - Liebert DH290; 1 - Liebert DS105		
	Pre-Retrofit	Post-Retrofit	Reduction
Cooling Power kW	67	34	33
Cooling Energy (kWh)	585,416	299,201	286,215
Energy Cost (\$0.12/kWh)			\$34,346
CO ₂ Equivalence			
Refrigerant Removal (kg)			211.47
Refrigerant Removal (lbs)			466.2
CO ₂ Equivalence Reduction			Metric Tons
	Due to kWh avoided		203
	Due to refrigerant removal		383
	Total		586

3.2. Room or Perimeter Cooling

Room scale cooling is where interior perimeter CRAC or Computer Room Air Handlers (CRAH) are used to remove heat from the space and provide conditioned air into the room. These systems are spaced around the exterior and in larger rooms near the center. This system typically provides bulk conditioned air into the room via raised floors, direct air discharge from the unit or through overhead duct work on a slab floor. Because of this bulk delivery approach several inefficiencies are evident due to hot and cold air mixing, by-pass airflow, high volume over provisioned air, and older fixed fan speed and staged compressor speeds. ECMs can be applied to improve efficiency.

3.3. In-Row Cooling

As rack heat loads increase a more efficient cooling method must be implemented to manage high density heat zones. In-row cooling is the deployment of multiple smaller units selectively placed between the cabinets within the rows of server racks. With the assistance of containment doors, curtains and sometimes row caps, a more controlled environment can be created. Having available space for the added in-row devices can be an obstacle for a retrofit application in legacy sites. As the density within the server racks increase so too will the added requirement for redundancy.

Figure 4 - Example of in-row cooling where air conditioning units fit inside rack rows.
Courtesy: PRWeb

3.4. In-Rack or Close Coupled Cooling

In-rack or close coupled cooling places the cooling much closer to the source of heat . The extremely short distance between the server exhaust and rear door coils is measured in inches vs feet for the room and row applications thus eliminating the opportunity for mixing and other efficiency losses. .

The rejection of heat is accomplished with pumped refrigerant or chilled water running through coils at the rear doors, to an in-room heat exchanger using outside condensers. The exterior components have either economizer or mechanical cooling to complete the cooling cycle. The refrigerant pump within the main heat exchange chassis can also be DC powered. The rear door heat exchangers, as shown below, can handle 10 kilowatt (kW) per fan pair and have redundancy when all 3 pairs are installed.

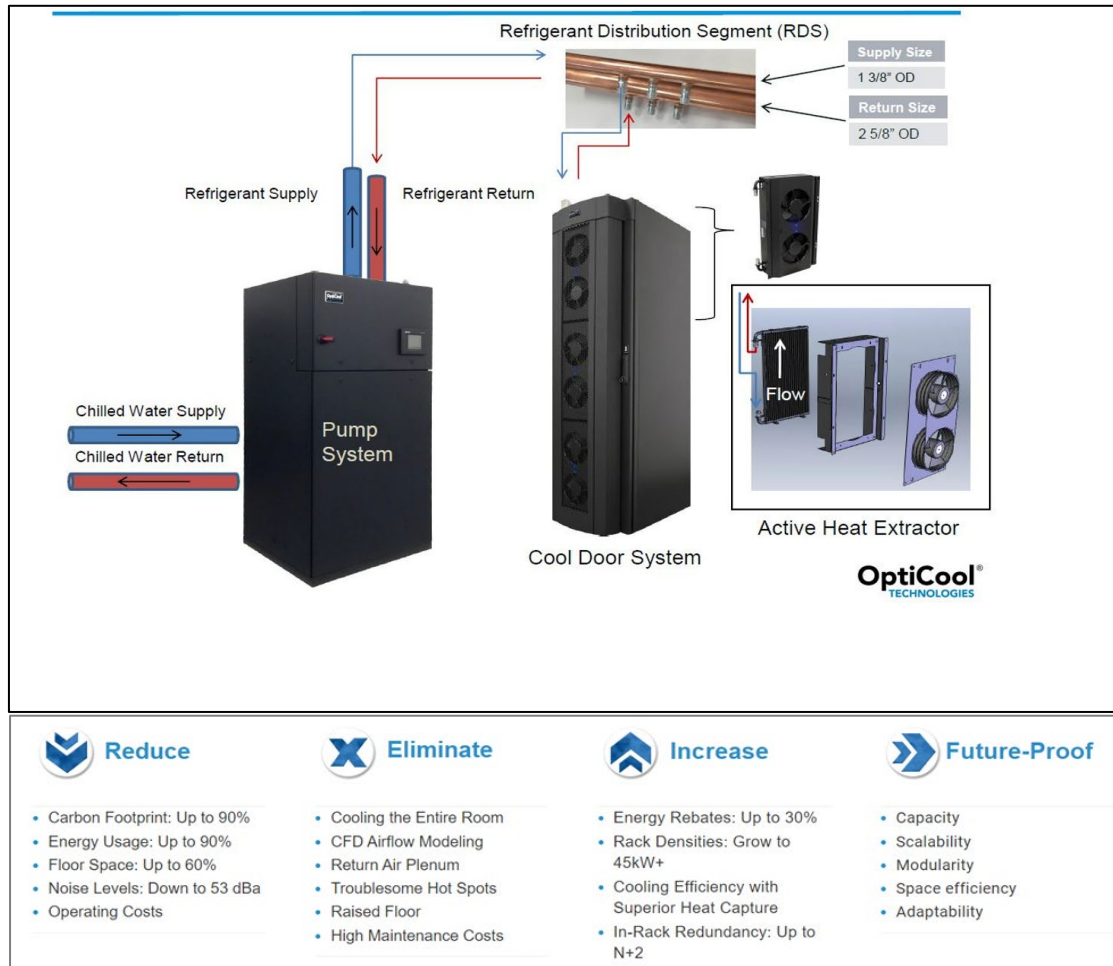

Figure 5 - Rear Door Cooling (Diagram credit: OptiCool)

Additionally, these systems require a minimal load working best on a high kW density (typically 10 kW to 30 kW per rack) applications. Overhead space is required for manifold piping and each rack depth is extended approximately 12-14 inches for the rear doors.

3.5. Investigating bulk rack exhaust fans vs server muffin fans for rack containment

Another innovative In-Rack cooling approach being developed is to utilize an existing raised floor environment or overhead ducted supply system to bring the cooling more efficiently where it is needed. This approach uses a clear solid door on the racks with a separate supply and return ducting with dual in-line fans reducing the need and cost of the server fans. Additional in-rack airflow manifolds have been developed to direct airflow for equipment intake variations. As shown, the doors would be solid and individual servers would be fed and exhausted via side discharge.

Figure 6 - Air Diverter System (Courtesy of Chillirack)

3.6. Why not Switch To CO₂ (R744) Refrigerant Based Cooling Units?

High pressure Carbon Dioxide, CO₂ or R744 systems were developed at the end of the 19th century. It has an GWP of 1 so it would seem to be the ideal refrigerant. There are real advantages to using R744 but also some drawbacks holding it back from general adoption in the industry.

The following table summarizes some of the advantages and disadvantages of R744.

Table 2 - R744 Advantages and Disadvantages

Advantages	Disadvantages
Refrigeration capacity is high, approximately 5 times that of R404A (smaller compressor displacement but the same motor size)	Operating and standing pressures are high with resulting higher leak potential. Components specific to R744 required
Pressure drops in pipes allowing longer lines	Compressors are R744 specific, steel, or stainless-steel welded fittings required
Evaporators and condensers have high heat transfer	System complexity resulting in higher costs
System pressure drops, compression ratios all result in higher system efficiency	Complexity can result in poor performance and reliability because commissioning and operation need to be done correctly
Thermosyphoning of the refrigerant is possible reducing compressor run time.	Not suitable for high ambient temperature areas
R744 is inexpensive to manufacture, has low toxicity so release, often just by venting, or leakage is not an issue as there are no disposal restrictions	Listed as an asphyxiant so leak detection is required in small, enclosed spaces and release needs to be in well ventilated areas.

As can be seen from Table 2 - R744 Advantages and Disadvantages although there are significant advantages to R744, the disadvantages, particularly the complexity that operational staff will need to deal with, and the specialized materials, have resulted in a low adoption rate of these systems.

3.7. Monitoring and Control Systems

3.7.1. Background

Mechanical thermostat controls are the most traditional form of control for HVAC systems that can still be found today in headend and hub locations performing basic on/off control of the HVAC systems. Unfortunately, these types of controls do not lend themselves to modern facilities and certainly do not provide the necessary data needed to monitor and control HVAC systems to ensure optimum performance. Fortunately, there are options available today to quickly and reliably upgrade existing HVAC to smart thermostats that network into a cohesive system.

The Building Management System (BMS) have been a powerful tool to help critical facility managers monitor and control key facility infrastructure support systems. These typically include main facility electrical and mechanical systems such as: electrical power distribution systems, central air conditioning and ventilation, fire protection and lighting.

BMS systems will tend to be a localized system consisting of a software and hardware. Older BMS systems however typically do not offer a more granular control for specific critical support equipment necessary for today's demands from critical processing servers.

3.7.2. Current Monitoring and Control Technologies

Critical facility management relating to energy consumption, costs, downtime as well as its carbon footprint contribution can be challenging to most organizations without the proper tools. For this reason, monitoring and control systems play a crucial role in assisting facility management. Although current systems such as BMS, have been a valuable tool for facility management, these systems are becoming dated and lack sophistication for optimizing energy consumption management. These existing systems, albeit provide critical information to the operator, and primarily serve as a historical data archive and

alarming system. These systems serve a limited capability with respect to data collection and usage as well as critical metrics and features for control optimization. As the industry looks towards updated systems offering enhanced tools and features, current systems employed are pushed to their limits of operation and obsolescence.

Systems are becoming more intelligent, providing access to significant amounts of data from their sensors regarding the performance of the equipment.

3.7.3. Data Aggregation

Most control and monitoring systems today have some form of a local user interface to view trend data such as room temperature and the ability to make adjustments. While this is necessary at a site level, it is important when managing multiple sites to have a central server-based monitoring software that can gather trending and alarm data from all of your facilities. Modern monitoring and control systems offer comprehensive monitoring and data acquisition and data storage capabilities. Many of these systems are now capable of integrating services and solutions across multi-vendor platforms for data centers and other complex mission critical facilities.

These systems have the capability to aggregate data from separate and disparate systems to provide a useful database for system comparisons, interactive intelligence and enhanced control decisions for energy savings, optimization, and efficiency. Incorporating data from ITE Assets and existing BMS systems into a single cohesive platform will provide the most comprehensive intelligence for monitoring critical facilities.

This provides the ability to identify outlier/trouble sites and prioritize maintenance resources.

3.7.4. Data Analytics

Central monitoring software is being used to provide operators with information that can predict operation of equipment and serve early warnings to impending failures which improves network reliability. These tools provide true real time situational awareness and insight to present operators with critical information to address system availability across a single facility or facilities throughout the enterprise. This approach integrates advanced energy analytics, asset management and facility monitoring tools with advanced analytics to increase visibility, improve overall efficiency, reduce costs, and mitigate risk.

This ability to create actionable data can be used to further optimize operation to reduce energy consumption of equipment and provide verification of carbon reduction. For example, the software can analyze excessive runtime with HVAC equipment at all sites. It can include frequency of ON / OFF occurrence and shortest duration between ON / OFF (To indicate unhealthy short cycling). The report can show historical performance, live data overlays, suggested targets, and remediation. Another example, the central monitoring software can poll the local control systems to gather the current cooling operation and then generate a report indicating zones where temperature setpoint is not maintained when cooling is on. Time between triggered cooling event and time to satisfy zone temperature are tracked to indicate degradation in cooling effectiveness.

3.7.5. Next Gen Controller Technologies

Control systems can use machine learning for adaptive control strategies. This is leading to control systems that can automatically adjust their settings to changes in the facility and better matching of the heat load. An example of this is the ability to adjust the economizer control setpoints based on successful cooling using outside air. Traditionally the economizer settings are fixed thresholds for when outside air can be used. Intelligent control systems can learn what outside air temperatures will provide necessary

Economizer Setpoint Change over Time
March 9th to April 9th

The graph displays the Economizer Setpoint (L1) over time. The y-axis represents the setpoint value, ranging from 55 to 73 in increments of 2. The x-axis represents time, from March 9th to April 9th. The setpoint starts at 65, drops to 61, then fluctuates between 61 and 67 before rising to 71, peaking at 72, and ending at 70.

Date	Economizer Setpoint (L1)
March 9th	65
March 10th	65
March 11th	61
March 12th	61
March 13th	61
March 14th	62
March 15th	63
March 16th	64
March 17th	65

Figure 8 - Control System Communicates to Smart Equipment and Smart T-Stats Connected to Legacy Equipment

3.7.6. Tie to Carbon

With the advancements of control and monitoring systems, organizations are able to realize significant reductions in direct energy usage and carbon footprint. Monitoring and control systems for today's facilities are at their best when they can take dissimilar or standalone intelligent systems and coordinate their control to ensure the facility is sufficiently cooled for their intended use. Intelligent controls are able to take advantage of alternate cooling methods such as outdoor economization to further reduces compressor run time. Charter Communications, Inc. reported in 2021 that "evaporative free-cooling avoided over 5,700 megawatt-hours of electricity usage"³. This translates to a CO₂ reduction of approximately 4,039 Metric Tons⁴. Another MSO has recently completed a free air economization proof of viability at a Northeast facility where a reduction in compressor run time provided a savings of approximately 19,162 kilowatt-hours (kWh) during a five-month period available for economization use. This will yield a CO₂ reduction of 13.6 metric tons.

The ability to remotely monitor the performance of a portfolio of facilities and make necessary changes prevents unnecessary travel to sites which reduces carbon emissions and saves on fuel expense. Through the advancements of the Internet of Things (IoT), additional sensing is economically being deployed to remote facilities. The ability to gather information and turn it into actionable data will further increase an operator's ability to document, categorize and manage their carbon footprint.

4. Next Generation

4.1. Next Generation Refrigerants

Refrigerants available are being updated to reduce their GWP. One of the drivers for this is the Kigali Amendment to the Montreal Protocol. This primarily affects R22 for Cable Operators at this time. Refrigerant properties are available in ASHRAE Standard 34 Designation and Safety Classification of

³ Charter-2021-ESG-Report.pdf, <https://corporate.charter.com/esg-report>

⁴ Carbon reduction calculated using the EPA calculator. <https://www.epa.gov/energy/greenhouse-gas-equivalencies-calculator>

Refrigerants which provides refrigerant numbering, toxicity, and flammability ratings. The pursuit of other refrigerants may take place over time and depends on low pressure, medium pressure, or high-pressure systems. The best choice today may change tomorrow. Although complex, the key decision for selecting a new refrigerant needs to be made on efficiency.

Nonetheless for GWP the HVAC system has a direct effect from the chemical refrigerant, and indirect effect from the energy use adding up to the total climate performance.

The biggest factor that can be controlled by the Cable Operator is then the indirect effect from energy use and the associated GWP of that energy source.

4.2. Next Generation Cooling Technologies

4.2.1. Phase Change Material (PCM)

The effectiveness of cooling systems that use outside air (free air-cooling systems), can be improved considerably with the use of (PCM). This can cool the incoming air reducing compressor run time, extending the free air-cooling time, and be recharged at night when the temperature is lower.

Figure 9 - Phase Change Material and Free Air Cooling (Diagram Courtesy of Energy Cool[®])

4.2.2. Liquid Cooling

As ITE heat loads increase, the effectiveness of air-cooling systems will reach a limit with reduced efficiency. In order to cool the higher heat loads and drive PUE down below 1.1, closer coupling of heat removal is required using some form of liquid cooling. This paper will not go into detail of the technologies that are available, but they are:

- Liquid cooling - A cabinet or plate to remove heat directly from the surface of the chips used by the ITE heat load.
- Immersion cooling - Removes all fans and submerges the ITE heat load directly in a dielectric cooling liquid.

Currently both are used for higher density computing above 50 kW per cabinet.

4.2.3. Internal Server Cooling

Internal server cooling may improve using hybrid two phase cooling using passive low height thermosyphons to dissipate the heat generated in high power components of servers. This augments traditional cooling of other server components.

5. Conclusion

Through the careful use of ECMs, and selection of cooling technologies that are appropriate, Critical Facility energy use for cooling can be significantly reduced as the ITE heat load increases. This in turn will help to reduce Scope 2 emissions and overall GHG impact.

Additionally the use of more environmentally friendly refrigerants can help to reduce GHG's. Refrigerants are being updated to reduce their GWP but must be selected carefully as this can in turn affect the HVAC performance.

It can be seen in Figure 10 - GWP Life Cycle Climate Performance, that the major climate impact of HVAC is the electrical power used, and how it is generated, over the equipment lifetime. The key factor in refrigerant selection then is its effect on the efficiency in the HVAC system. A refrigerant that results in overall lower HVAC cooling effectiveness per kW of heat load will result in a higher Scope 2 emission for the system as it will consume more electrical power.

With the source of the electrical power being a key factor in the critical facility life cycle, climate performance consideration must be given to reduce that impact through use of microgrids, Demand Energy Response (DER) and other solutions for greener energy sources.

1. Introduction

In this paper, we will discuss the basic operation of BGP and inter-provider Internet routing including some vulnerabilities of the system. We will then describe RPKI, a set of technologies developed by the IETF (Internet Engineering Task Force) to help address a sub-set of these vulnerabilities. Deployment of these tools is not without risk and complication, and we will describe how we went about assessing and enabling RPKI in a large MSO network including design tradeoffs and lessons learned.

This is a complex set of technologies which have matured over the course of a decade or more of implementation and deployment experience. It operates across many operational and software domains with many actors and interacting systems. Hence decisions whether to deploy it and exactly how to do so while minimizing risk and disruption must be balanced carefully. These risks and complexities are magnified as function of the number of resources, interactions, and systems involved.

Making use of RPKI to improve security for an MSO (Multi-System Operator) service provider network is just such a complicated scenario and special care must be taken. In this paper, we describe the various considerations we assessed and decisions we made in the course of this enablement.

2. BGP Background

In order to communicate with given resource on the Internet, it's necessary to send packets to the destination IP (Internet Protocol) address which can service that request. BGP (Border Gateway Protocol) is the method different networks that make up the Internet use to communicate what endpoints (IP addresses) can be reached on their infrastructure. As put in [RFC 4271](#), “[t]he classic definition of an Autonomous System is a set of routers under a single technical administration”. BGP speakers (routers configured with BGP) within an AS can communicate reachability information for IP prefixes which are reachable within the infrastructure of that AS to neighboring ASes.

As a BGP message (sometimes also called an “advertisement” or “announcement”), leaves an AS border router to an neighboring AS, if the first AS originated the announcement for a given IP address block, that AS puts its ASN (Autonomous System Number) in the BGP message as the “origin AS”. Each AS that conveys that reachability information onward via BGP appends its own ASN in a chain known as the “AS-Path”. The AS-Path has a few functions including preventing loops in the topology and also operationally tracing responsibility for handing routing and traffic for a given destination.

To take an example, if AS150 originated a BGP route for 2001:db8::/32 which was then received by AS280 and passed along from there to AS320, we would expect an AS-Path of “320 280 150” read from left to right as “nearest” to “furthest”, ultimately to “origin” AS.

[Include references and pictures.]

3. BGP “Hijack” Risks

The basic BGP protocol was specified almost three decades ago ([RFC 1654](#) superseded by later RFCs) and for more than two decades the operational community has recognized some security risks with the protocol.

One important aspect of the Internet routing system is that routing information flows not only between directly adjacent ASes but also, transitively, to distant ASes. The complexity and dynamic nature of the global Internet routing system historically has not had any “ground truth” declaration of the proper topology and relationships among the various ASes and IP address blocks connected to them.

BGP mis-originations, sometimes called “hijacks”, refer to cases where a network other than the legitimate address-holder incorrectly advertises reachability for a given IP address block. The term “hijack” suggests malicious intent however in most cases the intent of the actors involved is not disclosed or definitively known. Some cases appear to be the result of a configuration error where some characters in the address block may have been transposed or another typographical error has occurred. In some other cases, a bug in a router or other piece of network equipment seems to have caused the problem. The risk of such events can be visualized by this diagram:

Figure 1: BGP Hijacks steal and divert Internet traffic to attackers.

(Courtesy USA National Institute of Standards and Technology)

Perhaps the most well-known case is the 2008 Pakistan Telecom incident which appeared to involve a BGP redirection within the Pakistan Telecom network to possibly enable censorship of a popular Internet video provider in country. The bogus BGP information leaked out to the broader Internet and ended up disrupting legitimate traffic intended for said provider as illustrated in the diagram below

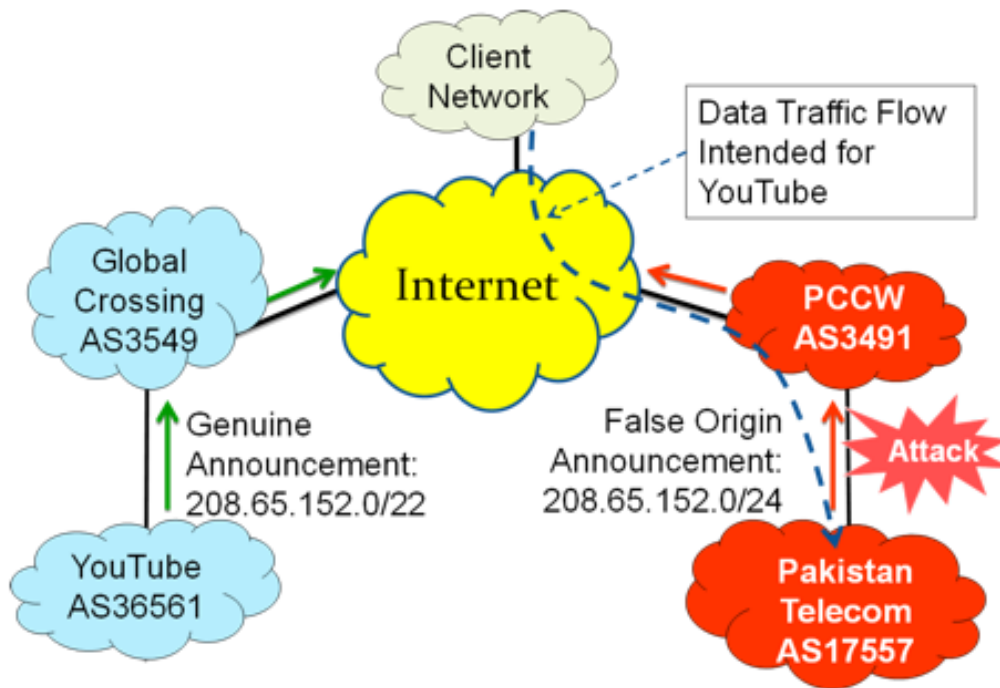

Figure 2: 2008 Pakistan Telecom BGP incident

(Courtesy USA National Institute of Standards and Technology)

A [catalogue of public BGP hijack incidents](#) on Wikipedia includes approximately twenty episodes spanning many years and that list is not exhaustive.

To address this particular weakness in the routing system, the [IETF SIDR](#) (Secure Inter-Domain Routing) Working Group worked to develop new enabling technologies. We will discuss the first one of those below and what Comcast did to utilize them.

4. RPKI and ROV Overview

RPKI (Resource Public Key Infrastructure) defined in RFCs 6480-6493, is a method which follows the IP address assignment hierarchy. The root of Internet addressing rests with IANA (the Internet Assigned Number Authority) which delegates addresses to the 5 Regional Internet Registries (RIRs) assign IP address resources to different network operators or delegate further to LIRs (Local Internet Registries which can be on a country (e.g., China, Brazil) or Service Provider level.

The structure of the RPKI uses X.509 digital certificates to enable cryptographic verification of the chain of authority and particularly to issue ROA (Route Origin Authorization) objects which describe a mapping of an IP address range and the origin AS (Autonomous System) which has authority to announce reachability via BGP.

The figures below illustrate the delegation hierarchy manifested in the RPKI as well as the components needed to create a ROA (Route Origin Authorization) object.

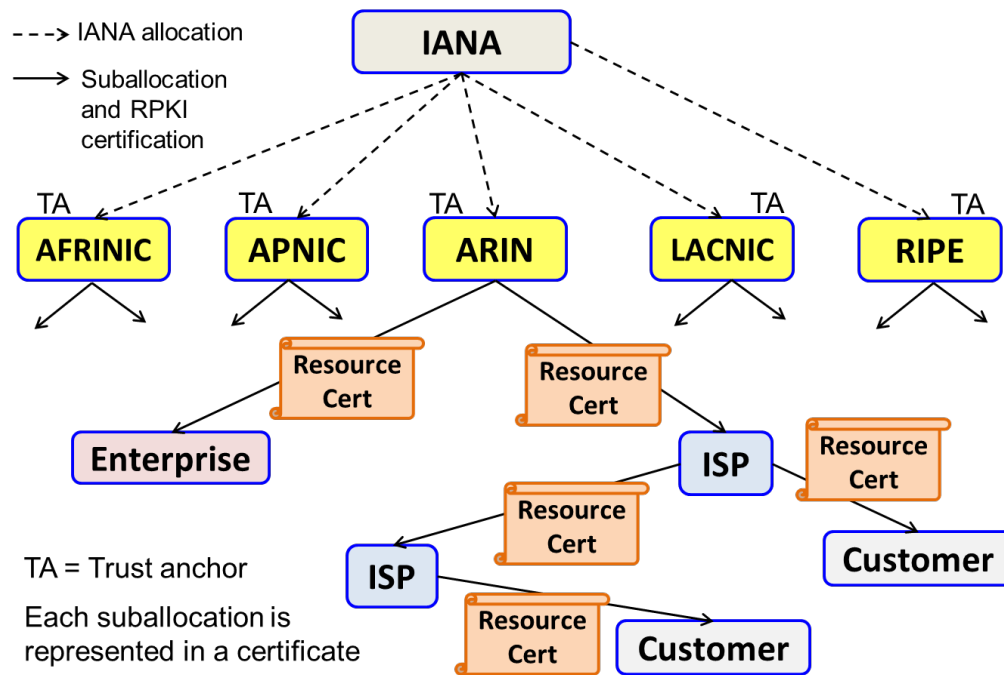

Figure 3: RPKI (Resource Public Key Infrastructure) Delegation Structure

(Courtesy USA National Institute of Standards and Technology)

A ROA consists primarily of three elements:

- IP prefix (IPv4 or IPv6) or range
- Maximum valid length for a prefix within that range
- The AS authorized to announce (“originate”) that prefix in BGP

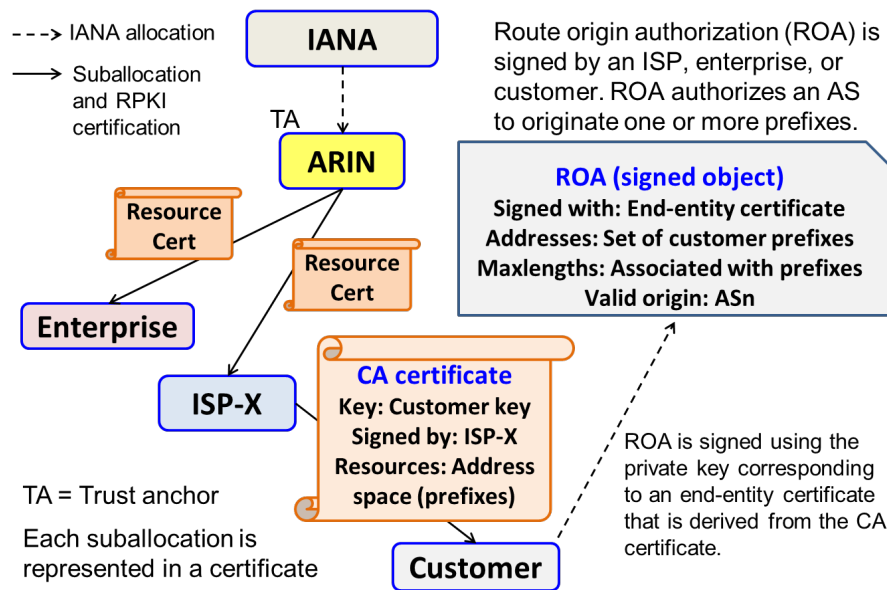

Figure 4: ROA (Route Origin Authorization) Creation

(Courtesy USA National Institute of Standards and Technology)

These objects and associated artifacts, e.g., manifests and CRLs (Certificate Revocation Lists) are published so that they may be verified using any of several compliant RP (Relying Party) software packages. Once the verification is complete, the VC (Validating Cache) system renders the output mappings in a form that can be consumed by routers using the RTR (RPKI To Router) protocol.

A compliant router can then be configured to use the information to validate incoming BGP announcements and take action based on comparing them to this set of authorizations. This process is known as ROV (Route Origin Validation).

5. Deployment - Reading and Writing (Validating and Publishing)

There are two aspects to RPKI ROV; validating and publishing RPKI data which can be thought of as “reading” and “writing”. It is not required to deploy these at the same time, in a given order, or for a given operator to do both, necessarily. We will discuss each below.

5.1. Validating

In order to perform validation of BGP information, the source data must be collected and loaded into the routers. In this section, we will outline the components and process.

5.1.1. Relying Party software

A number of freely available [open source software implementations](#) of the RP (Relying Party) function have been developed over the spread of several years. Some of them have been maintained more vigorously than others.

RP software is run on VC (Validating Cache) servers and must have access to reach any Internet destination via at least the *rsync* protocol (TCP port 873) and RRDP (RPKI Repository Delta Protocol) in order to collect the RPKI data from the various publication points which cannot be known a priori and are communicated via URIs, including DNS (Domain Name System) names, embedded within RPKI data; hence, DNS-based and not IP-address based and not amenable to IP-based firewall rules or access controls.

After fetching all the RPKI data and performing cryptographic and other consistency checks against it, the VC produces a list of VRPs (Validated ROA Payloads) consisting of an IP prefix (IPv4 or IPv6), a maximum length (often referred as “maxlen”), and an origin AS authorized to originate such a prefix up to the “maxlen” value.

Additionally, [RFC 8416](#) defines SLURM (Simplified Local Internet Number Resource Management) by which the operator of a VC can inject “local overrides” which will augment the public RPKI data as may suit the network operator’s needs.

5.1.2. Router configuration

The routers consume VRP data from the VC servers via the RTR (RPKI To Router) protocol, defined in [RFC 8210](#), which runs via a TCP connection by default port 323 but can be some other user-defined port. Multiple RTR servers can be defined, and, for most router vendors, the router considers the union of all VRPs received via RTR. Refer to the diagram below for illustration of the data exchanges involved.

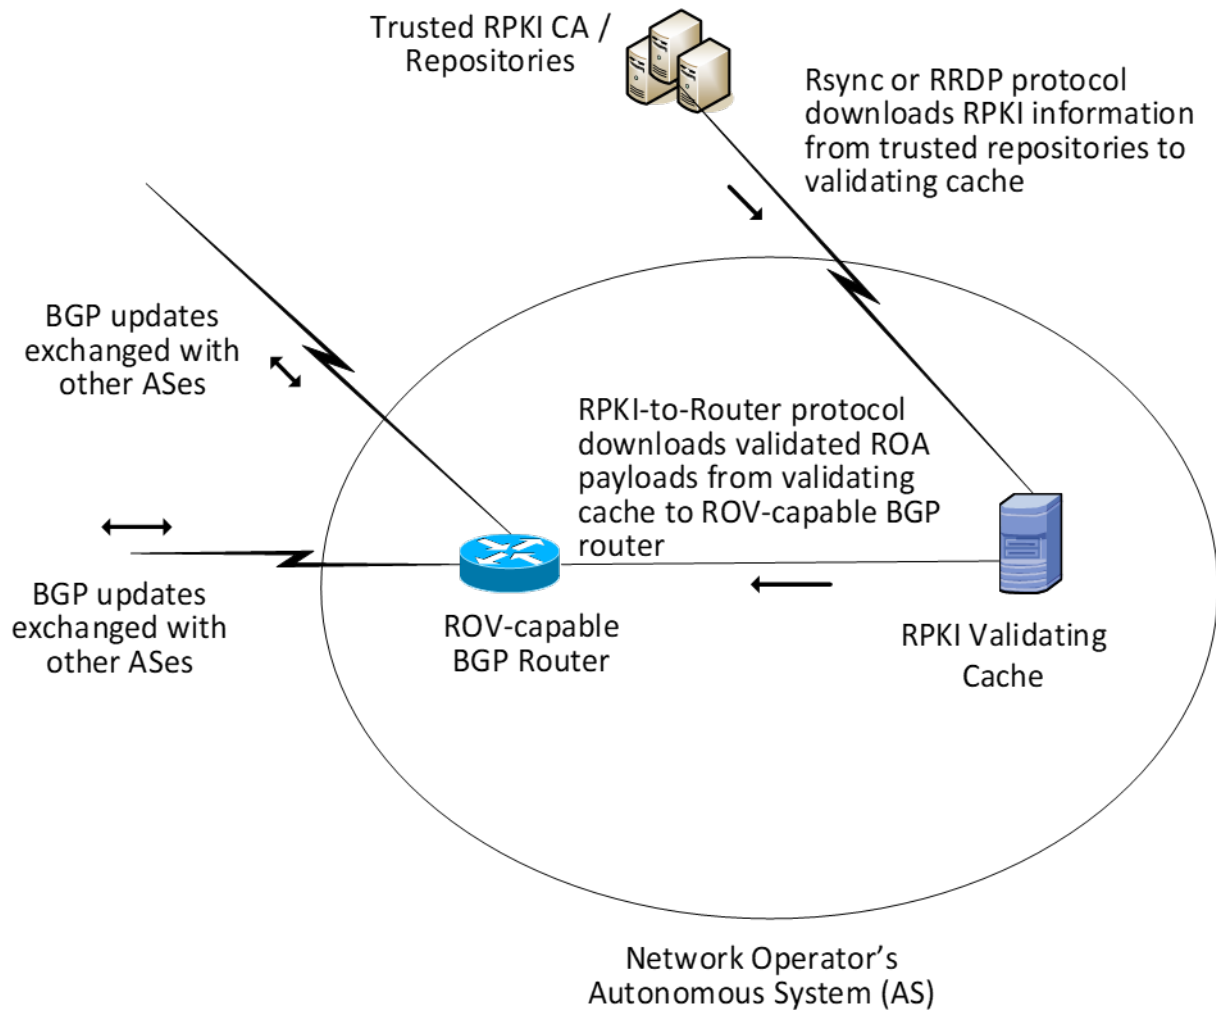

Figure 5: RPKI ROV (Route Origin Validation) Data Flows

(Courtesy USA National Institute of Standards and Technology)

Then the router is configured to perform ROV on the BGP table. The configuration options and implementation details among the vendors may vary somewhat but for our purposes, we decided that the most important risk of erroneous BGP announcements was from other networks; hence we would focus on eBGP sessions to other networks (in our case we have eBGP sessions between different ASes that are under our administration so not truly “external”). With the configuration we selected, each BGP announcement received over these eBGP sessions would be evaluated against a local table of VRPs (Validated ROA Payloads) received from the VCs. The validation of a BGP route against a ROA has one of three possible outcomes:

- **NotFound (a.k.a. Unknown)**
 - BGP route does not match any ROA
- **Valid**
 - BGP route matches a ROA – same Origin AS and same length or w/in “maxlen”
- **Invalid**

- The ROA and route announcement differ either of these ways:
 - Originating ASN
 - Maximum length ("maxlen")

It is very important to note that the operational model for RPKI ROV is that if a route is in the "not-found" category (no matching ROA in the routers local cache), the route should be accepted in the routing table and traffic forwarded to that destination. Routes which are "valid" should, of course, be accepted and "invalid" routes should be dropped. In this sense ROV is said to follow a "fail open" model which means that if the connection to the VC server is lost or the VC server loses its feed of RPKI information, traffic will continue to flow and not cause an outage.

At the time of this writing, (June 2022), below is a view of the global IPv4 BGP table and what routes are covered by ROAs. As this graph shows most of the Internet IPv4 routing table is not covered by any ROA but an ever-growing slice is covered, and a very small amount seems covered but not valid per the logic above. At the time of our deployment the portion covered by a valid ROA was closer to 30%. The net effect of these factors meant that, if there were to be some failure in the RPKI components as we were deploying them, we would end up in no worse a situation than we had been prior to the rollout.

Figure 6: RPKI ROV Analysis of IPv4 prefix-origin pairs

(Courtesy USA National Institute of Standards and Technology)

5.1.3. Deployment considerations

Given the fairly large number of variables that we had to confront, some basic guiding principles made it possible to narrow the world of possibility to a smaller set of options. We sought to reduce the potential risks involved with a new technology and these concepts helped:

- Diversity
- Redundancy
- Incremental rollout (and rollback)

5.1.3.1. Diverse RP software packages

One key decision was to utilize two different [RP software packages](#). RPKI is still a maturing technology with many different deployment insights and considerations coming to light over time. By using two different implementations, if one had a problem either transient or perhaps somewhat longer lasting, that package could be taken out of production temporarily.

Initially, we chose:

- [Routinator](#) (written in the Rust programming language by NLnet Labs)
- [RIPE Validator](#) (written in Java by RIPE NCC)

When RIPE Validator was [declared end-of-life in 2021](#), we replaced that with:

- [rpki-client](#) (written in C as part of the OpenBSD project)

5.1.3.2. Diverse data centers

Since a given data center could conceivably to offline or become isolated from some part of the network, we further refined our redundancy plan utilize one two VC servers in each of two diverse data centers (e.g., “East” and “West”). Each data center then would feature one of each of the above RP packages running.

Each edge router then would be configured with RTR sessions to each of the four VC servers. The final piece is to enable validation within BGP on a per-neighbor basis.

5.1.3.3. Incremental rollout which can be incrementally rolled back

Once a router is configured with RTR sessions with VCs, it is then ready to have validation enabled on eBGP sessions with other networks. We chose to enable ROV first on BGP sessions with a given partner network and went through a field trial working first with one, then another, and then began to expand the list. This deployment approach allowed for incremental activation and, if needed, incremental roll-back of the changes should any problems be encountered.

We started with a few partner networks and one router platform to be able to monitor for any possible ill effects and gradually expanded this circle to include others.

5.2. Publishing

In order to get protection from the RPKI-ROV system, an address-holder must publish ROAs to cover their IP address space indicating which AS(es) are authorized to originate BGP announcements for said address space. Comcast’s address space has been issued almost entirely

within the ARIN (American Registry for Internet Numbers) region so that was the focus of our considerations.

5.2.1. Hosted vs. Delegated (vs. Hybrid) model

At the time we were planning our deployment, there were two models for publishing RPKI data offered by ARIN and we will discuss each of those options here.

In the “[hosted](#)” model an organization generates a public-private key pair and sends the public key to ARIN and receives a “Resource Certificate” which covers the resources that ARIN has issued the organization. The organization is then able to sign ROAs with its corresponding private key and load them each into the ARIN system.

In the “[delegated](#)” model, the “parent” registry (ARIN in this case) issues a resource certificate to the “child” which hosts its own CA (Certificate Authority) and can issue ROAs for said resources or even further sub-delegate if desired.

There were (and are at the time of this writing) [two open-source software packages](#) which can be used as a CA and to issue ROAs:

- [Krill](#) (written in Rust by NLnet Labs)
- [rpkid](#) (written in Python2 and C by Dragon Labs)

In considering which model would make the best choice for us, the relative immaturity of these software packages and lack of broad operational experience suggested the best approach would be to use the “hosted” model for the initial rollout at least. Similarly, there had been a few instances operational problems of RIR repositories or CAs and should those happen, it would be preferable to share fate with a large number of RPKI users such that the most operational attention and expertise could be brought to bear on a solution.

One complication to the delegated model is that, as initially conceived, the publication of the ROAs and other RPKI material (manifests, CRLs – Certificate Revocation Lists) is done by the operator of the delegated CA. However, this represents an operational risk and has different availability requirements than the CA itself. Hence the “hybrid” or “publish in parent” approach has been developed and is offered by a number of RIR or LIR issuers. This option was not available from ARIN at the time of our deployment so could not be considered.

In either model, software mechanisms can be brought to bear to automate the issuing and analysis of ROAs against other information such as IP address management systems and routing tables. In both scenarios well-featured APIs (Application Programming Interfaces) are available for these purposes.

5.2.2. Risks

Before we started issuing ROAs for our address space, all our routes would be in the “not-found” status. As we start issuing ROAs, they must ensure they properly match the BGP routes that we advertise to other networks.

For many network operators, particularly many or most Enterprises and perhaps CDN (Content

Distribution Network) operators keeping these elements (BGP announcements and ROAs) aligned might be quite straightforward. However, for Comcast's network, the situation is rather complex. We have something over one hundred IP address blocks issued from ARIN however these are split up across more than twenty ASes, networks, and services. There is also a certain amount of dynamism in the addressing.

Our addressing design, generally, features the large IP address blocks being advertised from our Backbone network (AS7922) and different parts issued among our regional, data center, enterprise and other networks. Hence many different more-specific routes within our blocks would show up to other networks with different origin AS numbers.

5.2.3. Bottom-up ROA creation

Given this routing and addressing design, if we were to issue ROAs for the large blocks with an origin of AS7922, immediately all other routes which were properly visible for reasons of particular traffic flow would become "invalid" to other networks that were doing ROV which was a significant list by the time of our rollout.

Instead, the proper course was to issue ROAs for the various smaller-sized BGP announcements that were expected to be visible externally. (It is normal for a network to carry more-specific announcements internally and Comcast has thousands of these.) We gradually filled in ROAs for these pieces over the course of several weeks, starting very slowly until we had a good level of confidence we could properly detect if there was any problem caused. That detection included monitoring the level of traffic destined for a prefix using NetFlow data collected at our network edges.

Once all the more-specific routes in a given block were complete, we could "top off" by issuing a ROA for that large block and the over-arching advertisement from our Backbone AS. Issuing ROAs to deal with incremental changes after this first large deployment would be simpler and bear little risk.

All this work was considerably aided by software automation for the analysis and ROA issuance. Some was internally developed as well the [ARIN ROA request](#) script developed by Rich Compton of Charter Communications which, as the name suggests, uses ARIN APIs to effect bulk issuing (or deletion) of ROAs in ARIN's hosted system.

5.3. Learning

In the course of our deployment, a number of realizations came to light that we share here in hopes that it might be useful in the considerations of others who contemplate a similar course.

5.3.1. Bugs

Almost inevitably, bugs and unforeseen error conditions are discovered in the course of implementing new technology, particularly one as complex as RPKI. We had the good fortune to not be an early adopter and that strategy proved beneficial as many early growing pains had already been found and fixed by others and we appreciate their role in the development.

5.3.1.1. RP software

In some cases, one or another of the RP software packages would yield significantly different results from the other. Generally, these cases resulted from some differences in processing or implementation details sometimes including how they interacted with other infrastructure (e.g., publication points).

There have also been a few vulnerability reports (though none were catastrophic) and patches issued at different rates.

5.3.1.2. Router software

We worked with our router vendors for advice on best current code in the software trains that we use prior to enabling ROV. If there were outstanding bug reports, we examined the circumstances and impacts to help assess the relative risks.

5.3.2. Monitoring and instrumentation

From time to time, on one vendor's router platform we would see occasional situations where the number of prefixes received from the VC servers via RTR sessions would drop to zero and only slowly get repopulated as new VRPs came in. Monitoring the RTR sessions on each router which is configured with them is crucial for detecting and remedying the situation.

Each of our RP software packages comes with the ability to publish metrics for consumption within Telegraph, Prometheus or some similar monitoring solution and then to visualize the data over time using Grafana. This can allow for tracking any anomalous behavior to a given start time.

5.4. Future work

As of this writing, ARIN has begun supporting a [“hybrid” or “publish in parent”](#) ROA deployment model where the CA server is housed and managed by the network operator but the publication can be done on ARIN's high-availability Publication Point servers. We will likely consider making use of this which could also simplify administration of ROAs for address space issued by other RIRs.

The IETF [SIDROPS](#) (Secure Inter-Domain Routing OperationS) Working Group is where engineers from industry and other interested parties (e.g., academia, government, etc.) continue to convene to monitor the expanding deployment of RPKI and related technologies and discuss incremental changes or advice that may be appropriate. Also, under development are expanded uses of the RPKI architecture to further improve the security and resilience of the global Internet routing system.

6. Conclusion

The global Internet routing system is critical to the services, commerce, education, and entertainment of the world's population. Over the course of decades it has, through careful engineering and collaboration, managed to grow and scale to meet the changing objectives of its users. The fundamental security model is one piece that needed to evolve but also required

backward compatibility for incremental rollout while still realizing benefit with partial implementation. RPKI is the enabling foundation and ROV is the first realization of such improvements.

The operational model of RPKI is reasonably flexible to accommodate many different operational and deployment scenarios, however this malleability also means that deciding exactly how to deploy and in what order can seem daunting. By gradually narrowing options by adoption of guiding principles, it becomes easier to plot the way forward.

1. Introduction

Cable operators have vast amounts of network performance data available to detect and measure defects within the cable plant. Transforming this data into actionable intelligence can be a daunting task, especially having many existing systems and process already in place.

Failure Mode, Effects, and Criticality Analysis (FMECA) was first developed in the 1940s (Summy) and is now widely used in industries including aerospace, automotive, and electronics. The role of FMECA is to identify potential problems that may occur in a system or component, define how to detect the failures, and measure the effect. This analysis provides a consistent way to measure the criticality of common network failures and help prioritize repair efforts.

Authors Spaulding, Rupe, and Wolcott will present the jointly developed progress of the CableLabs and SCTE working groups for Proactive Network Maintenance (PNM), with an operator's perspective from the field. This paper will demonstrate how FMECA can be used to improve customer experience, reduce trouble calls, and increase operational efficiency.

2. Failure Mode Effects and Criticality Assessment (FMECA)

2.1. Background

FMECA is a highly detailed, disciplined process for understanding the impact and mitigation value of critical failure modes. Related to FMEA which is a similar analysis without the criticality component present in the analysis. This process has been around for several decades most notably used in the aerospace industry. The process was used in the aerospace industry to understand the needs for redundancy based on identified critical failures. In other industries such as healthcare, this same FMECA model has been used to identify high risk processes. In an American Society for health care Risk Management (ASHRM) White Paper, the FMECA process is described as “proactive examination of what could go wrong and the opportunity to fix it before it fails.”(Summy)

FMECA has been the underpinning of the pattern detection work in the PNM working group. Identifying failure modes based on distinguishable patterns has been one of the most widely used applications of FMECA within our industry. According to co-author Jason Rupe FMECA is defined as “identifying a system and determining if it performs as designed.” (Spaulding and Rupe) He further explained that if you are looking at a power network and a fuse blew, did the fuse do what it was designed to do? Yes. The question then becomes what failed leading to the fuse blowing and how do we prevent it. FMECA takes us through the process of understand the *effects, criticality, probability, and decay*. These pieces of information allow us to understand the value and timing of mitigation.

2.2. Definition

2.2.1. Failure Mode

Identifying a condition that signifies an abnormal operation of a system or component in a network, system, or process. These conditions can take the form of a process within a system that no longer meets the requirements of the desired outcome. In a hardware application, failure modes would indicate when components are no longer working as designed. The failure mode itself does not represent severity just the abnormal operation or outcome.

2.2.2. *Effects*

The meaning of effect in this document will be any empirical measurement of system performance. In Data-Over-Cable Service Interface Specifications (DOCSIS) systems, there are a number of measurements available including registration state, packet loss, latency, forward error correction (FEC), modulation error ratio (MER) and others. Each of the failure modes typically have gradient errors that can be detected, depending on the severity and capacity available for mitigation. For this reason, each failure mode can have discrete effects measurements.

2.2.3. *Criticality*

In FMECA, criticality assessment may be qualitative or quantitative. For qualitative assessment, a mishap probability code or number is assigned and entered on the matrix. For quantitative measurements, ratios may be applied. This can be useful in network analysis to scale problem severity with the number of nodes effected.

2.2.4. *Probability*

While not called out in FMECA, the probability of a failure mode is an important consideration when deciding what to do about it. Highly likely failure modes with high criticality should be aggressively mitigated through operations. These are the drivers of cost, friction, and many undesirable outcomes. But even high probability and lower criticality failure modes deserve attention, so they can be properly addressed through fault management, mitigation, and repair measures. On the other hand, highly critical failure modes must be addressed when they happen, no matter how unlikely.

2.2.5. *Causality and Decay*

Causality, describing degradation or decay, is key to how we can use this in our PNM efforts. In today's environment, we have become experts in identifying faults once an impairment starts to impact DOCSIS performance. We detect the impact of a failure mode through corrected and uncorrected packet errors, unbonded channels, etc. When these effects meet certain thresholds, we dispatch technicians to fix the network failure (DM, or demand maintenance). As we move the thresholds on these metrics further from severity, we are getting ahead of the most severe customer impacts (PM, or preventative and proactive maintenance).

2.3. Application

FMECA is a methodology and process, rather than an application. However, the elements of FMECA map nicely to our cable domain which can easily be implemented as practical applications. In this section, we will decompose the elements of FMECA including cable-specific adaptations and demonstrate how it can apply to real cable systems. Figure 1 shows an example of the FMECA process.

After defining the components of FMECA we will further consider how to operationalize it with data which is readily available to cable operators. Using the model below we combine the components together to determine a priority of events based on decay and criticality. Assigning severity rankings based on criticality and decay rate drives prioritization of how we should address the problems.

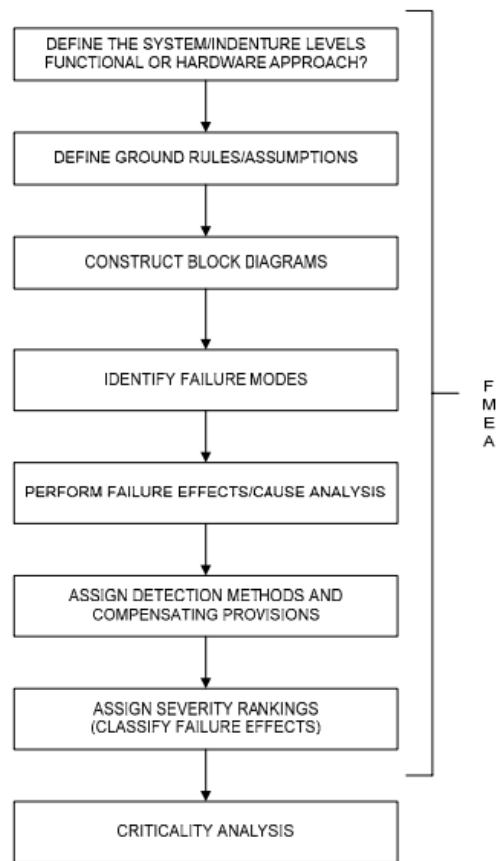

Figure 1 - Failure modes, effects and criticality analysis - United States Army

2.3.1. (FM - Failure Mode) Event Management

The most fundamental aspect of FMECA is identification of failure modes, or the places and reasons that components and/or systems can break. This might seem intuitive but many of our fault management systems have evolved based on symptomology, not necessarily specific cause-and-effect. For example, cable operators might have some form of network monitoring based on packet loss or FEC performance. However, these systems often lack in effective root cause analysis, delegating the troubleshooting process to technicians in the field or operations centers. Figure 2 shows an example of this symptomology-based event management, where potentially hundreds of individual errors are presented to technicians. Those technicians are then subject to analyze and repair based on their individual experience and training. Figure 3 shows this same system failure, modeled in FMECA which provides a root cause analysis, pointing the technician to the exact system component failure, including common repair recommendations. In this example, an amplifier module was experiencing a common form of failure associated to ground plane corrosion. The result was hundreds of symptomatic events which were difficult to interpret and repair efficiently.

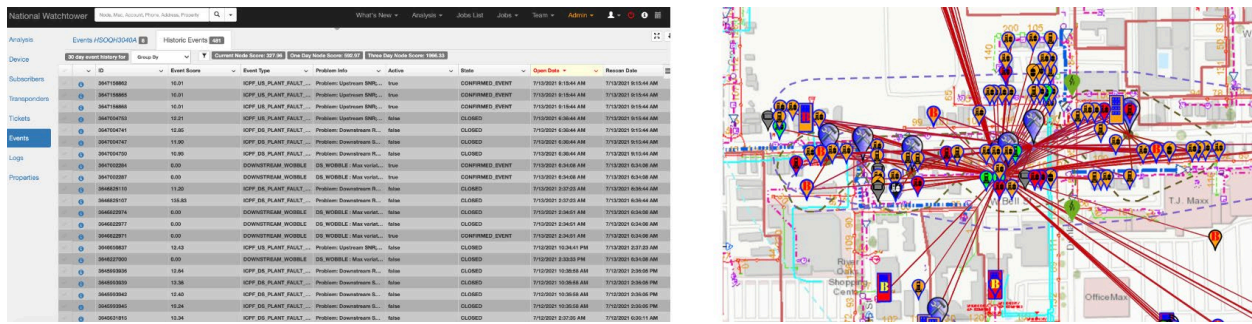

Figure 2 – Example of symptomology-based event management

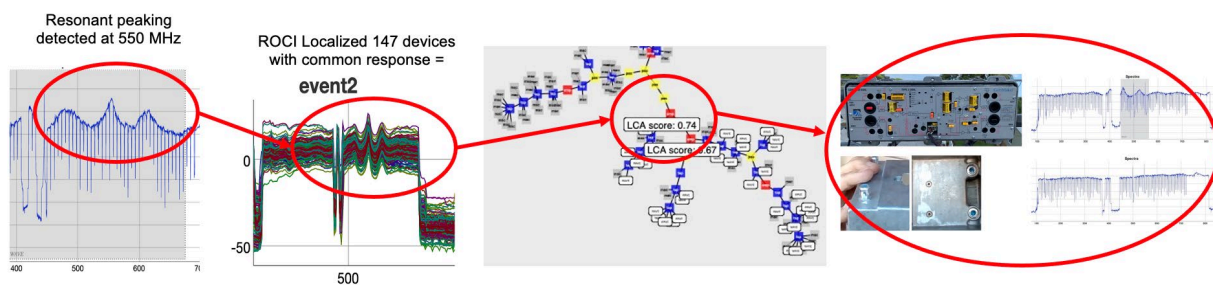

Figure 3 – Example of FMECA-based event management

2.3.2. (E - Effect) Localization and Service Impact

The first cable-specific adaptation is to determine the effect, which has additional complexity over some other component-based systems. In cable networks, HFC plant can be thought of (although not entirely correct) as a large, shielded antenna. The cable segments are largely passive with bidirectionality achieved with diplex filters. The performance sensors of our cable networks are typically at the transmitters and receivers (cable modems and CMTS) and often lack knowledge of the component chain between them, such as drops, taps, feeders, splitters, couplers and amplifiers. Because any one of these could be the point of failure, additional localization is usually required. In our example, a graph topology database and radio frequency (RF) signature analysis will be used to help provide fault location. Once the fault is localized, the tree-and-branch nature of hybrid fiber-coaxial (HFC) networks facilitates the cascading effect of service impact analysis (Figure 4).

Figure 4 – HFC Network topology represented as a graph model

Going beyond empirical measurements, we can also try to understand the subjective aspects of impaired service. For cable access network services, any friction incumbering the use of the service is an undesirable effect. For a user, friction builds up over time, but memory is not forever. If over a short period of time a customer experiences a lot of friction, their impression of the reliability of a service is damaged. If the friction to switch providers becomes lower, they may become a lost customer.

For network capacity, any signal impairment is an undesirable effect. But clearly, a complete loss of all services is a more significant effect than say noise or signal attenuation in a few frequencies which can be addressed through DOCSIS resiliency mechanisms, or an application that won't authenticate properly to work as intended. But some effects are early indicators of more significant issues to come. If any undesirable effect becomes significant, then it may rise in criticality.

2.3.3. (C - Criticality) Severity and Decay

The challenge in today's operating environment is showing the business benefit as we push to become more proactive. We look for optimization in initiatives on the basis of trouble call reduction and call-in rates; but what happens when you fix the network before the truck roll and before the calls? That is where modeling the causality as degradation or decay and adding that information to the methodology helps us to create the business and customer value. Through observation, we can determine the rate at which a particular failure mode will decay before it fails and creates the need for demand maintenance. By measuring the severity of degradation or decay, we can predict the point of failure and repair the failed component before the first call. This modeling doesn't work without a component of timing which is given through decay. With the decay timing we can then assign the value of fixing certain failure modes before they impact customers, which eventually generate the truck rolls or calls we've traditionally used to determine customer impact.

In DOCSIS access networks, there are a number of resiliency capabilities that help protect our services from network failures. A failure mode and its effects become critical if the effect becomes significant. That significance can be determined in a number of ways. But in systems and networks, significance is often estimated through a combination of the number of users impacted, the duration of the impact, and the severity of the impact from the effect. Complete loss of service is the most severe, whereas an

impairment that does not impact service is likely very low in severity from an end user perspective but may rise in importance if it signals an opportunity as it serves as an indicator of other issues. For example, an outage for an entire node is critical because it impacts all services ($S=\max$) for a large number of customers ($N \gg 1$); thus, there is strong incentive to return customers to service immediately, to reduce the outage duration (T). Criticality in this case could be estimated as $S*N*T$. On the other hand, a damaged drop is much less critical because it impacts a single customer ($N=1$) and may partially impact their services at worst case ($S \ll \max$); so, there is much less urgency with repair in these cases, thanks in part to the resiliency of DOCSIS.

Note that we don't need precise models to predict what will happen and when. It is often good enough just to recognize we found an opportunity to improve operational efficiency and delight customers.

2.3.4. (A - Analysis) Benefit Analysis

One of the outcomes of the FMECA analysis is to provide improved operational intelligence that helps transition from reactive to proactive network repairs. By modeling the number of faults with their severity and decay (Figure 5), the outcomes can be projected in new ways, such as network reliability (Figure 6).

Failure Subsystem	Failure Mode	Occurrence	Severity	Duration Days	Decay Rate	Decay Days	Criticality Model	Number of Subs

Figure 6 – Example of benefit FMECA output, including network reliability

2.3.5. Feedback Loop

This is not described in FMECA systems and methodologies but is important to maintain a modern machine learning (ML) and artificial intelligence (AI) based system. As our cable access networks continue to evolve, the management systems need to become more adaptive. Especially as these systems become more reliant on ML and AI systems, the models need feedback to improve. By providing feedback to the system, they may continue to improve and adapt (Figure 7).

1. Failure mode detection using ML and AI pattern matching
2. FMECA knowledgebase provides repair recommendations to technician
3. Technician makes informed repairs, reducing the analysis time
4. System automatically validates repair and potentially solicits feedback
5. Pattern matching models and recommendations adapt

Ultimately, as the systems continue to adapt and improve, gains in repair times and network reliability become realized.

Figure 7 – Closed loop detection, recommendation and repair validation

3. Use Cases

In both the CableLabs and SCTE Network Operations Subcommittee working groups for PNM, a number of failure modes have been identified and documented. The following Figure 8 shows examples of these documented downstream RF failure modes; these failure modes to RF transmission are often referred to as impairments or faults, to differentiate from the network failure mode which causes the RF failure modes. The working groups are continuing to make progress in this area including understanding and troubleshooting upstream RF impairments and developing a repair matrix. Additional examples of this upcoming work can be seen in Figure 9.

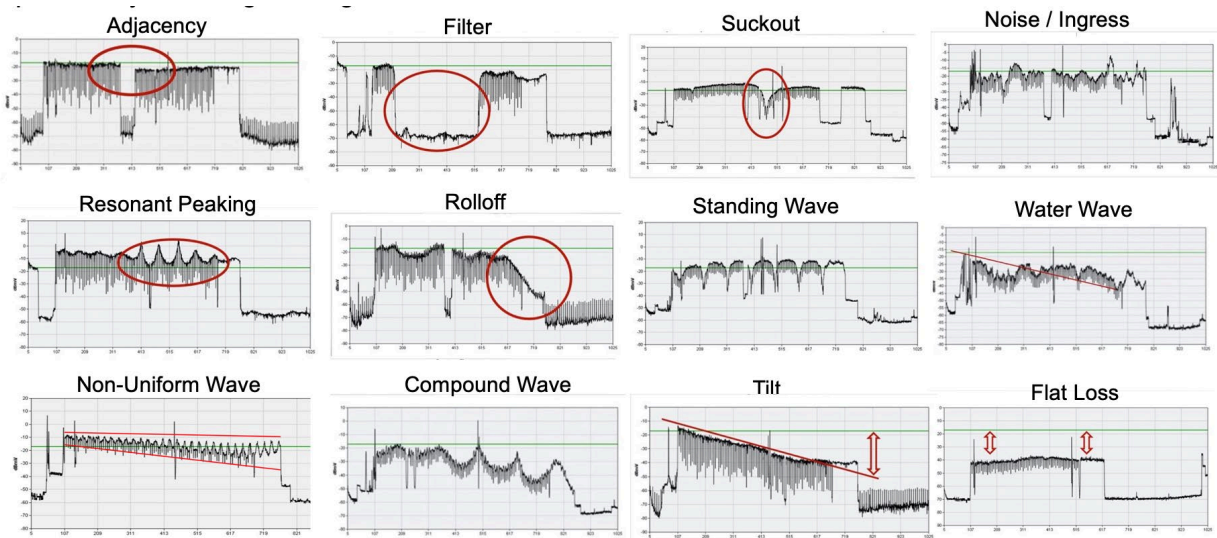

Figure 8 – Downstream RF failure mode examples from SCTE Industry Reference 208

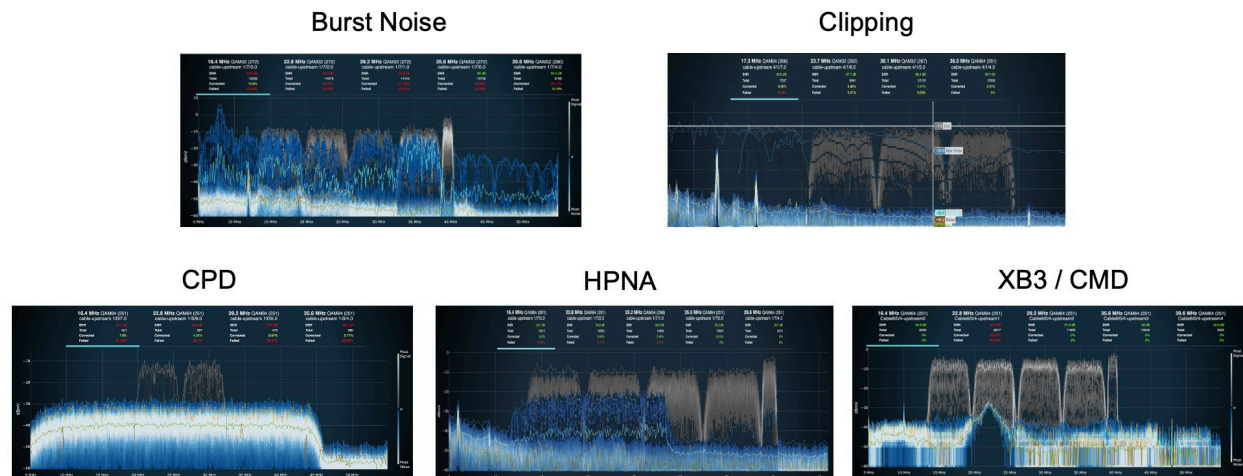

Figure 9 – Upstream RF failure mode examples from upcoming SCTE Industry Reference

3.1. Water Damaged Cables

In the previous material, we reviewed the fundamentals of FMECA and how the process could be adapted to work in a cable access network. In this section, we will apply what we've learned to a specific use case which has been a recurring theme in recent SCTE PNM working groups: water damaged cables.

3.1.1. Specification

The first step in our water damaged cable use case is to define the system and failure mode. Our implementation will rely on recent PNM advancements which allow cable operators to accurately detect, and measure cable failure associated to water ingress. This failure mode has been well documented and specified in previously published SCTE material, found in the bibliography.

3.1.2. Detection

Impairments in DOCSIS RF are easy to detect, but that is only the first step in efficient maintenance. A simple spectrum capture or RxMER per subcarrier plot will reveal an impairment in the signal, and the signature of the impairment indicates the type of fault. These and additional PNM tests and queries help us measure the impact on the RF signal, which we can translate to impact on service through a model.

Detection of the impairment and identifying its type allows us to do something about it and know how important it is to address the fault. Each fault type can behave differently over time, as it is exposed to elements such as heat, dryness, water, ice, and cold.

There have been many different methods devised for identifying one type of impairment from another, such as the CableLabs Spectrum Impairment Detection, or the CableLabs Anomaly Detector. (See [Zhu, Sundaresan, Rupe] for details on the machine learning based Anomaly Detector available for use by CableLabs members.) These methods all essentially match patterns in bin data, which are indicators of the fault type.

As explained in an Expo paper from 2021 [Fox, et. al.], water damaged cables are indicated from spectrum data with a signature of a few factors: a random (aperiodic) pattern of fluctuating attenuation

over frequency bins, and often a general trend of more attenuation toward higher frequencies. As a result, a pattern matching solution can be used to identify water in cables. As described in the paper mentioned here, a two phased approach works well: identify a standing wave, which is indicated by highly variable attenuation over frequency bins, and then use a secondary test that separates standing waves (which are periodic) from water waves (which are aperiodic).

Possible approaches, some described in that paper, include transforming the data further to find how periodic the variability may be, or calculating and removing any slope in the bin data. For example, taking the bin data, calculating and removing the slope trend from the data, and then using an FFT to transform the bin data into a new frequency domain to find the frequencies that might describe the variability in bin signal levels; a single strong frequency would indicate a standing wave, whereas several nearly equally strong frequencies would indicate water is the culprit.

We have also learned that water in a coax cable causes variability in the phase of the signal as well. With the ability to capture complex (I,Q) bin data, we can further confirm the presence of water in the cable.

All this information helps us localize too, as we'll explain next.

Figure 10 – Water impaired frequency response

3.1.3. Localization

As previously discussed in Section 2.3.2, localization is conducted through a cable-specific adaption to the FMECA model. Because of the tree-and-branch structure of our HFC networks, additional topology or location information is required to determine the effects. Fortunately, water-soaked cable localization is straightforward. Cables with water ingress are almost always outside, so that limits the localization to the drop network (Figure 11) or distribution cable such as feeders and trunk. The simplest, most effect method is to determine if the water signature is isolated to a single location, or multiple. There are a number of basic pattern-matching routines that can accommodate this type of localization. There are some examples where incorrect localization can occur with this method, but these should be considered edge-cases.

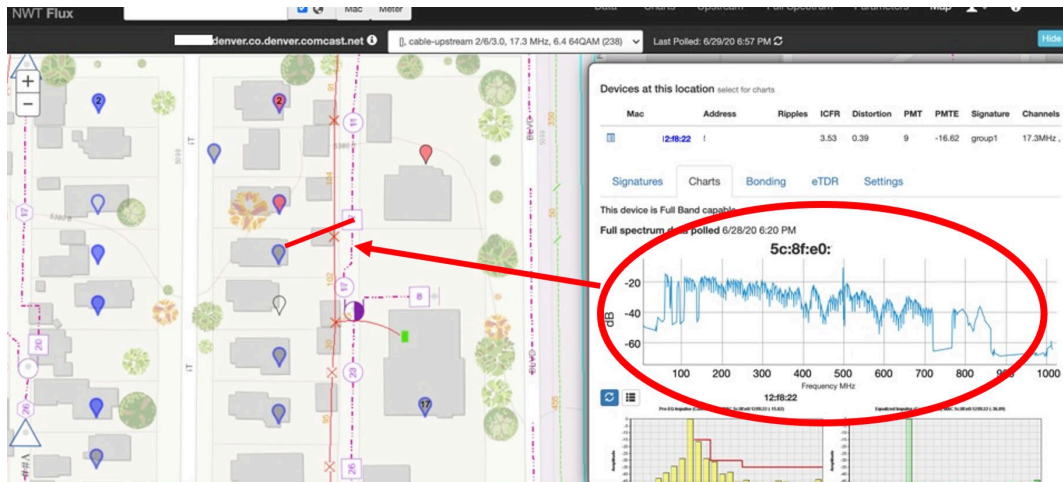

Figure 11 – Water signature localized to a single location indicating damaged drop cable

3.1.4. Criticality

One of the most intriguing aspects of our water damaged cable use case is that it has a predictable decay model. In the case of RG drop cables, the water damage always gets worse with little-to-no improvement over time, other than the transient effects of temperature. In the case of water-soaked RG6 drop cable, water can migrate or drain, but mostly it pools within the dielectric. Once the dielectric has been compromised, a chain of decay becomes inevitable. Figure 12 illustrates this degradation process.

As we explained earlier, the criticality of an impairment is estimated by the number of customers impacted, the severity of the impact (in terms of impacted services, potential service impacts, etc.), and the duration of the impact. While DOCSIS provides strong resiliency in RF signals, severity is estimated proactively in terms of potential impact to service. The potential impact is estimated through a model describing the degradation or decay path that the wet cable will take if left to degrade.

Again, see Figure 12, which describes the degradation path of a coax cable, such as an exposed drop. At first, the cable is protected from the elements. After time, that protection weakens, and the elements can begin to enter the shield. After more time, water gains access to the braiding of the shield, and fills the gaps between the wires. After some amount of freezing and thawing, the insulation begins to fail, and the distance between the shield and center conductor can change, leading to changes in the dielectric constant and multiple impedance changes. After more time, the water can get to the center conductor, and corrosion can occur throughout this degradation process. As this degradation progresses, PNM telemetry can indicate worsening degradation by showing a stronger water signature in the bin data.

Field observation and testing of recovered cables provides various snapshots of this degradation path, so we know it happens, and we can compare the impairment patterns to the failure modes found in the field to align our telemetry to the likely network failure modes. All this allows us to know that PNM is meeting its intent.

With additional work, we could develop prediction models to estimate the time to the next level of failure. But we already know enough. Once we find a failure mode, and we can estimate its severity in the future, we can determine its criticality, and therefore know the problem is worth addressing well before the cost of failure is inflicted.

Through PNM, we delight customers and save on operations costs. With water-soaked cables, the motivation is clear, as is the link from impairment to fault to failure.

Figure 12 - Example degradation of cable with exposure and water penetration

3.1.5. Effects

Empirical performance measurements can often be a good lead indicator of experience, which is subjective. In early field trials of our water detection, the effects were easily validated with before-and-after signal analysis (Figure 13). While the criticality model discussed in section 3.1.4 is a work-in-progress, and we intend to identify other degradation patterns to extend our knowledge, the merits of fixing these types of problems are agreeable. Starting with the worst problems first is obvious, and eventually we'll get ahead of the critical failures.

"We ran on this high-variance water in cable address over the weekend. The customer is internet only for the past 4 years and no trouble calls in history. This customer's service has definitely been suffering."

Tech Notes

- Yes, the recommended fix was correct
- Drop had had water damage for a very long time. Corrosion on center conductor and powder when fitting cut off.
- Drop had quite a bit of age to it, and I can tell it had come down and been driven over multiple times in the past. A lot of flattened sections along the line.
- Also, there was a return noise filter at tap for noise.
- Customer had, for quite some time, many intermittent issues with service dropping out for long periods of time.
- Home performance test was failing and is now passing.

- We contacted customer to make arrangements for access.

Figure 13 – Field trial, water wave before and after repair

3.1.6. *Benefits*

In the water damaged cable field trials, the benefits have been modeled to help provide a way to quantify and rationalize the value of proactive vs. reactive repairs. To support the field trial, a year's worth of drop replacements were analyzed. The analysis yielded interesting results in the repair time of typical drop replacement activity.

On average, by removing the need to troubleshoot and diagnose, repairing these water damaged drop cables resulted in 1 hour of improved operational efficiency. When multiplied by the number of instances, the operational benefits are compelling. However, there are additional benefits that are realized:

- Our proactivity delights our customers rather than forcing them to call us
- Improves network reliability in a measurable way
- Removes friction from customers that may be silent, but unhappy with their service

4. Conclusion

Most cable operators have network monitoring and management systems including PNM. In many cases, we've become excellent stewards of our network performance and aim to provide the best possible customer experience. FMECA provides an easy to understand and intuitive methodology for maintaining a consistent knowledgebase of failure modes, severity assessment, and repair prioritization.

By extending FMECA with DOCSIS PNM, we have access to network telemetry which can indicate an impairment. The impairment signature indicates the type of fault in the RF signal, which we can link back to a network failure of a particular type. We trace impairment to fault to failure mode in the network, and that helps us know what to look for and where, and what to do to fix it. When coupled with cable's PNM, FMECA helps us transition from "find failure and fix it" to "anticipate failure and prevent it".

1. Introduction

Cable operators worldwide are deploying passive optical networks (PON), realizing high-capacity, low latency performance with low maintenance costs. Although PONs are essentially passive, current architectures make use of outside plant (OSP) active optical components. Strand- or pedestal-mounted remote optical line terminals (R-OLT) can replace rack mounted OLTs of a few years ago. When fiber runs extend beyond optical transceivers' effective range, midspan erbium doped fiber amplifiers (EDFA) boost optical levels and extend fiber reach. Evolving PON architectures are designed to support higher speeds and extended service areas. Next-generation PON implementations will likely include high speed coherent optic links from headends to new OSP aggregation nodes, enabling even faster services to extend deeper into the network. Each active optical component in our PON architecture requires reliable, uninterrupted power to keep the network running.

This paper reviews aspects of powering the OSP active components of modern PONs including power levels, utility grid isolation, utility backup duration and power system status monitoring. Unique requirements for powering expanded rural fiber networks are discussed as well as considerations for addressing an aging utility grid and the impact of extended outages. Roles and methods for power monitoring and remote management are discussed as well as the need for predictive and restorative maintenance.

2. PON is Growing Brighter

Today's consumer broadband networks need high-speed symmetrical bandwidth and low latency to deliver superior customer experiences for applications like augmented reality/virtual reality, over-the-top streaming video, cloud gaming, videoconferencing, 5G backhaul and other peer-to-peer networking services.

All roads lead to fiber. Fiber optic cable as a data transport medium has no equal with respect to performance and total cost of ownership (TCO). However, DOCSIS over coaxial cable has outpaced consumer broadband demands exceptionally well. Most experts believe DOCSIS still has many years of life before running short on performance. So, there's no immediate or urgent need to replace the majority of installed coax with fiber. The low TCO and almost unlimited bandwidth of fiber are well understood by operators. As a result, operators have started migrating greenfield and network extensions to all fiber based. In 2021, global research firm Omdia polled broadband operators, asking which type of network upgrades do their companies plan to carry out by fall 2026. The poll results in Figure 1 clearly indicate FTTH deployments as the highest priority.

Figure 1 – Broadband Operators’ Poll (Omedia, 2021)

In a separate poll, broadband equipment providers were asked about access equipment revenue forecasts for North America. The poll results shown in Figure 2 clearly identify PON equipment sales leading the ranks and increasing dramatically through 2026.

Figure 2 – Broadband Equipment Providers Poll (Omedia, 2021)

There’s no doubt that investment in cable broadband access solutions will continue for many years. The strategy for most cable operators is not replacing coaxial cable with FTTH. The strategy for most

operators involves when and where to add FTTH. Another indicator of the trend towards FTTH from the Fiber Broadband Association reports that at the end of 2021, 43% of U.S. households and 60% of Canadian households had access to fiber services. [1]

2.1. Strand-Mount R-OLT

Silicon advancements in recent years have enabled R-OLT modules to fit within strand-mount optical node enclosures or housings. Distributed access architecture (DAA) node housings can be used for this application. The modules and node housing are designed such that a R-OLT or remote physical layer (R-PHY) module could be installed. Some equipment providers advertise the ability for their housing to support both R-OLT and R-PHY modules simultaneously, servicing PON and quadrature amplitude modulation (QAM) customers from the same node. This application has been nicknamed DAA-OLT. An example of a strand mount R-OLT module and housing is shown here.

Figure 3 – Example Strand-Mount R-OLT

Two large North American (NA) operators reported in June 2022 that strand-mount R-OLT equipment will be a primary fiber-to-the-X (FTTX) upgrade tool for the next few years. One R-OLT equipment vendor has reported that revenues for DAA-PON modules for NA increased from about \$300,000 in 2020 to over \$10 million in 2021. It looks like PON is here to stay. [2]

2.2. About RDOF

A major contributing factor to accelerated broadband fiber builds is the Rural Digital Opportunity Fund (RDOF). RDOF will provide \$20.4 billion in funding over a 10-year period to support broadband networks in rural communities across the US. Among the top RDOF awards, the U.S. based operator Charter qualified to receive \$1.2 billion in federal government support for deployment plans spanning some 1.1 million locations. Tom Rutledge, Charter's chairman and CEO, said that the company has RDOF work underway in all 24 states where it won bids in phase I of the RDOF auction. All told, Charter plans to build fiber and gigabit services to more than 1 million rural, unserved locations. Through RDOF, the company will add more than 100,000 miles of new network infrastructure to its existing 800,000 miles of infrastructure in the coming years. [3]

The RDOF program does not dictate specific technologies for new broadband services. However, the FCC has proposed creating performance tiers for RDOF funding. High bandwidth, low latency fiber solutions will be most favored.

3. Anatomy of a PON

During a recent CableLabs conference, Stephanie Mitchko-Beale, Charter CTO, stated “the speed of change keeps me up at night” [4]. This sentiment is likely shared by anyone responsible for the accelerated FTTX deployments in recent years. FTTX and PON are simple in principle but the popular cliché “the devil is in the details” was never truer than with PON deployments. For more details let’s review the sample broadband network block diagram in Figure 4.

Figure 4 – Sample Broadband Network Diagram

Network architectures vary with operators, geography and many other factors. This block diagram does not represent a specific installation but only a few of the more common network building blocks. Moving from the headend on the left through the access network on the right, the network elements shown in this diagram include:

- A headend based converged interconnect network (CIN) delivers transport and aggregation functions for diverse networking elements such as DOCSIS, PON OLT, DAA, 4G/5G, and so on. The CIN is the glue enabling various disparate elements to interact and interoperate.
- Fiber distribution is physically routed from the headend to hubsites, nodes and OLTs. Some operators refer to this fiber segment as optical trunk fiber. Today, this fiber would likely carry 10 Gbps Ethernet which is fast replacing the CWDM and DWDM analog fiber transmissions of the past.
- DAA node service groups can support QAM video and data using DOCSIS. R-OLT modules can be co-installed in node housings with DAA modules or installed nearby to support PON.

- In densely populated areas, multiple shelf mounted R-OLTs may be housed in curbside equipment enclosures along with fiber distribution, powering equipment and batteries.
- Remote OLT modules installed in strand or pedestal mounted node enclosures are an alternative to cabinet (rack or shelf) mounted OLTs.

Let's review a specific FTTX example presented at the 2021 Cable-Tec Expo by Cox Communications. [5].

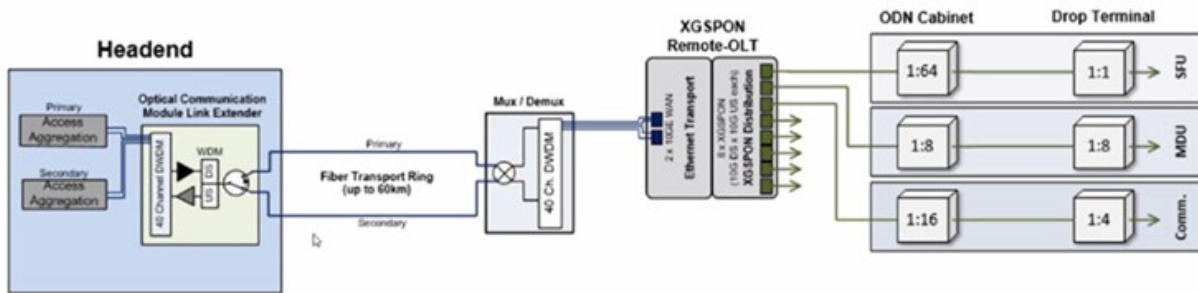

Figure 5 – Cox Communications FTTX Architecture

A few noteworthy details from this FTTX architecture include:

- The R-OLT is the only active element in the access network. When practical, the OLT is located near the HFC plant to utilize coax for both power and power supply telemetry.
- In greenfield installations where there is no nearby coax to power the OLT, a curbside enclosure may be used to house multiple OLTs, fiber distribution equipment and a backup power system for the OLTs.
- Headend-based EDFAs facilitated a fiber transport ring of up to 60 km to the R-OLT (either strand-mount or cabinet based). With a 1:64 split, the reach from the R-OLT to the premise is up to 20 km. From ODN cabinet to premise is 8 km maximum reach.
- The Cox network utilized XGS-PON optical signaling.

3.1. PON and 10G

The CableLabs 10G Platform promotes 10 Gbps symmetrical services using any number of technologies. Two predominant PON protocols are in use today: XGS-PON and 10G-EPON. Both can directly support the full intent of the 10G Platform. XGS-PON is an ITU standard with roots in the telecommunications industry while 10G-EPON is an IEEE standard more common in data centers. Both protocols offer approximately 10 Gbps symmetrical service. When it comes to powering PON elements, it doesn't matter which optical communications standard is used.

With change being inevitable, PON architectures beyond 10 Gbps are anticipated, and in some cases already here. Powering new and upcoming PON devices should be considered to assure that today's powering approach will support future upgrades. CableLabs has presented a next generation PON

architecture utilizing a new OSP active component: an optical aggregation node. This next generation PON is shown in Figure 6.

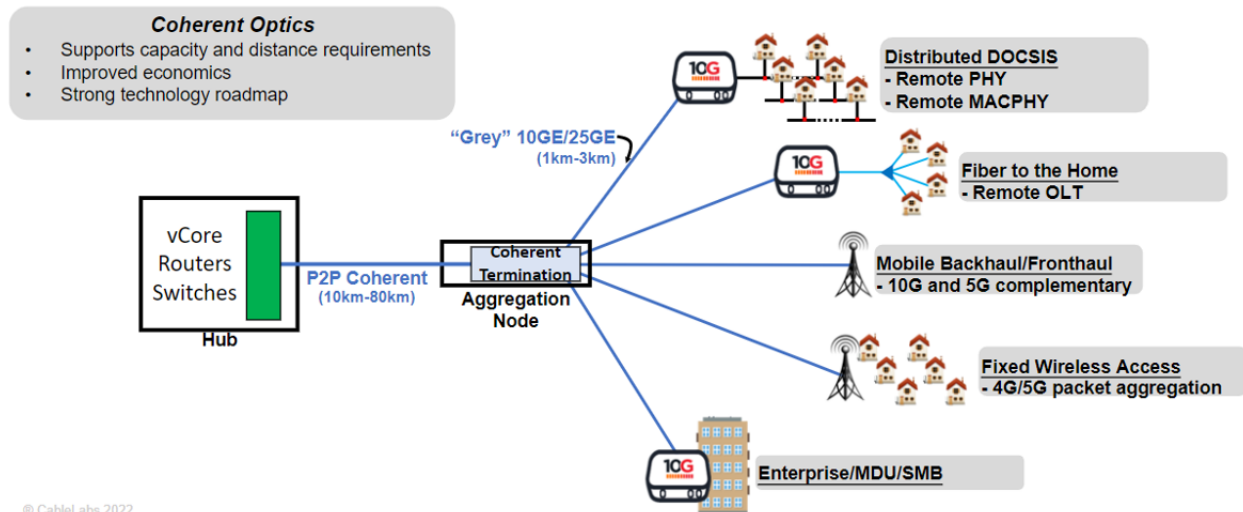

Figure 6 – PON Beyond 10G, CableLabs

This near-future PON enhancement contains a new active component, an aggregation node (AN). In this architecture, new high speed fiber communications are pushed deeper into the network by use of high-speed coherent optics between the hub and the new AN. This link could be 50 Gbps, 100 Gbps or faster. [6] The AN will act as an optical Ethernet switch providing lower speed (10 Gbps for example) optical links to downline elements such as DAA nodes and OLTs. The result is higher capacity services deeper into the network and closer to subscribers. From our PON powering vantage point, we've simply added another active element to the mix. Once AN elements begin to be deployed, power requirements will need to be analyzed. Given the current state of coherent pluggable modules combined with known high speed switching elements, we anticipate that an AN may require approximately 200 W in a fully configured state. This estimate remains highly speculative until actual networks using AN devices are deployed.

In general, backup power is fiber protocol agnostic. Optical wavelength, communication protocols (10G-EPON vs. XGS-PON), distribution methods and so on, don't affect power. We need to understand the location and power needs of the few but critical active components. Powering these active elements are discussed in the next section.

4. Powering PON

Powering broadband PON is similar, and often simpler, than powering traditional HFC networks. Optical actives can be powered from the coax network when an HFC plant segment is nearby. More often, PON equipment needs a dedicated uninterruptable power supply (UPS) and batteries for uninterrupted power. A side-by-side review of HFC and PON powering should illuminate noteworthy differences.

Table 1 – HFC & PON Powering Differences

Powering Consideration	HFC	PON
Powered equipment	Optical nodes, amplifiers, line extenders	OLTs, EDFAs and ANs (future)
UPS to equipment ratio	One-to-many	One-to-one (typically)
Equipment voltage	90 VAC	90 VAC (strand-mount R-OLTs); 48 VDC (shelf mount R-OLTs)
Distance from UPS to equipment	From co-located to 1,000s of feet via powered coax.	Co-located (1)
Total power required	HFC network designs often utilize full UPS capacity. Typical broadband UPS are rated from 1350 W to 1620 W	Powering a single OLT may require ~140 W.
Utility grid protection	Required	Required
Backup power duration	4 to 72 hours (2)	6 to 72 hours
UPS status monitoring	DOCSIS	Fiber

(1) OLTs may be coax powered in situations where HFC coax is nearby.

(2) The CPUC 72-hour telecommunication backup requirement is an extreme case. Operator backup time policies typically vary from two to eight hours.

Let's review some of the important differences between powering HFC and PON.

4.1. Powering HFC vs. PON

Traditional HFC networks include optical nodes, amplifiers, and line extenders. These active components are powered from a UPS through the coax. The number of actives that can be powered from a single UPS depends on a combination of the equipment's total static load and the combined coax span lengths between powered devices. Longer coax spans have higher loop resistance, creating greater joule losses (i.e., power loss due to resistance in coaxial cable, electrical energy is converted to heat). Cable resistance and current flow through the coax results in a voltage drop across each coax span and a lower end-of-line voltage. In most cases, cable plants will run short of power or end-of-line voltage before they run out of devices to be powered. Also, operators' internal design policies guide network designs to limit UPS loads to a percentage of the UPS' rated capacity, often in the 80% range. [7]

Powering PON equipment takes a slightly different approach than powering HFC. The broadband network in Figure 7 shows three different PON segments, each with unique powering schemes. A review of these PON segments and powering options will prove illuminating.

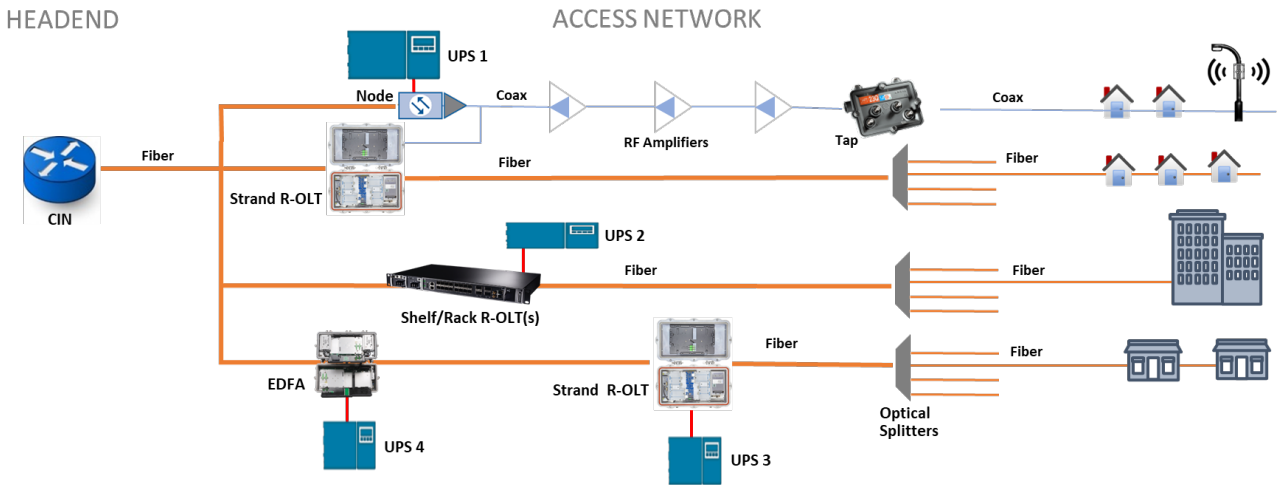

Figure 7 – PON Powering Examples

4.1.1. PON Example 1

The network diagram shows UPS 1 powering an optical node, downline amplifiers and a R-OLT. In this scenario the PON R-OLT is installed in the vicinity of a powered coax segment and can be powered from that coax. One operator's rule-of-thumb for coax powered R-OLTs is that if powered coax is available within one-half mile of the R-OLT location, they will extend coax to power the R-OLT. Beyond that distance, it's more cost effective to add a dedicated UPS to power the PON equipment. A typical R-OLT of this style (see Figure 3) would require up to 140 W to power and could be configured to support up to 512 FTTX customers through downline optical splitters. A typical broadband UPS used to power nodes, amplifiers and our R-OLT is shown in Figure 8. These UPS systems may be pole or ground mounted and typically consist of an enclosure, the UPS and one or more strings of three 12-volt batteries. If UPS 1 has sufficient power and battery capacity to accommodate the added R-OLT load, no additional powering considerations are needed.

Figure 8 – Typical Broadband UPS

4.1.2. PON Example 2

In service areas with a higher population density, PON architectures may dictate supporting many customers from a single fiber distribution point. One option is to utilize outdoor, curbside enclosures housing multiple R-OLTs. UPS 2 in our network diagram represents this scenario. An example of this type of enclosure is shown in Figure 9.

Figure 9 – High Capacity PON Enclosure

The multiple shelf or rack mount R-OLTs in this example will service far more subscribers than our earlier strand mount example. These cabinets would include fiber distribution as well as backup power for the R-OLTs. Shelf mounted OLTs are typically powered from 48 VDC. The cabinet would contain a 48 VDC rectifier system, likely in an N+1 redundant configuration, and batteries. The cabinet is connected directly to utility power.

Cabinet-based OLT systems can be scaled to specific applications. One North American operator has standardized on a curbside cabinet capable of servicing up to 8000 homes. This cabinet contains multiple OLTs, fiber distribution panels and a 48 VDC rectifier system with batteries to provide six hours of backup power during utility outages.

4.1.3. PON Example 3

The third PON example from Figure 7 represents a strand-mount R-OLT powered from UPS 3. This differs from the UPS 1 example in that there is no nearby coax for R-OLT power. For this application a UPS is dedicated to a single R-OLT or potentially multiple co-located R-OLTs. Figure 10 shows a typical broadband UPS sized appropriately for this application.

Figure 10 – Small Broadband UPS for Dedicated R-OLT Powering

This broadband UPS is similar to the UPS from example 1 with a few exceptions that are reviewed after a note about RDOF PON.

4.2. RDOF PON: Accommodating Rural Fiber Deployments

As previously discussed, RDOF is bringing broadband, specifically fiber broadband, to many un-served and under-served rural locations in the United States. Does rural fiber deployment differ from its urban or suburban counterparts? The answer is yes. There are two differences to consider. First, rural areas have lower population density than urban or suburban, which goes without saying. Rural areas will likely never need the service group density available from dedicated enclosures housing multiple high-capacity R-OLTs. Also, rural areas will most often be considered greenfield with no incumbent fiber or coax to leverage. This means that PON example 3 from Figure 7 will likely account for most of our rural fiber installations.

The second consideration with rural fiber deployments deals with fiber span distances. One operator mentioned that their rural deployments are seeing fiber lengths up to 160 km from headend to end users. To facilitate these distances the optical signal must be amplified. For this operator, the solution is to install optical amplifiers or EDFAs mid-span in the fiber run. An EDFA is shown in Figure 7 under PON example 3. Figure 11 is a typical EDFA used for this type of application.

Figure 11 – Sample EDFA (Optical Amplifier)

Like the R-OLT example, this EDFA is housed in an outdoor hardened aluminum housing and can be strand, pedestal or underground vault mounted. This EDFA requires about the same amount of power as our R-OLT and would be powered by a similarly sized UPS system. The following sections discuss UPS details that specifically apply to R-OLT and EDFA powering.

4.3. Sizing the UPS for Small Loads

Using coax to transport both power and RF has been a CATV practice for decades. This fundamental approach has not changed much over the years. A single stage UPS using a ferroresonant transformer is extremely robust and provides exceptional protection for active network elements from outdoor utility grid hazards. A later section discusses more about ferroresonant technology.

One important characteristic of the ferroresonant UPS is that it operates most efficiently when loaded to its maximum rating. Most traditional broadband UPS systems are rated for use between 1350 W to 1620 W. That ends up being 15 A to 18 A at 90 V. Using a simple Ohm's Law calculation: $\text{current} = \text{power} / \text{voltage}$ (we'll ignore power factor for now to keep things simple). In our PON example 3 from Figure 7, the R-OLT required about 140 W or about 1.5 A at 90 V. The efficiency for several similar 15 A ferroresonant UPS models is shown in Figure 12.

Figure 12 – Ferroresonant 15 Ampere UPS Efficiency Graph

If this 15 A UPS were dedicated to powering a single R-OLT drawing 1.5 A, the UPS efficiency would be under 65% as shown. The lost efficiency would be energy converted to heat in the ferroresonant transformer. This energy loss would occur both under utility power (lost energy means higher utility cost from consumed kW/h) and during battery backup (resulting in wasted battery energy and less available backup time).

The obvious solution is to use a smaller UPS system for smaller loads, like our R-OLT. Ferroresonant UPS systems come in many ratings down to 5 A or less. Additional benefits of using a smaller, dedicated UPS include:

- Smaller broadband UPS systems use a single 12 V battery instead of a 36 V string of three 12 V batteries.
- The UPS is smaller, lighter and can be mounted in a smaller enclosure designed for the UPS and a single battery.
- The system cost will be lower due to the size and battery configuration.

The available backup runtime during utility outages varies greatly with the type and condition of the battery used in the UPS system. For example, if our R-OLT UPS system uses a single case size 31, high quality TPPL (thin plate pure lead) battery designed for outdoor broadband applications, the UPS system would provide over six hours of backup runtime for our R-OLT during a utility power outage.

4.4. UPS Status Monitoring for R-OLT Powering Applications

Monitoring broadband UPS systems provides several benefits. The most common benefit is that operators receive real-time status. During extended utility outages it's critical that operators have advance warning with sufficient time to take action prior to battery depletion, resulting in dropped loads and customers losing service. UPS monitoring also notifies operators of equipment concerns. Notifications may indicate that immediate attention is required or issues that should be addressed during an upcoming scheduled maintenance visit.

Traditional broadband UPS systems incorporate a purpose-built DOCSIS modem, called a transponder, for status communications between the UPS and the monitoring software. UPS monitoring over DOCSIS has been used for over 20 years. Operators have well defined processes in place for installing, provisioning and operating DOCSIS modems for OSP UPS monitoring.

For PONs where DOCSIS is not available, an alternative UPS monitoring approach is needed. To address this need, modern broadband UPS systems include a SFP interface (small form-factor pluggable). SFP is a standard interface compatible with pluggable, optical transceiver modules from multiple vendors. A typical pluggable SFP module is shown in Figure 13.

Figure 13 – Example Pluggable Optical SFP Compatible Module

For status monitoring of a UPS system that is powering a R-OLT, a specialized SFP module would be installed in the UPS's SFP socket. This SFP would function as an optical network unit (ONU) or an optical network terminal (ONT), supporting the specific optical protocol used by the R-OLT. An ONT and an ONU are the same things. ONT and ONU both refer to the consumer end equipment in an optical fiber (FTTX) communication link. ONT is an ITU-T term, whereas ONU is an IEEE term. The term ONT would be used if the R-OLT is configured for ITU-T protocols including GPON and XGS-PON. The term ONU would be used when the R-OLT is configured to IEEE protocols including EPON and 10G-EPON. For simplicity, we will use the term ONU going forward to mean either ONU or ONT.

The pluggable SFP ONU would be provisioned and managed by the R-OLT in the same way a home-based ONU operates. This configuration is represented in Figure 14.

Figure 14 – Example of Pluggable ONU for UPS Monitoring

In this example the R-OLT provisions and manages all ONUs in this PON segment, including the ONU installed in the UPS.

This UPS monitoring approach seems straightforward. However, there is more to this story. UPS status monitoring must be routed to the operator's OSP power supply monitoring software. The operator would likely associate the power supply MAC and assigned IP address to the monitoring software in a router or Layer 3 switch in their back office. Also, the UPS needs to be configured with the IP address of the monitoring software to enable the UPS to send SNMP traps or alerts. The UPS would often be configured with a list of IP addresses of destinations where SNMP notifications are to be sent. Other UPS parameters may need to be configured as well. In a traditional HFC network where UPS systems use DOCSIS modems for status communications, the DOCSIS configuration files are customized to configure UPS systems, including trap destination addresses. Unfortunately, PONs have no equivalent to a DOCSIS configuration file, at least not one that can be used for UPS configuration.

At first glance, a CableLabs specification called DOCSIS Provisioning of EPON (DPoE) sounds like a promising option for UPS configuration. However, any hope in DPoE provisioning the UPS is short lived. DPoE enables DOCSIS configurations and service tiers to be passed on to the PON. For example, a PON customer could subscribe to a 100 Mbps downstream and 10 Mbps upstream service tier. DPoE can use existing DOCSIS services to configure the PON to support this service tier for this subscriber. The R-OLT and ONU supporting DPoE work together to implement this type of DOCSIS service. DPoE has no mechanism for configuring equipment behind the ONU on the subscriber side of the network. Within our UPS ONU configuration, the power supply resides behind the ONU in the network, much like a subscriber's computer resides behind a home-based ONU.

To date, two methods have been used to configure the UPS for monitoring and alarm reporting in a PON. First, some UPS systems support the use of a configuration file containing TLV (type-length-value) style information, similar to DOCSIS configuration file TLVs. When the UPS is provisioned and receives an IP address from the network DHCP server, the provisioning process typically provides the IP addresses for a TOD (time-of-day) server and a TFTP (Trivial File Transfer Protocol) server. The UPS will search the root directory of the TFTP server for a specific configuration file to be used for UPS configuration. This approach is similar to how a DOCSIS configuration file is used to configure cable modems.

The second method available for configuring UPS parameters is by using vendor specific DHCP options. A DHCP offer contains a variety of information fields beyond just an IP address. The standards for DHCP define various options that can be part of the DHCP offer, which the DHCP server can provide for all or selected requesting devices. For DHCP on IPv4, this information is provided using DHCP option 125. For DHCP on IPv6, this information is provided using DHCPv6 option 17. Options can specifically be used to configure SNMP general settings, access settings, and SNMP notification settings (issuing traps to specific destinations).

There are currently no industry standards defining either of these provisioning schemes. They are proprietary per individual vendors. Operators should proceed accordingly to ensure the selected configuration approach is well defined and meets their specific requirements.

4.5. UPS Status Monitoring for EDFA Powering Applications

In a prior section we discussed that powering EDFAs and powering R-OLTs are very similar. Status monitoring the UPS that is powering the EDFA is less straightforward than monitoring the R-OLT UPS system. Our monitoring solution using a pluggable ONU doesn't work without the corresponding R-OLT. If we're powering an EDFA somewhere midspan in a fiber-run, there's likely no nearby R-OLT or coax to for implementing familiar status monitoring methods.

Figure 15 – EDFA UPS Monitoring

Operators have tried multiple approaches to solve this quandary. Unfortunately, there is no one size fits all solution. A few options that have been explored so far are described here.

Dedicate DWDM or CWDM wavelengths. DWDM or CWDM (depending on the fiber traffic) transmit and receive wavelengths could be set aside for UPS traffic. A DWDM/CWDM SFP would be installed in

the UPS and the appropriate demux, filter and splicing mechanism would be installed near the EDFA and UPS to facilitate the fiber jumper physical connection.

Dedicated dark fiber. A dedicated fiber or fiber pair could be assigned for UPS traffic. A splice tray, patch panel or other appropriate mechanism to patch into the fiber would be installed near the EDFA and UPS. A SFP would be installed in the UPS using the desired optical format.

Cellular data modem. A cellular modem could be installed in the UPS system to implement an out-of-band (OOB) communication interface. A copper Ethernet SFP installed in the UPS would connect to the cellular modem via an RJ-45 (copper) Ethernet cable. A cellular antenna would be mounted on the outside of the UPS enclosure using weather tight techniques. The modem would be powered from a power converter connected to the UPS output, providing the modem's required voltage.

EDFA proprietary management port. Some EDFA manufacturers support a proprietary interface for configuring and managing each EDFA in the operator's network. Data from each EDFA is routed through the fiber and back to the headend where it is available at a central management console. If the EDFA supports a physical maintenance port to access this management interface then it's feasible for a fiber jumper from the UPS to connect to the port, providing a communications pathway from the UPS to the headend. This would enable UPS traffic to be routed to the UPS management system. A proprietary UPS monitoring system of this type was developed between a remote hub vendor and a UPS vendor and initially deployed in 2015.

Don't monitor the UPS. If none of the current options for EDFA UPS monitoring are desirable, operators may elect to leave UPS systems unmonitored. This could be a conscious choice or may be the result of a deferred decision due to lack of an ideal monitoring option. Either way, the results will be the same. Operators will have no advance warning of utility outages that are at risk of exceeding the backup runtime of the UPS system. This risk can be mitigated by installing additional batteries to extend runtime, combined with regular maintenance visits to maximize the probability that the UPS system will perform as anticipated during utility outages. Another tool operators should make use of, especially for unmonitored UPS systems, is the utility event history typically stored in nonvolatile memory in the UPS. Figure 16 shows the history log from a typical broadband UPS.

Figure 16 – UPS Event Log

This type of utility power history is typically available through the UPS monitoring system. However, for unmonitored UPS systems, a log of this type is only available on-site and may be the only indicator of the utility power activity at the UPS location. Operators should schedule regular site visits to retrieve and analyze these utility events. As an example of the value of this type of data, the entries from the log in Figure 16 are reviewed in Table 2.

Table 2 – UPS Event Log Review

ID	Event	Description & Implication
444-448	Utility outage	Short duration utility outages occurring at approximately the same time each day. This may indicate an external event affecting the utility grid.
443, 442, 440	Remote self-test	UPS test cycles appear to be initiated by the UPS monitoring system each month at approximately the same time of day.
441	Utility outage	A utility outage lasting 3h:42m. The UPS has sufficient battery capacity to support the network during this event.
439	Utility outage	A utility outage lasted 9h:03m. The UPS powered the network for approximately six hours before depleted batteries forced dropping the load.
438	Utility outage	A utility outage lasting 2h:08m. The UPS has sufficient battery capacity to support the network during this event.

If this UPS were remotely monitored, a network outage and service interruption could have been avoided (event no. 439) through advance notification of the extended outage. Also, repeated, short direction

outages (event no. 444-448) would be identified for investigation. During one example of these types of short duration regular outages, an investigation identified a nearby factory's daily start-up processes were the cause of utility transients that triggered the UPS to switch into standby operation.

Our list of EDFA UPS monitoring options did not mention that UPS data must be received in the headend, converted to IP traffic over Ethernet, and routed to the operator's UPS monitoring software. This step must occur regardless of the data transport method.

The viability of implementing any of these options must be evaluated by operators. In one recent example, an operator determined that the only viable options for their network was using dedicated DWDM wavelengths. They further determined that the negative impact from dropped customers outweighed the cost of implementing dedicated wavelength style monitoring. In another example the operator chose to leave the UPS unmonitored, mitigating risk by stepping up scheduled maintenance to unmonitored locations.

5. Outdoor Powering Hazards

Network operators understand the harsh environmental conditions that outdoor equipment must endure. Temperature extremes, wind driven rain, snow and ice can wreak havoc on equipment not designed to endure these conditions. The electrical utility grid presents a laundry list of hazards poised to dismember the best engineered gear. Broadband UPS systems are powered directly from the outdoor utility grid. These UPS systems must be engineered to endure a litany of power grid anomalies including:

Interruption, the complete loss of voltage for thirty (30) cycles or longer.

Transients, a temporary, rapid fluctuation in the measured quantity of total power.

Surges, voltage greater than 110% above normal

Spikes, sudden voltage peaks that can reach thousands of volts

Sags, under-voltage conditions where fluctuation exceeds allowable thresholds for at least a cycle.

Brownouts, intentional or unintentional voltage drop for an extended period.

For over four decades, broadband UPS systems have provided reliable network power through every condition imaginable. Like any technology, these UPS systems have evolved over the years. However, there is one component in the broadband UPS that has remained mostly unchanged throughout the years, the ferroresonant transformer.

5.1. Ferroresonant Overview

Broadband networks have used ferroresonant (ferro) based UPS systems since the early days of CATV. Figure 17 shows a diagram of a ferro transformer.

Figure 17 – Ferroresonant UPS Transformer

What makes the ferro transformer ideal for outdoor powering and how has it remained mostly unchanged throughout years of technology advancements? Let's review some transformer basics to answer these questions.

Transformers, both ferro and the more common linear variety, consist of two primary components: windings and cores. Windings are (usually) copper wire, wound onto a core material such as steel. Energy is transferred by magnetic induction from one set of windings to another by means of varying magnetic flux. In the more common linear transformer, the output voltage is determined by a combination of the input voltage and the ratio of primary windings to secondary windings. In contrast, the ferro transformer uses nonlinear magnetic properties and a resonant circuit to provide a stable output voltage over a wide range of input voltage. During each AC cycle, energy is stored in the resonant circuit (an inductive-capacitive “tank circuit”) and then consumed by loads connected to other windings. The tank circuit operates in magnetic saturation, resulting in the output waveform being square or trapezoidal, often referred to as a quasi-square wave (QSW), instead of the more familiar sinusoidal waveform produced at the output of a linear transformer. The ferro's QSW results in more available energy than the sinusoidal counterpart. The QSW vs. sinusoidal energy relationship is illustrated in Figure 18.

Figure 18 – Sine Wave vs. Quasi-Square Wave Energy

The QSW per cycle voltage rise time is greater than the equivalent linear sinusoidal risetime (dV/dt has a higher slope value). Practically, this means that within every 60 Hz AC cycle, the QSW output has more energy available for a higher percentage of each 60 Hz cycle than the sine wave, assuming equivalent power factors. Also, the QSW rise time results in more time per cycle above the usable threshold voltage. The threshold voltage is the minimum voltage required for powered equipment to operate. As an example, consider an RF amplifier powered from the ferro UPS. During each AC cycle there is a period around the voltage zero-cross threshold where the UPS output voltage is too low for the amplifier's power supply to operate. Since the ferro's QSW output voltage rises faster than a linear UPS sine wave output, the amplifier can draw energy from the ferro UPS for a larger percentage of time within each AC cycle.

Greater output energy is one benefit of a ferro UPS. Other important benefit is output short circuit protection. The ferro can operate for extended periods of time at 150% of its rated capacity. When this level is exceeded, the tank circuit can no longer keep up with the amount of energy being pulled from the output. The ferro will then "fold back" or drop its output voltage to zero. A ferro fold back is shown here.

Figure 19 – Ferro Output Fold Back Overcurrent Protection

HFC networks consist of active equipment separated by spans of fiber optic and coaxial cable. Damage and wear to equipment, power-carrying coax, termination components and technician mishaps can result in electrical short circuits or “faults” in network power. A fault causing the UPS output load to exceed 150% of its rated capacity will result in a UPS output fold back condition, dropping the output voltage. When the fault is remedied, the ferro output is restored and normal network powering resumes. Neither the UPS nor the powered equipment are damaged because of the fold back condition.

Another characteristic of ferro based UPS systems is extremely high transient and noise filtering. The ferro is one of the best-known mechanisms for filtering utility line noise and transients from reaching the output and affecting or damaging network equipment. The ferro boasts an impressive 1000:1 isolation ratio. The nature of the ferro design makes it extremely immune to electrical surges. This means that a 1000-volt surge on the input winding would produce only a 1-volt difference on the output winding. This isolation offers very robust surge protection for powered network equipment.

Ferro based UPSs also implement a single stage conversion design. Voltage from the input winding is transferred to the output winding and directly to the network without any additional power conversion steps. When operating on battery backup, the input utility winding is disconnected using a relay and a separate inverter winding is energized by an inverter circuit utilizing battery current to produce energy. The UPS backup function is only required to operate when utility power is lost. In most systems the inverter operates less than 1% of the life of the UPS. This means that for over 99% of the time, the UPS is providing output power by using only the ferro transformer. Since no electronic components are in the critical powering path, the reliability of the ferro based UPS is exceptional.

Since the ferro is constructed of copper and steel, it will typically only fail from physical damage or from catastrophic electrical events such as a direct lightning strike.

6. Conclusion

OSP active PON elements are subject to extreme outdoor conditions, including utility grid anomalies. The ferroresonant based UPS has been used for many years, effectively isolating network equipment from electrical utility grid hazards. An HFC network segment, including nodes and amplifiers, is typically powered from a single UPS with the coax transporting both power and payload. OSP PON equipment, specifically R-OLTs and EDFAs, are most often powered with dedicated UPS systems. PON UPS systems must be sized for the smaller load of a single active component for the UPS to operate efficiently. PON UPS systems can be housed in physically smaller enclosures with fewer batteries and smaller components than their HFC counterparts. Operators may also decide to house R-OLTs and EDFAs with the UPS system in a single enclosure.

Status monitoring UPS systems powering R-OLTs have recently become straightforward with the use of a pluggable ONU installed in the UPS. Monitoring UPS systems powering EDFAs is not yet as cut and dry. Several monitoring options are possible. Operators need to weigh the pros and cons of each option and determine the method that works for them.

UPS status monitoring provides multiple benefits. First, operators receive advance warning of utility outages that may extend beyond usable battery runtimes. This advance warning enables timely action to keep extended utility outages from becoming service affecting events. Unmonitored UPS systems provide no advance warning, leaving operators to glean outage data from other sources or to just hope for the best. Another benefit from status monitoring includes notifications of imminent and potential service affecting conditions. This could include advance indicators that batteries have reduced capacity or that UPS service is needed. Preventive maintenance should be scheduled to correct these items. Unmonitored UPS systems cannot report these conditions, leaving operators to identify them during scheduled maintenance visits, hopefully before a utility outage becomes service affecting.

1. Introduction

Operators of cable networks are very familiar with the mandated requirements for monitoring signal leakage. In standard and mid-split deployments, leaks are discovered using a variety of techniques such as direct Quadrature Amplitude Modulation (QAM) measurement, direct detection of Orthogonal Frequency-Division Multiplexing (OFDM) signal components, and detection of Continuous Wave (CW) signals generated at the headend or Node Remote PHY Device (RPD) in the downstream direction. In high split deployments, leaks in the aeronautical band are discovered by monitoring the upstream for a specific test burst generated by the cable modem under control of the Cable Modem Termination System (CMTS.)

With the introduction of Full Duplex DOCSIS (FDX), some of the status quo practices for leakage detection will need to be changed due to the inherent differences between the traditional network and FDX which pushes the upstream (US) frequency up to 684 MHz. This paper explores several subjects related to detection and measurement of leakage in the FDX network. We will discuss how this will now necessitate leakage detection methods in both the downstream (DS) and US direction simultaneously in the aeronautical band, and we will discuss the potential benefit to perform additional Long-Term Evolution (LTE) band frequency measurements for upstream leakage when using full bandwidth FDX implementations.

We will additionally share lab test results demonstrating concurrent upstream and downstream leakage detection and we will propose a new test methodology for use in a controlled environment which will allow meter sensitivity testing for the new simultaneous upstream and downstream leakage detection.

Capabilities of Full Duplex DOCSIS

Full Duplex DOCSIS is targeted at significantly increasing upstream capacity by using coaxial spectrum for synchronized upstream and downstream communications by means of full duplex techniques. As part of the industry “10G” initiative, the primary objective of DOCSIS 4.0 FDX is to enable multi-Gigabit symmetric data services over the Hybrid Fiber Coax (HFC) network, while also adding significant new upstream bandwidth for continued capacity growth. The DOCSIS 4.0 FDX specification in conjunction with FDX Node and Amplifier specifications are intended to provide the requirements that enable DOCSIS 4.0 Full Duplex performance over “Node+x” HFC architectures. The overlapping DS and US spectrum, which is the key new physical (PHY) component of FDX, necessitates the need for Echo Cancellation capability in the node and amplifier, as well as other digital processing blocks to manage two-way signal passage, while maintaining platform stability and signal fidelity.

Building on a long history of delivering significant capacity improvements – most recently powered by advances in the implementation of DOCSIS 3.1 -- operators continue to develop and build on customers’ future 10G needs leveraging DOCSIS 4.0.

FDX allows blocks of channels, via “Resource Block Assignments,” as shown in Figure 1 to be used in both the upstream and downstream direction dynamically, significantly increasing the upstream throughput capability of the HFC network. Figure 2 displays the spectrum grid definition called out in the DOCSIS 4.0 FDX specification along with the overlapping Aeronautical and LTE frequency bands. In addition to managing signal overlap at the physical layer, FDX operation also requires new scheduler techniques that groups users based on their relative isolation characteristics to prevent co-channel interference from one FDX US Transmit (Tx) onto another’s FDX DS Receive (Rx). The vCMTS (virtual Cable Modem Termination System) creates “Interference Groups” and “Transmission Groups” to ensure compatible devices are given access to the spectrum when it is shared. Finally, Figure 3 shows that due to

cable loss at higher frequencies, the cable modem will now be responsible for providing up tilt in the upstream direction out to 684 MHz to account for cable loss with a nominal tilt of 10 dB that can be adjusted to 8-12 dB (1 dB relaxation for 12 dB tilt).

Figure 1 - FDX Resource Block Assignments (“RBAs”)

Figure 2 - Configurable FDX Allocated Spectrum Bandwidths with Aeronautical and LTE Bands Shown

Figure 3 - FDX Cable Modem Upstream Output Power Spectral Tilt (64.5 dBmV TCP)

Differences in leakage detection for Full Duplex DOCSIS (FDX) versus tradition standard/mid/high split systems

In standard and mid split networks, aeronautical band signals are only transmitted in the DS. As such, DS leakage detection is required to comply with mandated leakage regulations. In high split networks, signals transmitted in the aeronautical band are exclusively in the US. As such, for high split US leakage detection where leakage test signals are generated from the cable modem (CM) becomes a necessity.

Figure 4 provides an illustration of the US and DS signal levels in an FDX network at 108 MHz and 684MHz. When looking at the levels the inverted nature of signal levels in the network becomes obvious, where US signal levels are at a maximum in the 'Drop', and DS signal levels are at a maximum in the 'Feed' section of the plant. This makes it such that legacy aeronautical DS leakage detection techniques are insufficient to maintain visibility to US leakage.

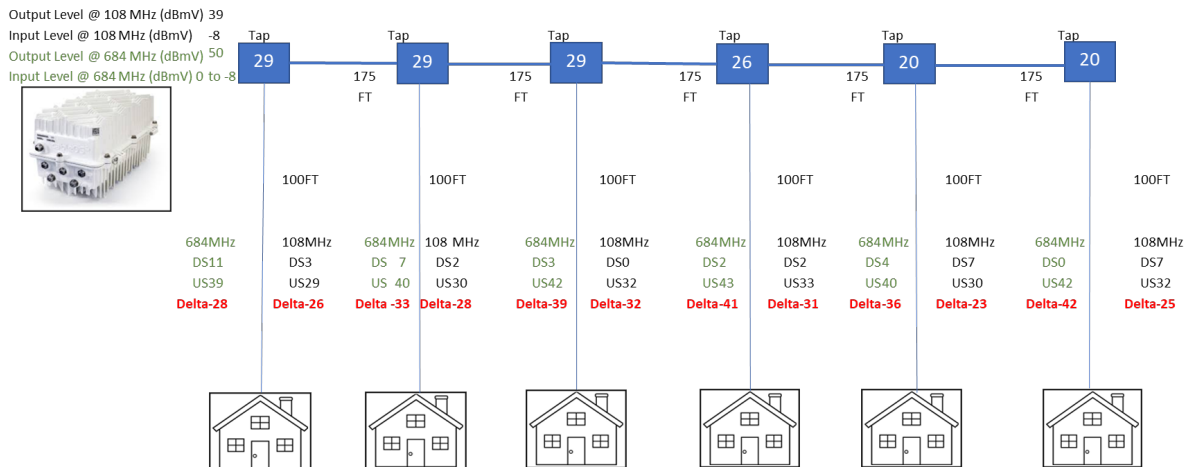

Figure 4 - FDX Network Downstream to Upstream Signal Level Deltas

With FDX, this drives a need for US leakage monitoring in the aeronautical band; in addition to the traditional DS aeronautical band leakage monitoring. This simultaneous monitoring provides full visibility to all aeronautical band network egress. If only DS detection was enabled, there would not be visibility to US leakage. And if only US detection was enabled, there would not be visibility to DS leakage.

2. Leakage detection techniques appropriate for FDX

There are many different techniques currently employed for leakage detection. Many of the techniques are optimized and directly tied to the signal format transmitted at the desired detection frequency. For example, DS detection at frequencies where OFDM signals are present is most easily performed by direct detection of existing signal components of the OFDM channel. This technique has the benefit of no extra signals being inserted into the network and no corresponding additional headend equipment required. It has an additional benefit that the amplitude of detected signal is significantly higher than alternative inserted low level carrier approaches, so depending upon the vendor implementation, the realized meter sensitivity can be superior to alternative approaches. Figure 5 illustrates the OFDM signal harmonics utilized for DS signal detection in one implementation.

Figure 5 - OFDM harmonics used for DS leakage detection-

The US signal format for FDX is Orthogonal Frequency-Division Multiple Access (OFDMA). The 2020 SCTE paper, Leakage in a high split world describes a methodology where an OFDMA upstream data profile (OUDP) test burst is used for aeronautical band leakage detection. The paper details how this approach provides ample sensitivity for Federal Communications Commission (FCC) compliance. This OUDP approach has now been accepted as a standard as the methodology used for US signal detection. With the OUDP approach, each CM on a node, under control of the CMTS – will sequentially generate an OUDP test burst with known signal characteristics. The leakage detector is then able to lock onto this OUDP test burst and detect signals egressing the coaxial network.

The spectrum of an OUDP burst generated by a CM is shown in Figure 6.

Figure 6 - Spectrum of OUDP burst generated by a CM

With FDX, regardless of the FDX bandwidth, the DS signal format will be exclusively OFDM. Similarly, the US signal format is exclusively OFDMA. As such, for DS leakage detection the direct detection of OFDM signal component techniques should be employed; and for US leakage detection the OUDP technique should be employed.

3. Monitoring of potential FDX LTE egress

As a best practice, in addition to FCC mandated aeronautical band leakage detection, cable operators today regularly monitor downstream LTE frequencies for leakage ingress. Benefits resultant from this effort include hardening of the plant which improves network quality, and it additionally helps to ensure that signals egressing from the plant do not adversely affect the licensed spectrum utilized by mobile operators. Figure 2 shows the spectrum bandwidths configurable for FDX and highlights the overlap with the aeronautical band and a lower LTE band. In the full 576 MHz FDX implementation, there is an FDX bandwidth (BW) overlap with the 600 MHz LTE band which is widely utilized by a mobile operator in the United States. As such, if a network is utilizing the full 576 MHz FDX bandwidth, attention should be paid as to not cause harmful interference to this licensed spectrum.

The 2012 Society of Telecommunications Engineers (SCTE) paper, Another Look at Signal Leakage, explored the lack of correlation between signal leakage in the aeronautical band and signal leakage at 700MHz LTE frequencies. A conclusion of the paper was that monitoring solely at the aeronautical band provides inadequate visibility to signal leakage at or near the LTE band. This was an impetus for the high frequency DS leakage detection performed today. This conclusion holds true with FDX – if utilizing full 576 MHz FDX, the OUDP US detection performed at the aeronautical band will not provide visibility to any US egress in the 600MHz band. Depending upon the detection frequency and upon antenna BW, the DS detection at or near the LTE band should provide adequate coverage of DS egress at the 600 MHz LTE band, but it will not provide visibility to US egress at this band.

What will be required in such a situation in order to effectively monitor US egress is a 2nd OUDP US detection session, performed at some frequency below 684 MHz.

An additional factor which supports the conclusion that aeronautical band US detection does not correlate with egress in the 600MHz band is related to the significant tilt between 108 MHz and 684 MHz. This tilt which is illustrated in Figure 3, will result in any signal leakage at the higher FDX frequencies having correspondingly higher levels as compared to leaks at lower frequencies such as the aeronautical band.

Simulated Full Duplex DOCSIS Leakage Detection Test Results

A signal leakage meter was designed and built for FDX operation, capable of simultaneous US and DS detection. Testing was performed within the CTA channel 16 bandwidth. To verify the concurrent US and DS aeronautical band detection, a test setup was built as shown in Figure 7.

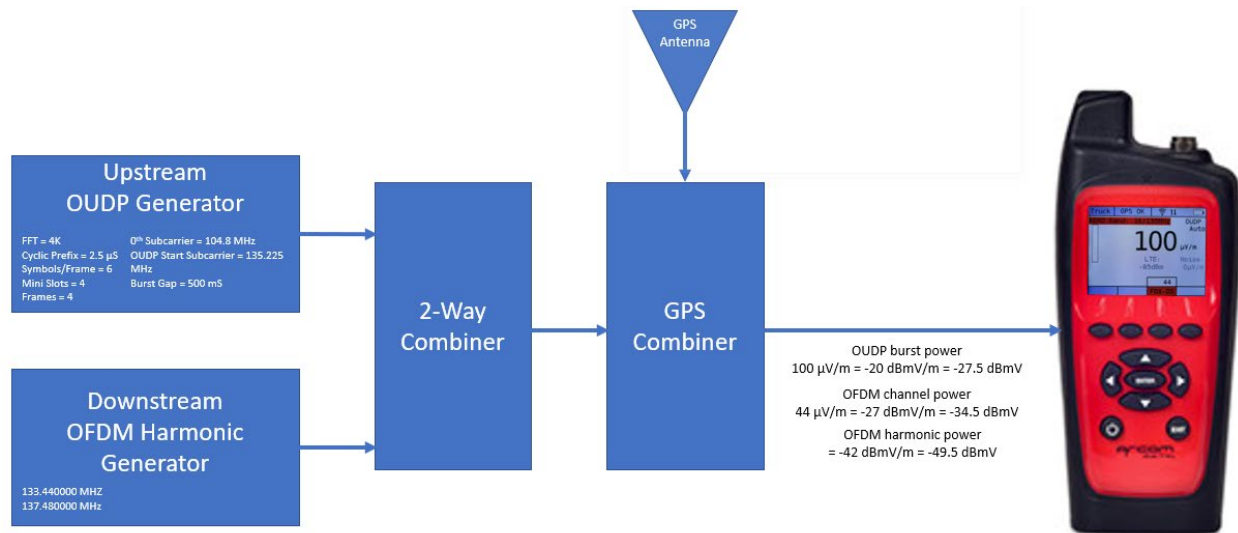

Figure 7 - FDX test setup block diagram

Channel type: FDX					
AERO band channel:	16/135.0MHz	Cyclic prefix, µs/Ts:	2.5/256	Number of minislots:	4
OFDMA:	4K, pattern 11	Symbols per frame:	6	Number of frames:	4
OFDMA zero subcarrier freq., MHz:	104.800	OUDP start subcarrier freq., MHz:	135.225	Tuner freq., MHz:	136.0125
OFDM F1, MHz:	133.440	F2, MHz:	137.480		

Figure 8 - FDX meter configuration

The detection results are shown on Figure 9, where the meter displays the measured signal level for both US and DS. Here, the US OUDP showed the expected 100 $\mu\text{V/m}$ and the DS OFDM detection showed the expected 44 $\mu\text{V/m}$, which were the measured signal level input into the meter as illustrated in Figure 7. Two views of the display are provided, each with the prominent US/DS detection location alternated.

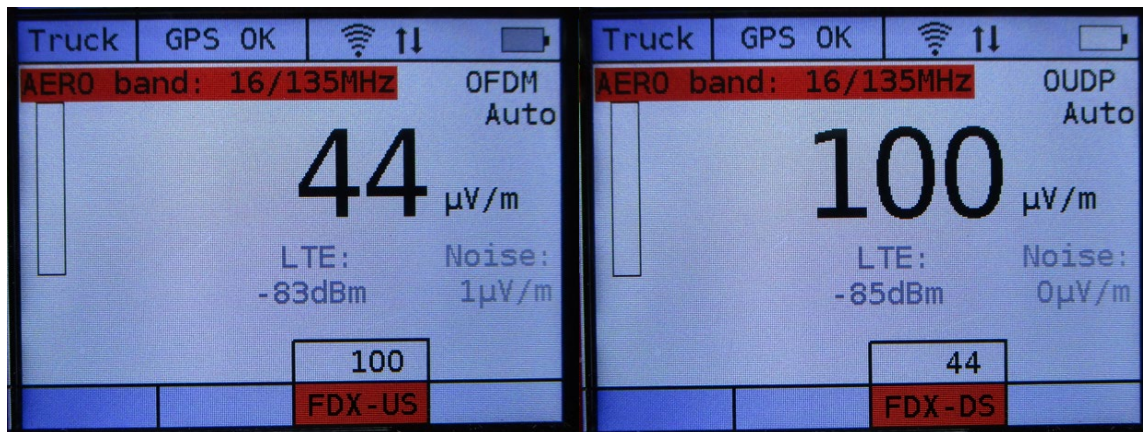

Figure 9 - FDX DS and US detection results

Radiated Three Meter Open Air Sensitivity Testing in an Anechoic Chamber

The test procedures described below can be used for all HFC Standard, Mid and High split leakage meter testing as well as Full Duplex DOCSIS testing. Legacy downstream OFDM and upstream OUDP bursts will be retained as the source signals as defined in previous technical papers and specifications. By simultaneously transmitting an upstream OUDP and downstream OFDM signal, FDX functionality of the leakage detection meter can be evaluated.

1 Source Signal Details

US OUDP Signal Details:

1. Symbols Per Frame (K) = 9
2. Modulation Order = 256 QAM
3. Pilot Pattern = 11
4. Center Frequency of OUDP Signal = 136.0125 MHz, 603 MHz
5. 4 Mini-slots (1.6 MHz Upstream Bandwidth with the 4 adjacent mini-slots to the center frequency above)
6. Number of Frames = 8 and 2.16 mS in transmit time duration. (For 256 House Holds Passed roundtrip time = 563.2 mS)
7. 4K Fast Fourier Transform (FFT) = 40 μS per symbol + Cyclic Prefix
8. Cyclic Prefix = 1.5625 μS
9. Window Roll off Period = 0.9375 μS

DS OFDM Signal Details:

1. Channel 16, 88
2. 135 MHz, 609 MHz
3. Cyclic Prefix = 2.5 μ S
4. 4K Fast Fourier Transform (FFT)

2 Baseline Test Setup

Figure 10 - Baseline Leakage Detection Setup

3 Baseline Test Procedure

1. Set the Radio Frequency (RF) Signal Generator to output a CW carrier at each of the center frequencies given in the “Source Signal Details” section.
2. Connect the RF signal generator, all cables used for the test, and the RF variable attenuator to the power meter. Confirm the RF power level with the RF power meter and account for any cable loss and 0 dB attenuator setting using the Amplitude offset on the power meter.
3. Verify that all of the switches in the RF variable attenuator are within 5% tolerance of their expected values.
4. Connect the RF Signal Generator to the Very High/Ultrahigh Frequency (VHF/UHF) transmit antenna.
5. Measure and verify the distance between the VHF/UHF transmit antenna and Electric Field Strength Probe is 3 meters.

6. Connect the RF Power Meter to the Electric Field Strength Probe and measure the RF level of the CW carrier.
7. Confirm the measured field strength is correct taking into account the gain/antenna factors of the antennas and Free Space Path Loss (FSPL) during calibration.
 - a. 3m Free Space Path Loss is ~24.65 dB at 136 MHz
 - b. 3m Free Space Path Loss is ~36.68 dB at 609 MHz

4 FDX Leakage Detector Test Setup

Figure 11 - Leakage Detection Meter Test Setup

5 FDX Leakage Detector Meter Test Procedure

1. Configure the FDX cable modem/gateway to output continuous OUDP signals defined in “US OUDP Signal Details” and the FDX node to output downstream signals defined in sections “DS OFDM Signal Details.”
2. Confirm each RF power level with the RF power meter and account for any cable loss and RF variable attenuator insertion loss.
3. Verify that all of the switches in the RF variable attenuator are within 5% tolerance of their expected values.
4. Connect the FDX cable modem and Node to the VHF/UHF transmit antenna through the RF variable attenuator.
5. Measure and verify the distance between the VHF/UHF transmit antenna and leakage detection meter is 3 meters.

6. Make sure the meter is configured properly to the settings given in “Source Signal Details” and measure the RF level of the Aeronautical Band Signals in both the upstream and downstream direction.
7. Make sure the meter is configured properly to the settings given in “Source Signal Details” and measure the RF level of the LTE Band Signals in both the upstream and downstream direction.
8. Add 6 dB of attenuation to change the distance to ~6m. Repeat Steps 6-7.
9. Continue to add attenuation in 6 dB steps doubling the distance each time until you get to ~192m (36 dB total attenuation). Repeat Steps 6-7 each time. Record all Measurements.
10. Configure the FDX cable modem to output an OUDP burst 2 times per second with the parameters given in “US OUDP Signal Details” and repeat steps 6-9.

Note 1: The Device under Test (DUT) should rotate 360 degrees while the antenna raises and lowers in 1 or ½ meter steps up to 3 meters to account for antenna patterns.

Note 2: A more advanced test setup can be created to simulate mobile detection in the anechoic chamber by connecting a function generator to the RF variable attenuator and simulate signal strength increasing to a peak and then decreasing in a real-world scenario where the leakage detector meter’s position is changed relative to the source of leakage.

Conclusions

With cable networks advancing, the demand for higher download and upload speeds continues to be met. FDX is a great way of utilizing existing bandwidth in the network transmitting data in both the downstream and upstream directions at the same time. These state-of-the-art FDX networks require leakage detection meters that can detect and record leakage levels simultaneously in the DS and US direction to stay in compliance with FCC regulations, as well as keeping the entire network integrity in good working order. In FDX implementations utilizing the full 576 MHz bandwidth, there is the potential for egress affecting licensed 600MHz LTE – so additional US leakage monitoring using a second high frequency OUDP test session should be considered. Test equipment capable of the concurrent US and DS monitoring was demonstrated. Lastly, with the test procedure given in this paper, operators can reliably assess the sensitivity of FDX and all HFC leakage detection meters in a precise setting allowing for continued leakage monitoring that not only allows for sustained regulatory compliance, but also reliable plant monitoring and maintenance for optimal system performance.

Abbreviations

BW	bandwidth
CATV	community antenna television
CM	cable modem
CMTS	cable modem termination system
CPE	customer Premises equipment
CW	continuous wave

1. Introduction

As the network becomes more powerful through 10G technology, resiliency in our extensive power supply network is essential to ensure our customers are always connected. The stability of outside plant (OSP) power supplies (PS) is key to keeping the network online and serving customers. Maintaining accurate location and active telemetry information is vital to keeping the power supplies in optimal health. Machine learning is employed to analyze this massive amount of telemetry data and provide actionable insights related to operating conditions and the overall health of the power supplies and batteries.

The authors, Stephanie Ohnmacht & Matt Stehman, will present a multi-tier solution that was developed to address this at scale. The solution includes the integration of mainstream mapping technology, with machine learning (ML) routines to optimize location probabilities and use of big data pipelines and advanced data science techniques to inform proactive and demand maintenance activities. Predictive models are built on top of this large dataset to help detect long term variations in power supply performance as well as real-time performance evaluations during active outages. This paper will illustrate a proven approach to improving PS resiliency, leading to increased network reliability, and satisfying the requirements of a 10G network.

2. Identifying Power Supplies

Historically Comcast has had to maintain multiple information sources and databases to manage the network of power supplies. These separate databases included those used for network designers, technical operations, and asset inventory management. This disparate data provided an opportunity to find a solution to enable all systems to talk to each other with one unique key. Creating an innovative system to maintain PS information in the future. To start, a team was formed to begin a 4-step process to validate and correct location information for Comcast's PS across databases.

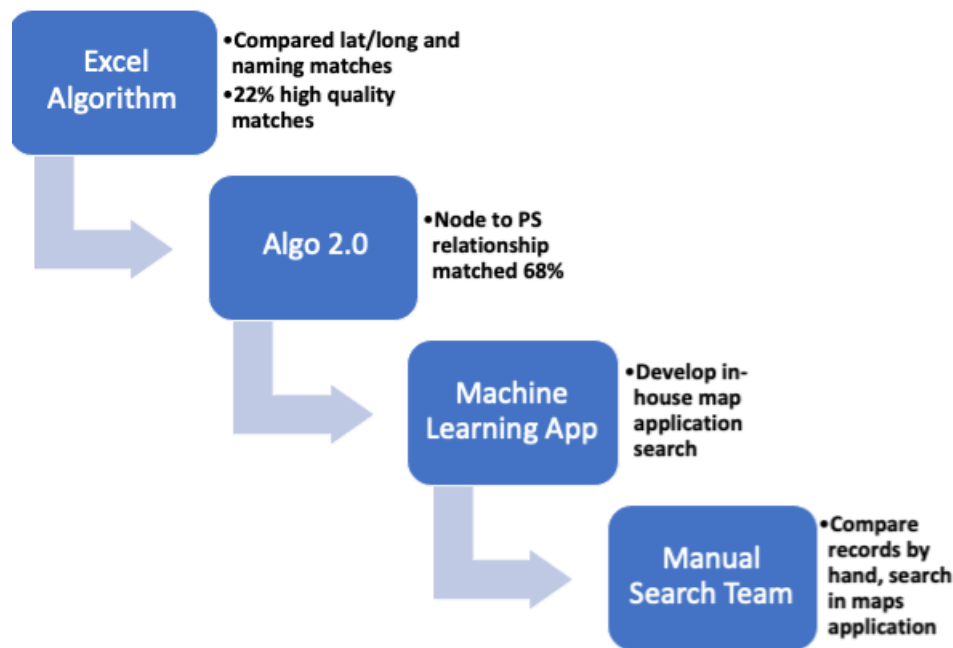

Figure 1 - Architecture

2.1. Geolocation Match via Excel Algorithm

The goal of the geolocation match was to begin to narrow down location discrepancies across databases. To determine a single PS referenced in multiple databases, the team developed an algorithm to compare the delta of linear feet between the two locations in the databases. If the PS locations were within 300 ft, then it was marked as the same location. In situations where the distance was greater than 300 ft, an index was applied to show a level of confidence of a match based on the linear feet differences. This level of geolocation matching resulted in 22% of the total population identified as having a high-quality match within the total population.

2.2. Algorithm 2.0

Once completing the first algorithm, the next phase of the analysis was to narrow down outstanding matches based on other known links within the databases. This approach focused on using node-to-power supply relationships to solve for additional location matches and increase level of confidence. This analysis increased matched records to 68% of the PS population.

2.3. Machine Learning to Identify Power Supply through Open-Source Mapping Tools (Find My Power)

A tool was developed that would identify PS in its natural environment (street or pole) using existing mapping applications to confirm the actual location. To initiate the project, power supply photos were taken in the field, then loaded into the application to begin training the system to identify different power supply types and installation environments. These examples were integral to the ability of the tool to accurately detect a PS in all situations. Once the right training model was developed, an open-source visual mapping tool was integrated into the tool that captured real street view imagery and provided associated latitude and longitude coordinates for the exact location of the identified power supply. After an attempted PS match, a level of confidence was determined by the tool and applied to the record which was then confirmed manually by a team.

This new system was able to find power supplies for 65% - 70% of the locations. The mapping tool did not have images for about 10% of the locations (given easements, landscape, and gated communities). About 45-50% of the power supplies predicted were correctly identified by the artificial intelligence and significantly boosted the team's productivity by 2X when verifying manually.

2.4. Manual Intervention

Once the team confirmed proposed matches from the machine learning tool, outstanding PS matches were set aside to be reviewed by field teams and updated.

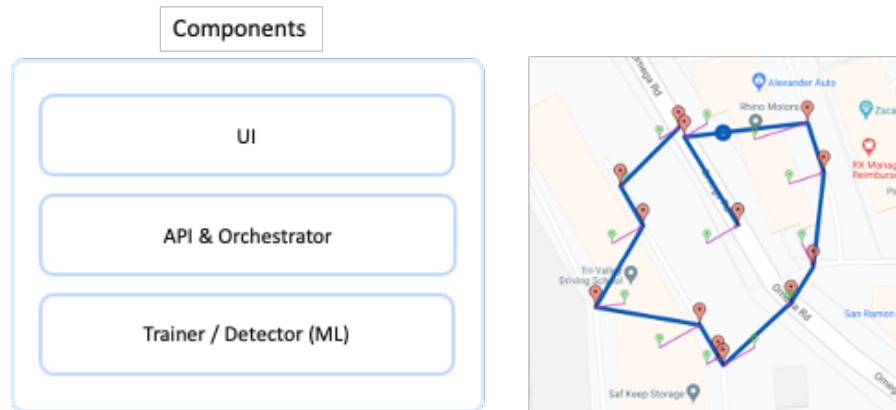

Figure 2 - Geolocation Matching Algorithm

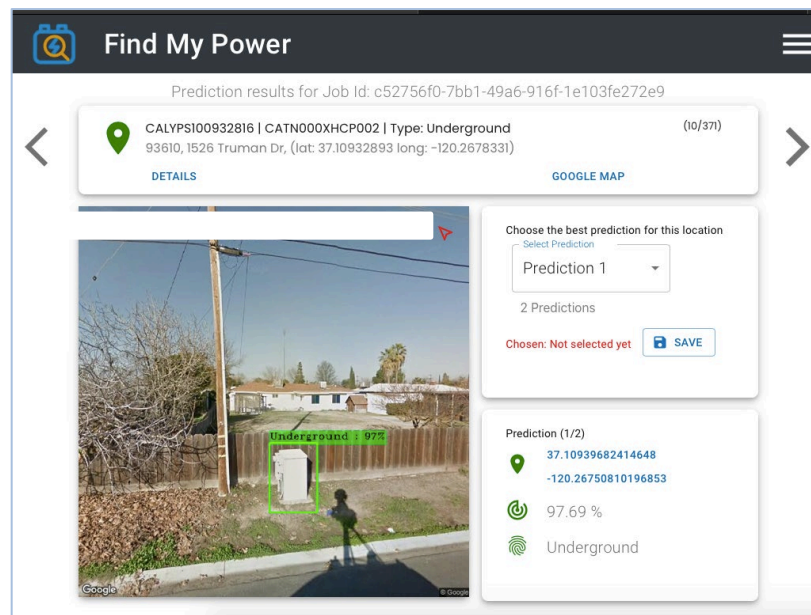

Figure 3 - Example Output from Find My Power

3. Asset Inventory Interface

Updated PS location information and node associations provided the opportunity to create a tool for management, field techs and operations called Power Supply Notebook (PSNB).

3.1. Asset Inventory User Interface

The team created a source of truth User Interface (UI) for all PS asset details. Including PS make/model/serial number, location, batteries, transponder, installation date, and maintenance records. For new PS the asset information is loaded once the PS is built and online. Ongoing updates and changes can be completed by administrators, technicians, business partners and the network help desk. Depending on the user's permission level, changes are added to a queue and approved by appropriate staff. All changes are tracked and recorded for historical purposes and investigation needs.

3.2. Alarming Interface

PS are polled every minute by in-house software. This data is monitored by the Correlation Engine (CE). As changes in telemetry flow through CE, anomalies are monitored to determine if an event is in progress. CE references all active devices on plant, downstream from the power supply and can correlate the impact of an event to number of devices impacted. Based on pre-determined threshold levels, by event type, an alert is sent to PSNB. PSNB is the presentation layer that displays current and historical alarms and events. Telemetry can be viewed by battery string, as well as the historical trends in battery voltage, input voltage, output current, temperature, output voltage, and output power. Events that need dispatching are sent to an automated dispatching system to be processed according to business rules. Alerts include PS on stand-by (on battery), PS loss of communication, and low battery.

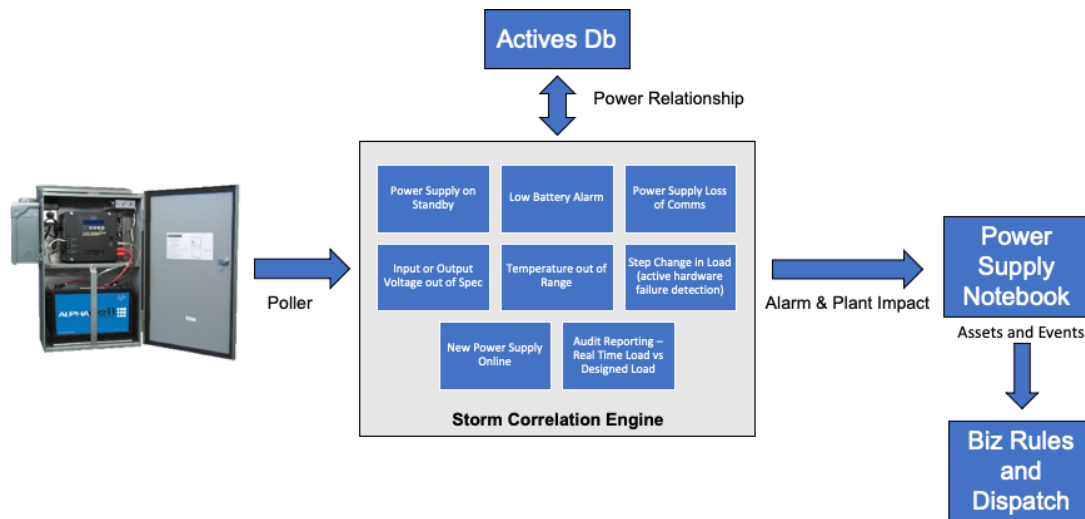

Figure 4 - Inventory/Alarming Tool Architecture

3.3. Impacted Actives (nodes, cable modems) on Plant

The data output from CE and passed to the PSNB UI, provides insightful data about outage impacts. In the past, it was assumed that any PS power outage affected all actives. Based on preliminary data, that is not the case. Data suggests that on average, 30-40% of customers stay online (have power) during a PS on discharge scenario. The geography of the power grids from the utility company and broadband provider do not overlap. As you can see in the example below, an outage from a PS only impacted a portion of the cable modems supported by that power supply. Empowered by this additional layer of information, teams can make more informed choices about how, when, and where to send a technician.

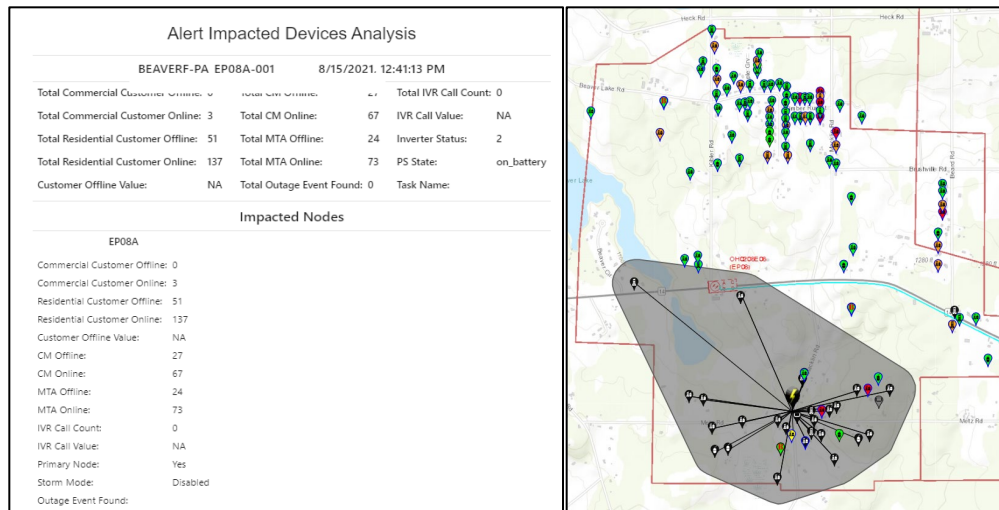

Figure 5 - PS Outage Impact Analysis Example

4. Power Supply Telemetry

The previous sections discussed the effort to build a source of truth that is foundational to the overall tracking and management of a power supply network. Once the global tracking and visibility for each power supply is established, live telemetry from individual power supplies can be incorporated to provide the status of each power supply as well as the entire network of power supplies. This section will discuss the telemetry gathered from each power supply in Comcast's plant and how the raw data can be used to make informed decisions.

Each power supply is made up of several sub-components where each is responsible for various aspects of overall operation. Understanding the function of the different components as well as the various telemetry metrics captured is key to modelling the health of the power supplies. See Figure 6 for a simplified summary of the power supply with components relevant to this paper.

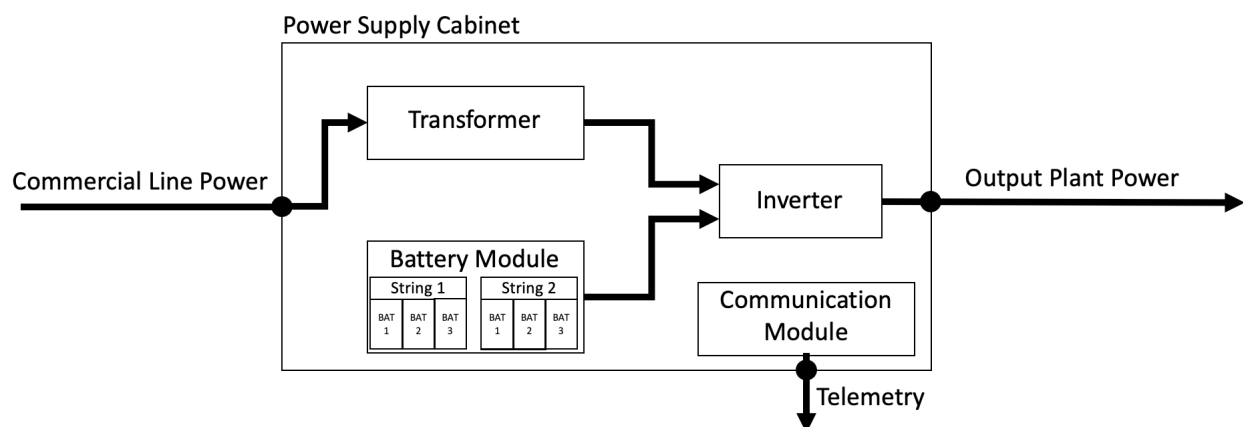

Figure 6 - Power Supply Overview

The transformer component is responsible for converting the commercial high voltage AC power down to operational range and format for the power supply. The battery module houses the strings of backup

batteries that are used to power the plant in case of a commercial power outage. The Inverter is used to convert the DC voltage from the backup batteries into AC as required by the elements of the RF plant (RF nodes, RPDs, amplifiers, etc..). The inverter also controls which power source to use in the event of a change in input voltages. The communications module is responsible for relaying all relevant information about the power supply through DOCSIS[®] protocols back to Comcast HQ for continuous monitoring.

The following sections will discuss the different telemetry metrics and data pipelines to consume the streaming data which allow for analysis and insights.

4.1. Telemetry Overview

The communications module is responsible for combining all measurements of the power supply state from the individual sub-components and packaging them into a telemetry stream that can be read through DOCSIS protocols. The PS telemetry is polled via simple network management protocol (SNMP) at two sampling intervals: every 60 seconds for high frequency engineering telemetry and hourly for configuration and system level information. The PS can also push alarms in between SNMP polls in the case of specific conditions being outside of acceptable values. Table 1 contains a simplified list of the telemetry available from the communications module.

Table 1 - Relevant Power Supply Telemetry Metrics

Frequency	Context	Telemetry Metrics	Description
Minute	Input to Power Supply	Voltage, Current, Power	Measurements of electrical input to the power supply transformer from commercial line power
	Power Supply Operation	Inverter Status	State of power supply: commercial input, battery backup/standby (outage), battery backup (self-test)
		Tamper Status	Indication of whether PS has been tampered with
		Internal Temperature	Environmental temperature of the power supply cabinet
		Alarm	Internal PS Alarms. Major: service impacting, Minor non-service impacting
	Battery Operation	Individual Voltages	Measured voltage at each battery terminal
		Total Voltage	Total voltage from all battery strings at the input to the inverter
		String Charge Current	Measured charging current at the input to each battery string
		String Discharge Current	Measured discharge current from each string of batteries
		String Float Charge Current	Measured floating charge current for each string of batteries

	Power Supply Output	Voltage, Current, Power	Measurements of electrical output from the power supply to the outside plant
Hourly	Power Supply Info	Vendor, Model Number, Serial Number	General information about the individual power supplies
		Configurations and supported functions	Overview of various configurations for each PS and which functionalities are supported
		System	Software versions, device ids, Ip/Mac addresses, etc....

The table indicates the general families of live telemetry captured from the communication modules of each power supply in the field. The minute polls tend to include more engineering specific information about voltages, currents, and statuses relevant to the functional operation of the power supply. The hourly polls contain more stable information useful for understanding the configurations and settings of the power supply.

From an operations standpoint, the power supply input telemetry gives an indication of the health of the underlying commercial power network. The inverter status is used to determine whether the PS is being powered from commercial power or back-up batteries. The output telemetry is useful for quantifying the size of the plant the power supply is powering and is a key feature in validating the power supply against design specifications. The output telemetry is also a key feature in outage runtime prediction models (will be discussed in Section 5), since how long a battery will last is largely dependent on how much current/power draw the plant requires. The PS temperature field is also useful in this regard because it is well known that batteries tend to perform worse in colder conditions due a resulting reduction in the chemical energy in each cell.

The individual battery metrics are very useful for monitoring batter health. For instance, inspection of the voltage discharge and charge curves can contain a lot of information about the health of the batteries. The durations and boundaries of these individual events contain a mass of information related to battery performance and health. Since voltage data is stored for each individual battery, a determination can be made about whether a specific battery may be performing sub-optimally as opposed to assuming the entire string of batteries needs to be addressed.

This section introduced the individual power supply telemetry metrics and gave some indication of how they can be used to monitor the health of the power supplies. The next sections will discuss the data pipelines built to consume and analyze the real-time telemetry data to provide more insights and help guide the field with resource allocation and maintenance activities.

4.2. Streaming Infrastructure and Real Time Eventing

The telemetry from each individual power supply is streamed through a real time alerting architecture where alarms and warnings can be generated based on a variety of conditions that may require action to be taken. The data is then landed in a short-term storage solution to support further deep dive analyses on recent events if needed. Due to the shear amount of telemetry being generated by the network of power supplies the raw data is only stored for a short time to minimize overhead. More information on how this challenge is handled will be provided in Section 4.3.

The streaming architecture allows for real time alerting and eventing to be performed as the raw telemetry is collected. The events are then landed in a front-end user interface for prioritization and determining the appropriate action. A general overview of the type of alarms currently implemented is given in Table 2.

Table 2 - List of Real Time Alerts

Context	Name	Description
Inverter Status	No Commercial Power	Power supply has no commercial power and is operating on battery
	Power Supply Running Test	Power supply is running a scheduled self-test to check battery performance
	Power Supply Test Failed	Power supply self-test did not last the intended duration (requires investigation)
Telemetry Variations	Output Current, Voltage, Power	Alert when measurement varies significantly from its nominal value
	High Temperature	Power supply temperature is reaching unsafe levels
	Low Battery Voltage	Power supply is operating on battery and voltages are reaching depletion levels
Communications	Loss of Communications	SNMP can no longer communicate with communications module
	PS Internal Alarm	Forwarding of internal power supply alarms

These alerts are meant to be an indication that a given power supply is currently experiencing an event of interest and requires an assessment. These alerts are currently logic based and developed from an in-depth knowledge of the operating conditions of the power supplies. A history of these alerts (including the duration the alert was active) are kept for analysis of long-term trends so analysts can evaluate trends and provide appropriate courses of action when needed.

These types of alerts are industry standard and allow for a live view of activity on the network. These alerts are only aware of a local time window around the present time stamp and thus are limited in their abilities to find complex patterns in the raw data. Thus, there is a large opportunity in this space to adopt a machine learning approach that can gain more complex insights from historical data in combination with real time data.

4.3. Big Data Pipelines for Efficient Storage and Analysis

In order to build predictive models that can learn from historical events, a historical database of training data is required. However, due to the size of Comcast's power supply network which typically generates hundreds of billions of data points a day, it is cost prohibitive to store all the raw telemetry metrics for a long duration. To overcome this obstacle, Comcast has developed a staged strategy for identifying and storing events relevant to modeling the health of the power supplies. Figure 7 outlines the approach to only storing data that is useful for modeling.

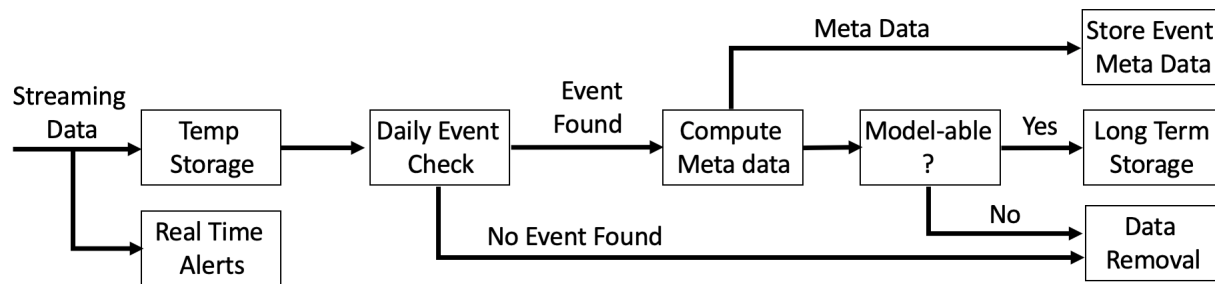

Figure 7 - Big Data Processing Pipeline Architecture

The big data pipelines consume the raw telemetry from the temporary storage solution discussed in Section 4.2. A daily job is then run that processes a single day's worth of data for the entire footprint in one go. This was implemented because some meta data that is calculated for the individual events requires more information than a local time window would afford and thus event meta data cannot be calculated through the streaming event/alerting process discussed previously. The daily job processes the raw data and determines if the criteria for any model-able events were found. The set of events that are checked against are events that contain information related to the health of the power supply, namely: battery discharge and charge events. By looking at how batteries charge and discharge, one can infer the health of the batteries and the different approaches for this health prediction will be discussed in Section 5.1.

If an event check does determine that a model-able event has occurred for a given power supply, the entire set of raw data for the duration of that event is stored indefinitely in a long-term storage solution. All raw data outside of these model-able events are then removed as part of the standard temporary data retention policies. When the event is processed, there is a litany of meta data calculated that is stored to help describe the characteristics of the event which is placed in an event database that has no retention policy. This table is light weight since every event is only a single row in a table and the meta data allows for insights into the physics of the events computed from raw data. This approach results in storing only 0.25% of the original raw data for an equivalent period of time. Obviously, this number can change based on the number of events but by implementing this staged storage approach Comcast has significantly cut down on the cost of storing data while not missing anything relevant to long term modeling efforts.

The model-ability of an event is determined by another set of criteria on the event meta data, a few examples are event duration, data quality, etc. For example, while a power supply may need to go into battery mode for a split-second commercial power outage, that event might not be useful for modeling the health of power supplies due to the very short duration. The next section will discuss more about the modeling objectives and how the raw telemetry values can be used in building models that can deliver on those objectives.

5. Modeling Power Supply Health

The previous section introduced the power supplies and telemetry metrics as well as the data processing pipelines that consume the raw data to provide real time alerts and pre-process for future modeling efforts. This section will discuss the different objectives of predictive models in the power spaces as well as the different modeling approaches and some initial results from this relatively new initiative.

5.1. Modeling Objectives

In the cable domain, a positive customer experience is the main objective of all efforts. For outside plant power that means keeping the plant online and customers connected at all costs. Thus, a predictive model should use all available data to determine if a customer impacting event is imminent or the impact assessment of any live customer impacting events. These types of scenarios in the cable world are typically referred to as proactive maintenance and demand maintenance. Many initiatives exist in the RF network maintenance realm such as Wolcott, et al. (2016) and Wolcott, et al. (2018) and many practices have even become industry standard as documented in CableLabs PNM Best Practices Primer (2020). For the power supply domain most efforts have been focused on improving the engineering models related to the power supplies such as Anderson and Burgett (2014). The authors believe that there is a large opportunity to enhance the overall field of power supply management and maintenance with machine learning which can consider many more inputs outside of raw engineering data. Figure 8 showcases the distinction between proactive and demand maintenance.

		Customer Impact	Resolution Window
Customer Impact	Resolution Window	<p>Now: Experiencing Impact Future: Impact Imminent</p>	<p>(Now, Now) Demand Maintenance</p>
	Resolution Window	<p>(Future, Future) Proactive Maintenance</p>	<p>Now: ASAP Future: Months, Weeks</p>

Figure 8 - Proactive vs Demand Maintenance

Proactive maintenance is the ability to proactively detect and fix any potential issues on the network before a customer is impacted. For power supplies a simple but effective passive technique would be to do a standard workup on every power supply on a regular schedule, say annually. While this approach is generally good at keeping power supplies operational in the long term a more active approach can help address any potential issues in a more targeted fashion. This is where the telemetry-based models will be able to thrive. For example, by monitoring the charge and discharge curves during all events for each power supply, models can be built that attempt to catch any long-term degradations in power supply performance. This type of model can start to predict slow variations in the performance over many months of run time and help alert the field that certain power supplies may need to be visited sooner than others.

In a demand maintenance scenario, there is an active situation, and a model would need to predict the outcome of a given event to help the field teams allocate resources in real time. In this instance the data related to a specific event is heavily relied on in addition to any relevant historical data to predict and score potential outcomes of the current event. For example, say a severe weather event results in a loss of commercial power and the power supply needs to operate on battery backup to keep the plant and customers online. A predictive model in this case would need to estimate how long the batteries will run

until they will reach end of discharge. Based on the model outputs, the field teams can prioritize which power supplies may need a backup generator if the run time is expected to be less than the commercial power outage duration.

In either case, the output of the respective model will be consumed by field teams and prioritized and worked accordingly. Therefore, any additional information that can be supplied to the teams performing the work will help increase efficiency and add confidence to how the work will be prioritized. For this reason, the models that will be explored in this effort need to have some avenue for explainability of the given prediction. Examples of explainability not only include a level of confidence in each prediction but also elements like global and local feature importance to indicate what features the model believes to be most important in making a prediction.

Comcast is currently focusing on a demand maintenance use case using a machine learning based run time prediction model for power supplies operating on battery backup during commercial power outages. Comcast sees many potential avenues for using the aforementioned data sets and methodologies to enhance the outside plant power domain on many fronts, from long term budget planning and global resource allocations to using the power supply telemetry in other models related to access network root cause analysis.

5.2. Data Sets Used for Battery Runtime Prediction

For the goal of predicting how long the power supply can power the plant in the absence of commercial input power a machine learning model will need access to data that contains predictive power in this instance. It is apparent the telemetry related to the electrical circuitry discussion in Section 4.1 would be required to describe the physical principals occurring. In fact, the state-of-the-art modeling in the battery domain pretty much solely rely on the electrical data to make run time prediction, i.e., physics based and even more modern time series-based approaches.

However, as discussed in previous sections, Comcast has put in a significant amount of effort to create an accurate inventory of all the power supply assets which can provide extra enhancements to the modeling efforts. Items of particular interest are the battery manufacturer, age, type, install date and number of batteries in each power supply. This battery specific information will help enhance a predictive model using global patterns from various meta data fields related to the identity of the batteries and power supplies.

The final class of data under consideration as input to a machine learning model are features that can be engineered from the aforementioned data sources. The process of feature engineering has proven to be one of the most important aspects in developing high performing machine learning models. Features that are derived from the raw input data can produce significantly more accurate results than the raw features alone. While Comcast is still exploring the different approaches to feature engineering in this capacity, some immediately obvious features of interest for a run time prediction could be: information about the last discharge (test or outage) of a given power supply like time since, duration of, ending voltage, variance of individual battery voltages; other relevant statistics as well as historical information including number of discharge cycles in last n months, number of cold temperature cycles, time since last maintenance visit.

5.3. Machine Learning for Battery Runtime Prediction

The requirements for a run time prediction model are straightforward: when commercial input power is lost the model should predict how long the power supply can run on battery power before it can no longer power the plant. Figure 9 outlines the overall architecture of the desired model where the model takes

inputs from the aforementioned data sources and makes a run time prediction at the moment that the commercial power outage begins, as well as a confidence in the prediction and some form of explainability in what led the model to making that prediction. The 3 outputs combined will be the key aspect of how the field will prioritize and ultimately address predictions that indicate intervention will be needed prior to commercial power coming back online.

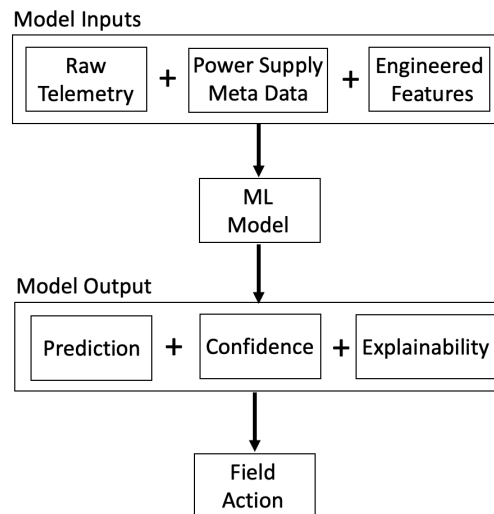

Figure 9 - Machine Learning Run Time Prediction Architecture

Given the variety of input features and the desire to have a form of model explainability, the initial machine learning architecture is a random forest (RF). Random forests have proven to excel in finding nonlinear patterns in data with limited initial assumptions and they also have the added benefit of the ability to add some sense of explainability. The results of the random forest model will be compared against a baseline physics-based model to determine the efficacy and potential enhancements over the baseline model that is implemented in production. More information on the baseline model can be found in Lin and Nispel (2022).

The random forest was trained on approximately 2500 examples where the power supplies operated on battery backup until it reached end of discharge and safely shuts downs. The features used in this initial model include the initial conditions of the physical properties at the beginning of the event and some meta data on battery information (type, age, count). The model then makes run time predictions on a test data set of 500 examples compared against the predictions from the baseline model. The results of the random forest are shown in Figure 10 where Figure 10a shows what features the model found most important during model training and Figure 10b shows the distribution of individual prediction errors in minutes compared to the baseline model.

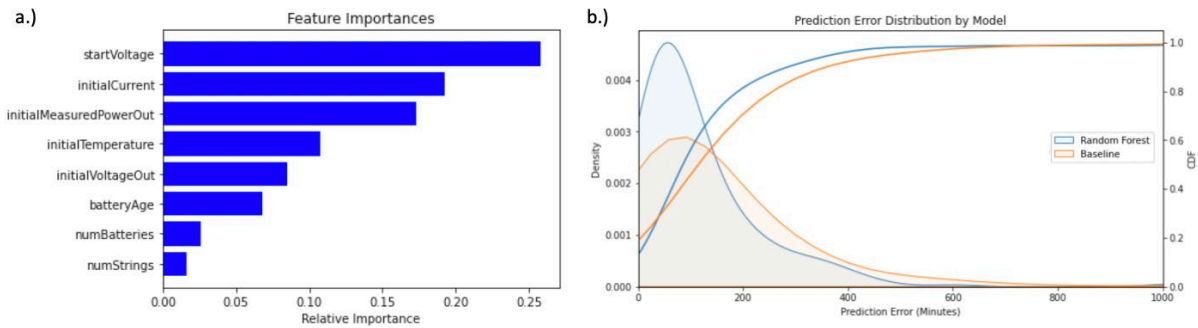

Figure 10 - Random Forest Performance. a.) Feature Importances, b.) Prediction Errors Compared to Baseline

As expected, the random forest model finds the most important features to be the average battery voltage in the first minutes of the event as well as the initial current draw and power consumption of the plant. These features combined essentially indicate the current capacity of batteries and how demanding it is to power the plant. The next group of features which are also found to be important are the ambient temperature at the beginning of the event, the output voltage of the power supply and the battery age in years. The model indicates that the number of batteries and the number of battery strings are marginally important for predicting the run time, likely due the majority of samples having a similar configuration. The random forest model tends to produce smaller errors compared to the physics-based baseline model as shown by the smaller tail in the distribution. As the model is enhanced with more features, the distribution of errors is expected to continue to shift lower indicating improved performance.

As discussed previously a random forest can also provide a measure of explainability for individual predictions. Figure 11 displays an example prediction from a particular sample. One can see that the output includes the prediction, confidence interval and a form of insight into the prediction. In this case the predicted run time was 270 minutes while the actual run time was 222 minutes. Along with the raw run time prediction, the 50% confidence interval is derived from the distribution of all the individual decision tree predictions. The width of this confidence interval gives an indication of how confident the model is in its raw prediction. Finally for a random forest, the raw prediction can be thought of as mean prediction plus a contribution from all the feature values for a particular sample. In the case below the model's mean prediction from training data is 239 minutes and features with blue bars increase the predicted duration over the mean and red decreases the predicted duration relative to the mean. In this case the most significant contribution is due to the battery age field, in this case the batteries are only 1 year old, so relatively new, which is why it is increasing the predicted duration. These types of supplementary information in addition to a run time prediction can help the field action and prioritize more efficiently.

Figure 11 - Example Random Forest Prediction of Battery Run Time

This section presented an initial proof of concept model using random forests for predicting the battery run time for power supplies which performs on par if not slightly better than the current physics-based prediction model. More advanced features are being developed which are expected to significantly improve the predictive accuracy over the current models. Comcast hopes to use the results of this model (once fully validated) over the long term as an input to a proactive maintenance model. For example, this model could be run periodically during nominal conditions (in the absence of a commercial outage) to determine if a power supply would perform to spec in the event of an outage and therefore open a window to perform proactive maintenance on suspect power supplies.

6. Conclusion

Spending time and resources to go deep into the power supply environment and build a product to support and improve network powering reliability has the potential for huge resource savings. We now have visibility into customer impact during power outages by correlating backend systems and building powerful a front-end interface. The new systems and interfaces combined with real time power supply telemetry open the doors for machine learning models to significantly enhance the proactive and demand maintenance capabilities of field teams. Machine learning models can not only provide more accurate predictions but also allow for explainability of given predictions to further support planning efforts. These initiatives are rooted in providing an amazing customer experience and having a more resilient power supply network is helping Comcast continue towards that goal.

Acknowledgements

The authors would like to acknowledge our colleagues that contributed significantly to the success of this effort. Chris D'Andrea was instrumental to setting up the big data pipelines and exploratory data analysis of the events in preparation for machine learning models. Ilana Weinstein developed the first iteration of the random forest model and is continuing to make enhancements.

Cory Thompson was a key resource during the development of PSNB, CE and Find My Power to ensure the functionality, benefits, and accuracy were developed and working in production as designed. Alex Falcon led the strategy and prioritization of the tool user story, minimum viable product outcome and change management in the field.

1. Introduction

In today's network, data plays a very important role in helping the operators gain more visibility into their networks to make their networks more reliable and more performant. For example, for Cable Modems (CMs), by calculating robust DOCSIS 3.1[®] profiles using Profile Management Application (PMA), impairments are mitigated, and the OFDM/OFDMA channel's performance is maximized. The profiles calculated by PMA can also be used to target low performing Cable Modems.

For other remote devices such as the Remote PHY Device (RPD) and Remote MAC Device (RMD), YANG modeling language is used in developing their north-bound data models and interfaces, which allows Google Remote Procedure Call (gRPC) Network Management Interface (gNMI) Streaming Telemetry to be easily implemented for advanced real-time device monitoring, largely reducing the probability and duration of service disruption events.

The complexity of data collection itself is also increasing as new devices support more sophisticated measurement functions. For instance, comparing to DOCSIS 3.0 data collection, collecting data from DOCSIS 3.1 CMs requires following much more complex procedures, increasing the amount of resources that the data collector uses and the number of states the data collector needs to track during the data collection process. Therefore, five years ago, CableLabs developed the first Common Collection Framework (CCF) [1],[4] as the initial work of diving into DOCSIS 3.1 data and shared its source code with the industry. The goal was to provide a reference implementation to converge the south-bound data collection interfaces, which are the interfaces for working with devices such as CMs and CMTSs, automate the data collection procedures and the handling of states, and provide standard interfaces to applications on the north-bound of the data collector. Its original goals have been achieved as it has provided operators and vendors a well-documented reference implementation and has served as the go-to data collector in many small-scale trials such as lab trials and limited field trials [2].

However, in the past field trials, CCF's performance wasn't impressive. When collecting data from around 8,000 DOCSIS 3.1 CMs, CCF spent more than 1 hour to complete the tasks even when it's multi-processed and was occupying 100 percent of the CPU resources on the data collection server. While acceptable for trials and development sandboxes, and could be scaled, it was not as scalable as we wanted.

Considering the scale of the whole network where some operators may have many millions of CMs deployed, and the increase in data collection frequency and the number of measurements, a better reference design of CCF is much desired.

In this paper, we use CCF as an example to identify and analyze potential performance bottlenecks and other pain points that could exist in today's network data collectors. And we share the experience of building the Next-Generation CCF (ng-CCF) to tackle each pain point and overcome scalability challenges. We hope the experience we share could provide references to others who are looking for such a data collection tool, on their way of building their own, or seeking for ways to improve the performance of their existing data collection tools. And we would like to share the new software, ng-CCF, with the cable industry as a reference design.

2. Background

2.1. The Complexity of DOCSIS 3.1 Data Collection

Since DOCSIS 3.1 technology was developed, multiple advanced measurements have been added to the CMs to collect and upload comprehensive physical layer metrics. Such data include:

1. CM downstream orthogonal frequency-division multiplexing (OFDM) symbol capture
2. CM downstream OFDM channel estimation coefficients
3. CM downstream OFDM constellation display
4. CM downstream OFDM receive modulation error ratio (RxMER) per subcarrier
5. CM downstream histogram
6. CM upstream orthogonal frequency-division multiple access (OFDMA) pre-equalization
7. CM upstream OFDMA pre-equalization last update
8. CM downstream OFDM forward error correction (FEC) stats
9. CM downstream spectrum analysis (full-band capture)

These test and query results provide rich information of the physical layer of the access network and are the fundamental requirements of advanced applications such as PMA. They require the data collector to perform multiple sequential simple network management protocol (SNMP) set steps on CMs for each test, and integration with trivial file transfer protocol (TFTP) servers for reading data uploaded by the devices.

On the CMTS side, DOCSIS 3.1 PNM results often require information that are challenging to gather or configure manually, such as the interface index numbers of OFDMA channels. These interface index numbers are often used as unique channel identifiers but are usually a reference number pre-determined by the CMTS and are offered through SNMP only, which suggests that an ideal data collector should automatically collect and prepare such intermediate information prior to data collection tasks that have dependencies on it.

The above aspects make data collection of these advanced PNM measurements significantly more sophisticated than data collection of traditional, common metrics where the collector usually queries the devices with one SNMP get or SNMP walk step for each data type and does not need to manage states.

As of today, this problem is solved as there are existing data collectors that are capable of handling the complexities, such as the first generation of CCF. But it has an impact that it encourages the data collectors to be highly concurrent for simplicity and scalability and to be microservice-like applications for the ease of scaling horizontally.

2.2. CCF Architecture

To allow flexible deployment, CCF version 2 was designed to consist of two microservices at a high-level: the Rest Agent (RA) and the Workflow Controller (WC). For the actual data collection tasks, modular “drivers” are introduced as plugin-like programs in CCF to provide extensibility and support rapid development. The RA provide hypertext transfer protocol (HTTP) APIs for the applications to use, and the WC handles the lifecycles and states of each individual data collection “driver” in parallel; the communication between RA and WC are done through

RESTful API calls. With this architecture, CCF can be scaled horizontally by applying multiplications of RA, WC, and coupled RA and WC instances.

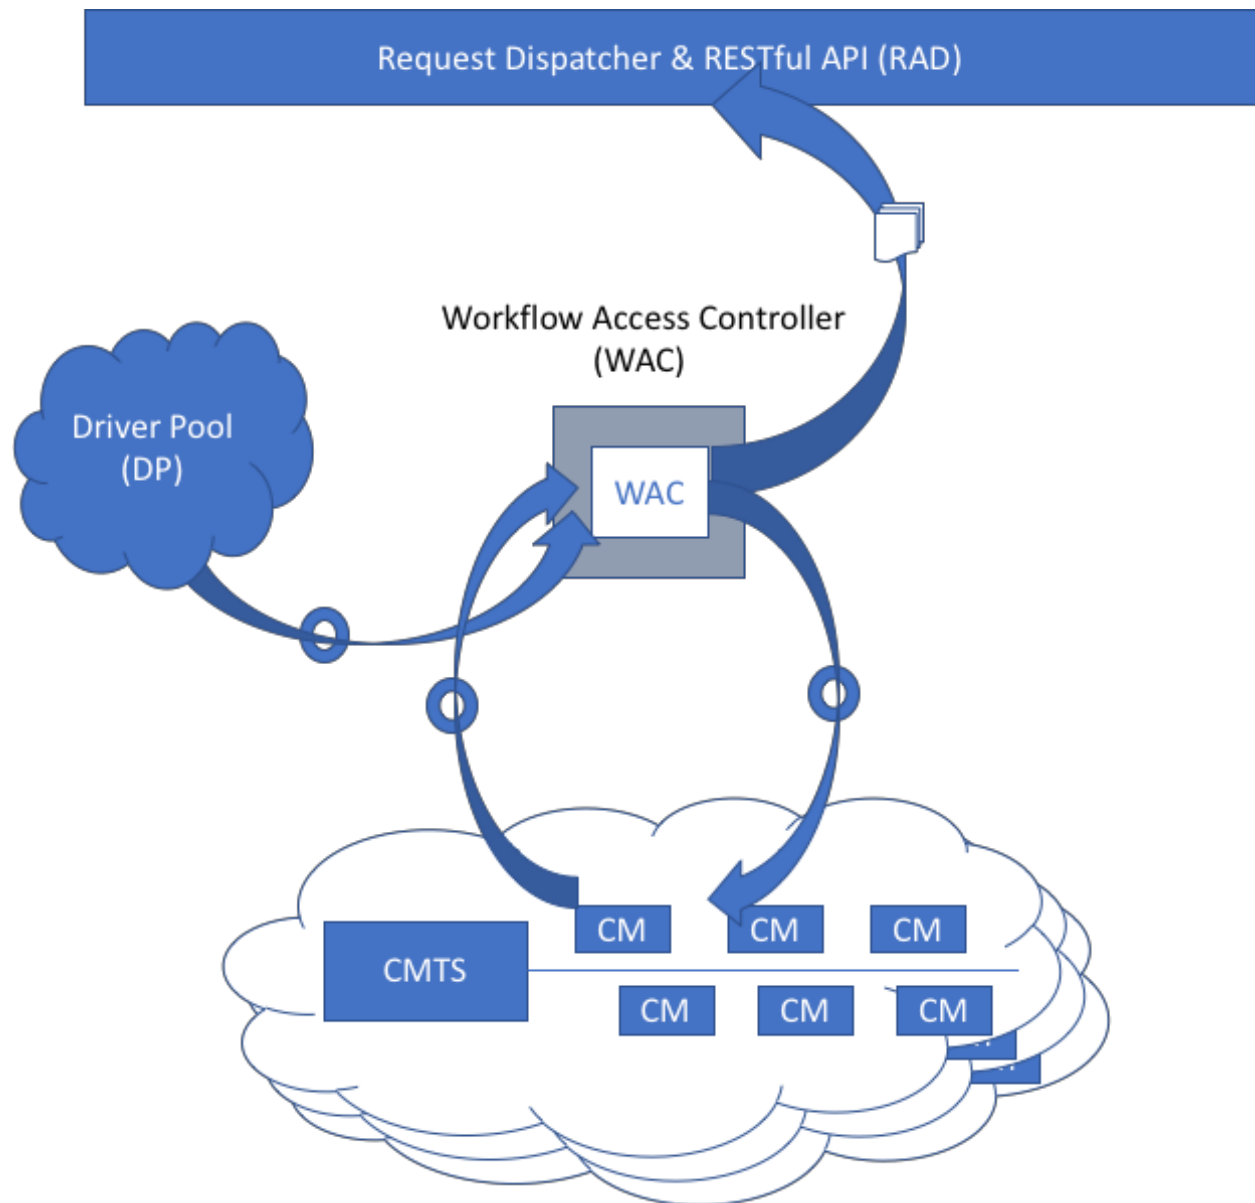

Figure 1 – CCF Architecture

CCF also integrates with external resources such as a local/remote TFTP server for gathering CM and CMTS uploaded PNM files, and an in-memory or filesystem datastore for storing data collection states and results. This architecture has been proven to provide benefits as applications can be easily built upon CCF's abstraction layer and its common APIs, while CCF scales the underlying interfacing activities with the network elements and provides protection to the devices' resources as the duplicated data collection is avoided and the same data is reused by different applications.

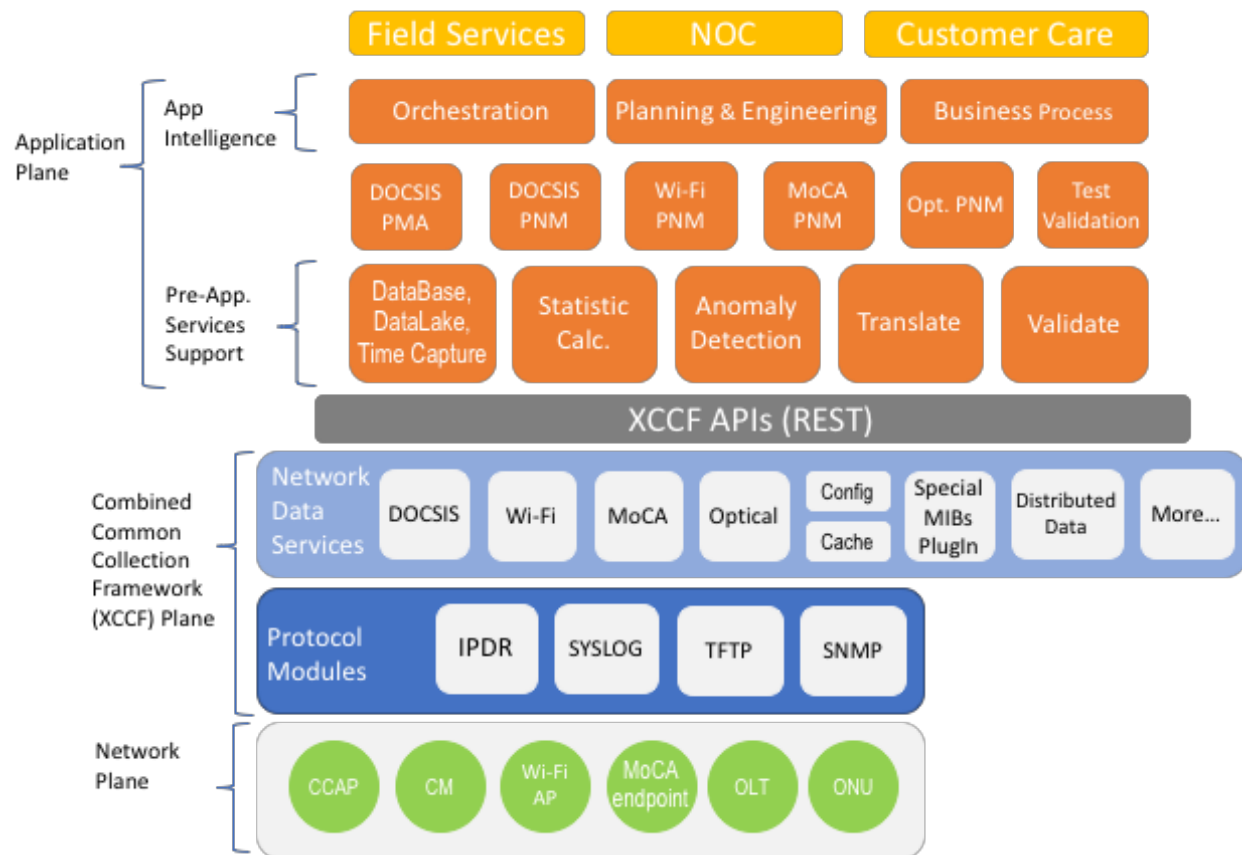

Figure 2 – CCF's role in today's data-driven system

Since the CCF is not intended to be coupled directly with a database, it's often deployed with a data collection scheduler to manage data collection cycles asynchronously, retrieve and decode the data collected by the CCF, and store the decoded data to a data service for applications to use. By doing this, the CCF only stores temporary data from the network and becomes straightforward to manage and maintain.

The drivers of the CCF perform individual data collection tasks that are designated for different devices and different measurements. The driver layer provides a simplified framework for users to easily add or modify data collection processes because the complexity of handling worker states, multiprocessing, and storing the data etc. are handled by the upper layers within the CCF. The drivers are also easy to develop and test as they can be tested individually from the command line.

2.3. CCF Technology Stack

The first two major versions of the CCF were developed in Python3. Python allowed us to quickly develop a working prototype and demonstrate the architecture and functionalities of the CCF. The HTTP APIs of the CCF were implemented with the Flask[9] Python library which provides a simple way to define and develop RESTful APIs. For communications between the

CCF's microservices, namely the RA and WC, the CCF uses Python3's requests [10] library to perform HTTP API calls.

For data storage, the CCF uses an in-memory cache to store temporary data as the default option. As an alternative, the CCF can use the Linux filesystem as a persistent data storage. This approach makes it easy to configure for a quick setup, but also provides persistent data storage options to the users.

For SNMP functionalities, the CCF uses a library python3-netsnmp which provides Python3 bindings for the NET-SNMP C library. Because of this, the SNMP dependencies are not portable and have to be pre-compiled for the system or compiled on the running system.

Last but not least, because DOCSIS 3.1 PNM measurements require the devices to upload the encoded measurement results to a TFTP server, the CCF integrates with an external TFTP server through the filesystem. This requirement allows the CCF to flexibly integrate with any TFTP server by pointing to their upload file directories. However, this method may have potential performance costs as the uploaded files are searched and identified using their filenames on the filesystem.

2.4. Parallelization

Because the CCF was designed to handle many data collection tasks in parallel for efficient data collection, multithreading/multiprocessing/concurrency is required in CCF's implementation. To simplify the driver layer, each driver runs single-threaded tasks, and multithreading/concurrency is handled by the WC.

Because Python has a Global Interpreter Lock (GIL) and it prevents the threads in Python from being "real" threads that use computing resources from multiple CPU cores, multiprocessing is needed for true parallelization that can use multiple cores from modern CPUs. However, in Python, this comes with significant CPU and memory overhead which prevents the CCF from efficiently handling a large number of concurrent data collection tasks using limited machine resources. The Python CCF implementation worked around this by starting a limited number of subprocesses and concurrently handling tasks assigned to each individual subprocess in event loops. This approach significantly helped improve the CCF's resource efficiency when it comes to parallelization. However, based on the trial results, this approach couldn't scale as optimally as desired, so higher efficiency is needed for handling a very large amount of concurrent data collection tasks.

3. Analysis of Pain Points and Challenges

During the past 5 years of using the CCF, helping operators and vendors configure and use the CCF, and building applications around the CCF at CableLabs, we've identified several pain points and challenges that are worth sharing and may be helpful for others to identify similar issues in their data collectors. These pain points and challenges are discussed in the following sections.

3.1. Estimated Data Collection Performance

The first challenge we identified is the CCF's ability to handle data collection for a large number of network devices. To understand the performance challenges at the high level, we can start with estimating the resource requirements of the data collector with the data collection requirements. An example of today's data collection requirements is:

1. the number of devices is around 10 million (DOCSIS 3.1 CMs)
2. a 6 hour data collection interval is required
3. 1 or 2 PNM data metrics are collected

However, in the foreseeable future, the following requirements may be asked given the increasing demand for field data, and the increasing number of deployed CMs, internet of things (IoT) devices, and more.

1. the number of devices is around 50 million
2. the desired data collection interval is 1 hour
3. multiple PNM data metrics are collected

With these future requirements, one can estimate that the data collection system will be required to collect data from around 56,000 devices every second on average. Based on the CCF's performance we observed in the previous field trials where 1 CCF instance spent more than 1 hour to collect Receive Modulation Error Ratio (RxMER) per subcarrier data from around 8,000 CMs, it infers that around 25,000 CCF instances will be required to handle this target workload to complete the data collection tasks within the required interval. This estimated number is overwhelmingly large, and it's asking for the computing power of a data center for a straightforward task of collecting data from network devices in parallel.

Although the CCF is considered a reference design, its performance is not ideal. Even if we consider a potential 10 to 100 times performance improvement for CCF, it will still ask for hundreds if not thousands of servers or virtual machines (VMs) on the cloud to be dedicated to data collection tasks. As the data collection demands continue to ramp up, it could only become more challenging for data collectors such as the CCF to catch up. Not only the resource consumption and cost of such data collection applications is significant, but it also increases the workload and complexity of managing such a large number of servers or VMs, not to mention databases.

3.2. API Performance

Another important aspect for microservice performance analysis is the application programming interface (API) performance. The CCF APIs are the interface for north-bound applications, these RESTful APIs are often called frequently during the data collection sessions as the north-bound applications may continuously check the data collection status of each individual measurement or each batch of measurements. This often results in the APIs being called thousands of times if not more, during the data collection sessions.

The baseline of how many API calls a performant microservice should handle varies by the context and requirements of the application. However, from the API performance testing results, the CCF could only handle up to 300 requests per second, which is significantly less than an ideal number.

The limited performance of the CCF's representational state transfer (REST) APIs can cause the north-bound applications to hang on measurement status checking requests. Low performance APIs could also cause high CPU or input/output (I/O) usage by the application. In CCF, the CPU usage spiked to 100% during the API performance test, which indicates that the CCF's HTTP APIs have a low CPU resource efficiency. When a large number of data collection tasks is being run, and when the north-bound application checks the measurement status frequently, the inefficient APIs can introduce issues to the entire data collection system by competing with other processes in the data collection application on CPU resources.

3.3. Data Store Performance

The CCF comes with an internal data store for saving and managing states, configurations, restricted amounts of collected data, and any other intermediate information. Usually, the CCF is configured to work with the following 2 types of data stores:

- filesystem
- in-memory

Because most web services are I/O bound, it's important to understand the CCF's data stores' performance and identify potential disadvantages of them.

Both data stores keep track of historical data and are implemented with in-memory file indexes. The use of in-memory file indexes makes data operations, such as insertion, deletion, and searching to be efficient. However, accumulating historical data increases the data operation costs over time. When working with hundreds of thousands of data entries, the performance impact is significant. This could further affect the CCF API's performance because slow data operations could shift the CCF APIs from CPU bound to I/O bound, further reducing the number of APIs the CCF can support during data collection sessions. We've observed this causing performance issues on long-running CCF instances in the lab setups and field trial setups.

Because the CCF's historical data storage has not showed value in multiple practical lab and field trials as the CCF has never been used as a primary data storage service itself, it is suggested that the fundamental design of the CCF's data store should be changed to offer improved data store performance. Removing historical data entries could be one of the improvements. In addition, compared to modern databases and caches, such as postgresql and redis, it doesn't provide benefits to implement the CCF's own data store while not taking advantages of the well-adopted data stores, especially when the performance differences are large. Replacing the CCF's data store with well-adopted, open-source databases or caches could further improve the CCF's data I/O and storage performance.

3.4. Configuration

Another pain point we've identified is that the configuration of the CCF requires knowledge that relates to Linux, software engineering, and networking. The prerequisite knowledge has blocked many users from setting up fresh CCF instances quickly without having to come to the developers of the CCF with questions. This situation also renders the CCF's setup documentations difficult to understand for users who are new to this field.

In addition, a typical set of the CCF's configuration files contain around 60 lines of configurations in JavaScript object notation (JSON) format, which further introduces work for the users to build a fresh CCF setup. Each of the decoupled microservices of the CCF (RA and WC) requires a separate configuration file, which adds difficulties and challenges to configuration and debugging for the users.

Considering the purpose and overall complexity of the CCF, the configuration and setup of it has been a major pain point since we shared the CCF with the industry and should be significantly simplified.

3.5. Deployment Challenges

The deployment challenges of the CCF are the collective outcome of the issues and pain points discussed in the previous sections. The performance of the CCF determines the size of the infrastructure that hosts CCF for large scale data collection. With CCF's performance being non-ideal, it's estimated to require a significant amount of computing resources for field data collection from millions of devices, which could add cost, maintenance work, and overall complexities to the data collection system.

In addition, the dependencies of the CCF are not compiled with the CCF's source code nor statically linked, making it complex to manage all of the CCF's dependencies in an internet-less deployment environment. Also, as the CCF is developed in Python and it depends on the NET-SNMP C library, the host of the CCF is required to run a complete Linux operating system which introduces overhead in CPU and memory usage for running the operating system (OS) and OS processes. When containerizing the CCF, this could result in large CCF images and heavy-weight containers.

Finally, the sophisticated CCF configuration process not only makes its instances difficult to set up, but also makes it harder to locate issues for the users to debug.

4. Resource Usage and Efficiency of Data Collection

As discussed in the previous sections, a high-performance, scalable, and easy to configure and deploy data collector is highly desirable to be the foundation of future network maintenance innovations and cost savings as the data collection demands continue to grow. The initial version of the CCF did not meet the requirements based on the pain points discussed in the previous sections. To build a data collector that could meet these requirements, we start from analyzing

the resource usage of common network data collection tasks, and then identify potential solutions. This analysis is discussed in the following sections.

4.1. Computation

First, understanding what computation tasks the data collector is responsible for during the data collection session is an important step to estimate how efficient the data collector could become.

During a network data collection session, the majority of computations happen remotely on the devices. For example, downstream RxMER per subcarrier data is measured, encoded, and uploaded by each CM. During the data collection session, the data collector is only responsible for facilitating and managing multithreaded tasks, sending requests to the devices, and waiting for the measurements to complete. An individual data collection task should use a negligible amount of CPU resource for most of the time during its lifecycle, which makes it promising that the data collector could become highly CPU efficient and could handle a very large number of data collection tasks at the same time if the concurrency is done efficiently.

Figure 3 shows the roughly measured procedure runtime of performing the DOCSIS 3.1 RxMER per subcarrier measurement and the DOCSIS 3.1 Spectrum Capture measurement.

Figure 3 – PNM procedure runtime measurement

We tracked how much time the measurement procedure actively spent for triggering the data collections and how much time it spent on idling and waiting for the collections to complete. In the results shown in Figure 3, the measurement procedure only spent negligible amount of time triggering the measurements compared to its idle time. During its idle time, the computing resources should be made available for other processes.

4.2. Networking

When collecting data from network devices, the data collector uses the server's network connection to query for data or trigger asynchronous measurements on the remote devices. For example, this procedure could involve sending user datagram protocol (UDP) packets (for SNMP) to CMs and CMTSSs. To provide a reference data point, the measured number of UDP (SNMP) packets sent to the Cable Modem during a downstream OFDM RxMER measurement session is shown in Table 1.

Table 1 – Downstream OFDM RxMER SNMP network load

Type	Number of Packets	Total Size	Direction
SNMP GET request	9	828 bytes	downstream
SNMP GET response	12	12,369 bytes	upstream
SNMP SET request	2	360 bytes	downstream

The SNMP GET responses transmitted the most amount of data because the data collector periodically checked the measurement status on the device by walking its measurement status MIBs. The entire measurement spent roughly 5 seconds to complete, which can add up quickly.

For RxMER measurement, the data collector performs SNMP SET on 6 MIBs; however, these SNMP SETs can be put into a single SNMP packet to reduce network loads. In the above measurement, the SNMP SETs were completed by sending 2 SNMP packets to the Cable Modem, resulting in 360 bytes of network usage.

If a data collection task uses longer time to complete, the number of SNMP GET request/response packets will increase as the data collector waits for longer durations while continuously sending SNMP GET requests to check the measurement status.

Based on the measured network load of downstream RxMER data collection from one CM, we can estimate the total network load for collecting downstream RxMER data for 1 million CMs at the same time, as shown in Table 2.

Table 2 – Network load estimations for concurrent data collection of OFDM RxMER from 1 million CMs (duration: 5 seconds)

Type	Traffic Rate	Direction
SNMP downstream network usage	1.9 Gbps	downstream
SNMP upstream network usage	19.79 Gbps	upstream

Both downstream and upstream traffic usage are high if the concurrent data collection for 1 million CMs is initiated from a single server.

In addition, packet per second (PPS) is another important statistic to estimate for network load as the servers and routers tend to be PPS bound instead of network throughput bound during large scale data collection. Table 3 shows the estimation of PPS loads.

Table 3 – PPS estimations for concurrent data collection of OFDM RxMER from 1 million CMs (duration: 5 seconds)

Type	PPS
SNMP downstream	2,200,000
SNMP upstream	2,400,000

The PPS numbers are also in the high range especially when we consider that most of the servers or VMs would be challenged to handle millions of packets per second. However, because the network usage is highly dependent on the protocols the data collector uses and the data collection procedures the devices implement, the data collector's network usage is primarily related to the deployment and scheduling scenarios. The data collector software may have limited room for improvement around network usage. Therefore, the above estimations are informative for the large-scale deployment of the data collector.

After the OFDM RxMER data collection from 1 million CMs completes, the CMs upload their measurement results to their designated TFTP servers. Assuming that the PNM files have an average size of 4 KB, 1 million CMs will upload roughly 4 GB of data to the TFTP server once the measurements complete. This would add additional network load to the system and transmit a considerably large number of packets per second through the network upstream as TFTP by default uses a packet size of 512 bytes. This calculation also leads to the analysis of data storage in the next section.

4.3. Data Collector's Storage

Data storage, or temporary data storage is another resource we should consider while building a large-scale data collection system. Assuming that a single instance of the data collector is responsible for data collection from 1 million devices, and each individual measurement data has an average size of 4 KB. This assumption results in 4 GB of storage usage per round and per measurement type during data collection.

For a high-performance data collector, an ideal design is to use dedicated long-term data stores for the collected data, and only cache the latest data collection and internal states within the data collector's temporary storage. This way, the performance of the data collector is less limited by I/O speeds as it would require less storage for data and could take advantage of in-memory caches for high-speed data access.

Ideal implementations of such caches could take advantage of open-source libraries such as BigCache for Golang, or take advantage of well-maintained and widely adopted caches such as Redis. Both are performant options and provide protections to the memory consumption through

configuring memory usage limits and aging off old data entries. And based on the above estimation of temporary data storage requirements, the data collector's cache can be fully implemented in memory while keeping the memory consumption within a reasonable range.

4.4. Data Collector's APIs

The data collector's APIs are responsible for the interactions between the data collector and northbound applications, schedulers, or the users etc. The APIs' performance is primarily determined by three factors:

- CPU processing speed
- Data I/O speed
- Network speed

The APIs' performance could be CPU bound if the API calls instantiate processing loads on the data collector which use significant amount of CPU resources. When the API calls require the data collector to communicate with the data store(s) very often, the performance of APIs could be I/O bound. And finally, when the data exchanges between the API callers and the data collector introduce significant network loads, the APIs' performance could be bound by the throughput of the network interface. The throughput of the network interface could be a limitation that's outside of the scope of the data collector's design considerations. However, minimizing the data payload sizes for API calls would be recommended. In addition, although the data collector could use high-speed in-memory caches as data stores, it's always recommended to reduce the number of direct data store hits from the API calls.

Ideally, for scalability, the data collector's APIs should not introduce high CPU loads and should focus on providing efficient connections to the data collector's data storage.

4.5. Parallelization

Highly optimized implementation of parallelization could drastically reduce the amount of resource the data collector uses for large-scale data collection tasks in deployment. In contrast, an inefficient implementation of parallelization could introduce a significant amount of memory overhead and CPU overhead. For example, the initial version of the CCF implements parallelization in Python using multiprocessing and event loops, which has the following shortcomings.

- High memory overhead introduced by multiprocessing in Python
- High CPU overhead introduced by increased Internal Procedure Calls (IPCs)
- Python as a programming language is not ideal in performance and efficiency

Fortunately, these shortcomings have already been addressed in modern programming languages such as Golang. With the Golang source code being compiled to native code and due to the goroutines and channels, highly efficient parallelization could be achieved for the data collector.

5. The Next-Generation CCF (ng-CCF)

Based on the analysis around resource usage and efficiency in the previous section, we now have clear objectives to develop the Next-Generation CCF (ng-CCF) [3] to resolve the pain points we've identified in the initial version of the CCF. The main objectives of the ng-CCF are to have

- High performance and efficient concurrency,
- High API performance,
- High data I/O performance,
- Efficient resource usage,
- Simplified installation and configurations,
- Simplified dependency management, and
- Implementation of all CCF's data collection functions and APIs for compatibility.

In addition to the main objectives, we also identify features that could be useful additions for ng-CCF:

- Having a built-in TFTP server
- Supporting the integration with remote/external TFTP servers
- Having a built-in data store
- Supporting the integration with external data stores
- Having a built-in SNMP client
- Supporting integration with gNMI targets/clients
- Cross-platform
- Horizontal and vertical scalability
- Small executables

Based on these objectives, we designed and developed the ng-CCF which has significant advantages and improvements compared to the initial versions of the CCF. The design, implementation, and performance analysis are discussed in the following sections.

5.1. Technology Stack

Referring to the analysis around resource usage and efficiency in the previous section, we decided to start the development of the Next-Generation CCF from completely rewriting the software in Golang as many objectives would be impossible to achieve if we build the ng-CCF based on the source code of the CCF which is in Python. This decision has a trade-off that the entire source code of the data collector needs to be rewritten, but it allows us to take advantage of Golang's ability to handle concurrency in a highly efficient way. This choice also allows the source of the ng-CCF to be compiled into a single statically linked executable which provides benefits to installation, configuration, and deployment of the data collector.

To implement the HTTP APIs for the ng-CCF, we chose to use Golang's Fiber [6] library instead of the built-in HTTP package because the Fiber library is built on top of Golang's Fasthttp [11]

package which provides superior API performance as shown in the benchmark results in Figure 4.

Figure 4 – gofiber’s API benchmark (requests per second)
<https://docs.gofiber.io/extra/benchmarks>

For data storage, we chose to define an interface for the ng-CCF’s data stores and implemented the interface with a built-in cache built on top of Golang’s BigCache library and a Redis client to communicate with the external Redis cache as 2 supported options. This interface can be conveniently implemented for the ng-CCF to integrate with any other types of data stores such as MongoDB or PostgreSQL. The built-in cache allows the users to start the ng-CCF without relying on external services, whereas the Redis cache allows multiple ng-CCF instances to share the same remote cache and make the cache accessible to be backed up, duplicated, or persisted. The Redis cache option is particularly useful in deployment because it largely reduces each ng-CCF instance’s memory usage and allows the users to host and manage the caches on dedicated servers. The built-in cache’s speed is bound by the time complexity of the in-memory data structure and the memory speed. And the Redis cache’s speed is bound by the speed of Redis, memory speed, Redis API call’s speed, and potentially network speed if the cache is remote.

For SNMP, we decided to not rely on OS dependencies such as NET-SNMP and chose an SNMP library gosnmp [7] which is fully implemented in Golang to make the executable portable. This SNMP library supports all SNMP functionalities the data collector needs, such as GET, SET, WALK, BULKWALK, and SNMPv3. Using this well-integrated library also allows the data collector to provide very detailed debugging messages for SNMP down to a per packet payload

level, which could be helpful for debugging the system when the devices don't respond as expected.

We also decided to give the ng-CCF a built-in TFTP server so that it becomes a completely self-contained software solution when there's need for a quick setup and trial. In the initial CCF, the TFTP server is an OS dependency and is integrated with the CCF through the Linux filesystem. In the ng-CCF, the TFTP server is implemented with Golang's tftp [8] library which allows the ng-CCF to process all uploaded files into memory without relying on system calls and using the slower hard drive.

In addition to the built-in TFTP server, the ng-CCF has TFTP, SFTP, and HTTP clients to handle different types of integrations with external TFTP, SFTP, and HTTP servers. For example, the ng-CCF can integrate with remote or external TFTP servers using its TFTP client. This ability could be particularly useful if there are already TFTP servers in deployment. Some CMTSs may implement an SFTP server for the applications to download PNM measurements instead of uploading the measurement results to a TFTP server. The SFTP client in the ng-CCF allows it to automatically switch between the TFTP client and the SFTP client based on the detected CMTS types. For integration with external HTTP services such as Prometheus, the ng-CCF driver can leverage its built-in HTTP client.

Finally, for concurrency, although Golang's goroutines are used in many submodules in the ng-CCF, we decided to employ Golang's "ant" package to build the primary data collection task pool to automatically manage task lifecycles and potentially achieve higher performance compared to using unlimited goroutines.

5.2. Architecture

The architecture of the ng-CCF is largely simplified compared to the initial version of the CCF. In the ng-CCF, there's no longer separate microservices that introduce communication overhead. To reduce the amount of computation, the architecture tries to reduce the amount of CPU processing and data store access when possible. The architecture drawing is shown in Figure 5.

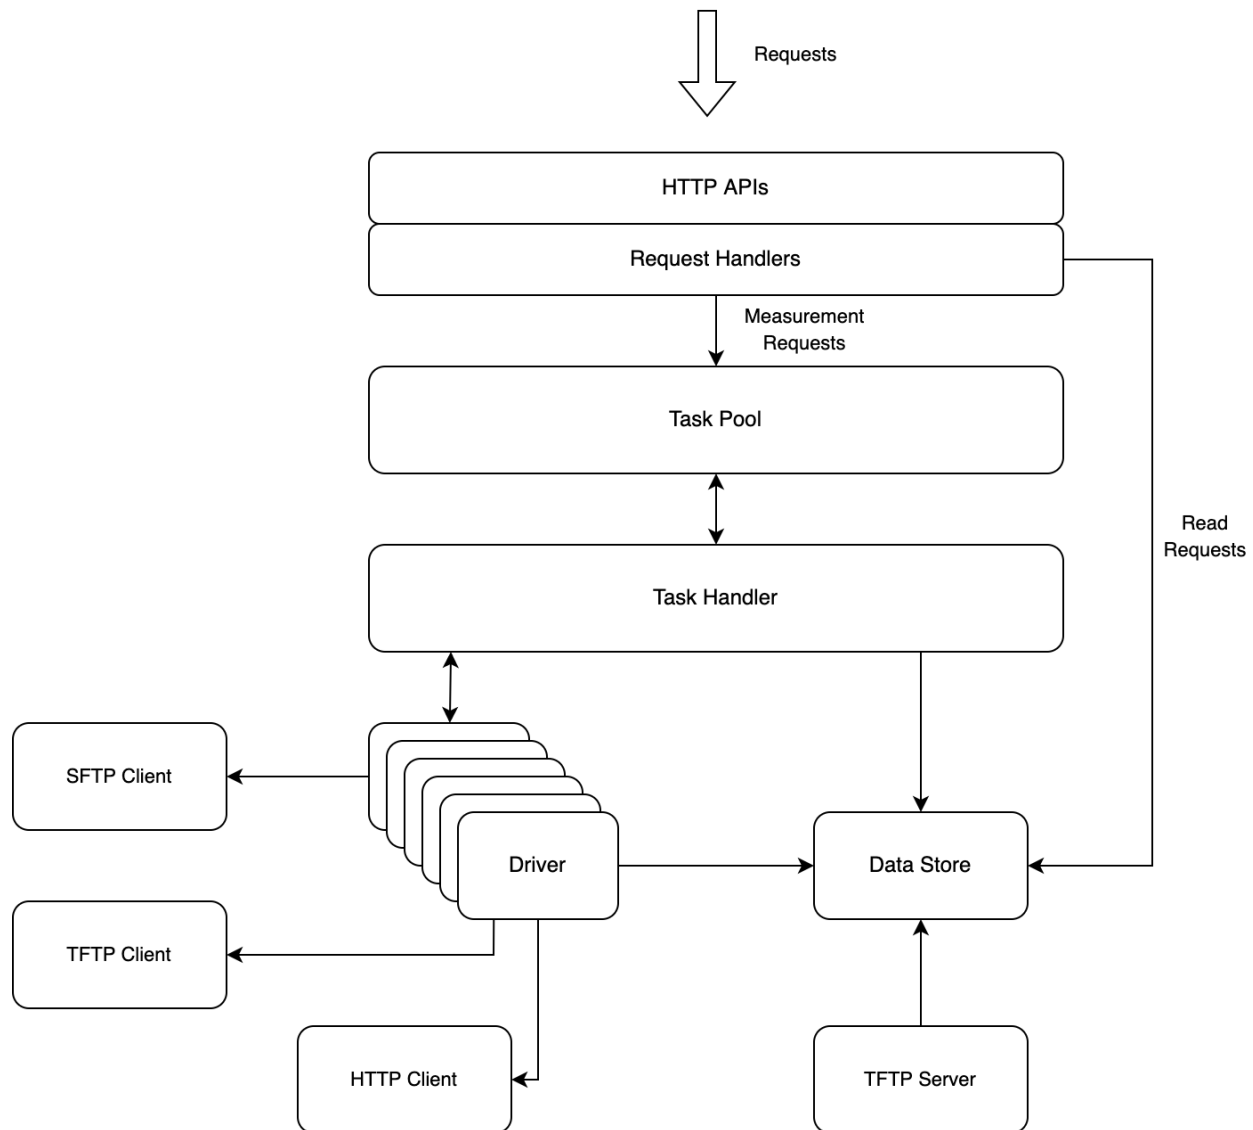

Figure 5 – ng-CCF's architecture

The ng-CCF's data store keeps the latest temporary data and serves as the state storage for data collection tasks and the storage for the TFTP server. The data store operations are thread-safe which makes the data store ideal for the goroutines to pass states and data blobs in addition to using Golang channels for local messaging between goroutines.

When a read request comes to the ng-CCF, the request handlers directly connect the request to the data store for the data request. Because the ng-CCF is designed to use in-memory caches, there's currently no need for an additional caching layer before the data store.

When a data collection and measurement request come to the ng-CCF, the request handlers create the description objects of the tasks according to the request and pass the task description objects to the task pool. The task pool then instantiates an individual, concurrent task handler for this specific task, and proceeds with executing the task and sub-tasks and managing their life

cycles. When the data collection tasks complete, the resulting data are collected from the drivers by the task handler and then stored into the data store along with the updates task states for future read requests.

In this architecture, the task pool handles the majority of the concurrency in the data collector, and the task handler manages sequential and parallel execution of individual sub-tasks and their life cycles, making the software easy to manage and maintain.

Concurrency can also be implemented within the drivers to boost data collection performance. For example, a driver can concurrently send SNMP GET and WALK requests to different MIBs for faster data collection. This is optional for the implementation of the ng-CCF drivers, and it is local to the drivers, which means it's isolated and modular and doesn't increase the overall complexity of ng-CCF's concurrency and internal messaging.

This architecture also makes it easy for testing each individual data collection drivers and testing the API handlers with mock drivers. The modular design makes the ng-CCF easy to maintain and update during long-term development and deployment.

5.3. Data Collection Functions

To make the ng-CCF compatible with existing applications that depend on the CCF and also improve its data collection capabilities, a wide variety of data collection drivers have been developed for the ng-CCF. The drivers provide functions to collect DOCSIS 3.1 specific data elements as well as DOCSIS 3.0 data elements. They also provide data collection functions from external services such as Prometheus, which can be used for integration with gNMI collectors. The current list of ng-CCF drivers is shown in Table 4.

Because the drivers are similar to plugins in the ng-CCF, new data collection functions can be conveniently added to the ng-CCF with concurrency, data storage, and API calls automatically handled.

Table 4 – ng-CCF data collection functions

Type	Description
CM OFDM downstream RxMER	A DOCSIS 3.1 specific data element that provides per subcarrier RxMER data of OFDM channels used by the CM
CM OFDM channel estimation coefficients	A DOCSIS 3.1 specific data element that provides per subcarrier channel estimation data of OFDM channels used by the CM
CM OFDM constellation diagram	A DOCSIS 3.1 specific data element that provides constellation diagram data of OFDM channels used by the CM
CM downstream histogram	A DOCSIS 3.1 specific data element that provides downstream power histogram data measured by the CM

Type	Description
CM OFDMA upstream pre-equalization	A DOCSIS 3.1 specific data element that provides the upstream OFDMA pre-equalization coefficients that the CM is using
CM OFDMA upstream pre-equalization last change	A DOCSIS 3.1 specific data element that provides the last adjustments to the OFDMA pre-equalization coefficients that the CM is using
CM downstream OFDM FEC summary	A DOCSIS 3.1 specific data element that provides a OFDM FEC summary for each individual modulation profile over a 10-minute or 24-hour time frame
CM upstream OFDMA RxMER	A DOCSIS 3.1 specific data element that provides per subcarrier RxMER data of OFDMA channels used by the CM
CM downstream spectrum capture	This measurement provides the full-band capture data of the CM's downstream spectrum
CM SC-QAM upstream pre-equalization	This measurement provides the upstream SC-QAM pre-equalization coefficients that the CM is using
CM capabilities	Collect and decode CM capability requests and responses per TLV 5 defined in the DOCSIS 4.0 MULPI specification
CM events	Collect CM device event logs, event times, and event IDs
CM OFDM channel topology	Discover the OFDM channel based logical topology
CM OFDMA channel topology	Discover the OFDMA channel based logical topology
Prometheus data	Collect any data from Prometheus APIs

5.4. Packaging

The source code of the ng-CCF is written in Golang compiled into a statically linked executable which contains all required dependencies, and no other software packaging process is required. This packaging allows the ng-CCF to run inside of a “scratch” docker container which is an empty container that has minimal storage overhead. The size of the ng-CCF’s “scratch” image is only negligibly larger than the executable’s size, making it extremely resource efficient in cloud deployment scenarios.

The original size of the ng-CCF executable is 15 MB. However, optionally, it’s possible to further reduce its size by using an executable packer such as Ultimate Packet for eXcutables (UPX). We used UPX to compress the ng-CCF’s executable, which doesn’t affect the requirements on the running system and doesn’t add any dependencies, yet it reduced the size of the ng-CCF’s executable from 15 MB to 3.7 MB which is only 24.67% of its original size.

Having such a compact executable could have benefits in deployment scenarios. Although it won't optimize memory consumption because the executable is auto-decompressed before running, it significantly reduces ng-CCF's storage footprint and potentially results in more efficient network usage during software updates, especially if we consider future development and extensions being applied to the ng-CCF where the executable size may continue to increase to hundreds of megabytes.

5.5. Configuration

Configuration challenges are a major pain point of the initial version of the CCF. Therefore, simplifying the ng-CCF's configuration is one of the high priority focuses of its development initiative.

The initial version of the CCF typically requires a certain level of knowledge in software engineering, Linux, and network engineering, and it requires 3 separate configuration files that consist of around 60 lines of JSON for the users to work through to get a minimal setup.

In the ng-CCF, because of the addition of a built-in TFTP server and a built-in data store, with default parameters, the user can start the ng-CCF using only one command and specifying only one command line parameter. The integration of ng-CCF and external TFTP servers and data stores is also largely simplified. For example, specifying an external Redis data store only requires three additional command line parameters, and replacing the built-in TFTP server with an external TFTP server only requires two additional fields in the API request payload.

From the trial experiences of the ng-CCF after its release, we've heard significantly less confusion regarding the setup and configuration of the data collector. The users have found it intuitive to start the data collector with one command, without having to work with the source code, installing dependencies and OS dependencies on offline machines, configuring microservices and debugging potential connectivity issues and package compatibility issues. The configuration improvement is an overall significant user experience improvement, and it largely reduces the friction of deployment of the ng-CCF as the data collector.

5.6. Scaling

Because the ng-CCF has a highly efficient concurrency implementation and one instance of the ng-CCF can fully utilize the computing resources on the host machine, it can be flexibly scaled vertically and horizontally depending on the use case needs.

Scaling the ng-CCF vertically requires computing resource upgrades on the host machine. Depending on the data collection requirements such as the number of devices, the number of measurement types, and the frequency of data collection, upgrading the computing resource on the host machine may not be viable if the data collection requirements exceed a limit. However, because of the ng-CCF's capabilities, this limit could be very high on a server with reasonable computing power. Therefore, the ng-CCF may have the potential to support large scale data collection using the computing power of a single server. The details and reference performance numbers are described in the following performance testing section.

Scaling the ng-CCF horizontally could be a more reasonable approach to consider in deployment scenarios. It's possible to balance the data collection loads by assigning dedicated ng-CCF instances to each CMTS's data collection needs. However, since the ng-CCF instances can share remote Redis caches for data storage and state storage, a better approach could be flexibly managing the number of running ng-CCF instances or containers based on the immediate data collection needs, and load balance by routing the ng-CCF's API calls to the ng-CCF instance pool. This approach draws an overall simpler and more flexible deployment system and can more efficiently utilize the computing resources as the granularity of load balancing becomes a single API call. Note that, in this approach, the Redis caches may need to be scaled to satisfy high volumes of access requests. An example drawing of such a deployment architecture is shown in Figure 6.

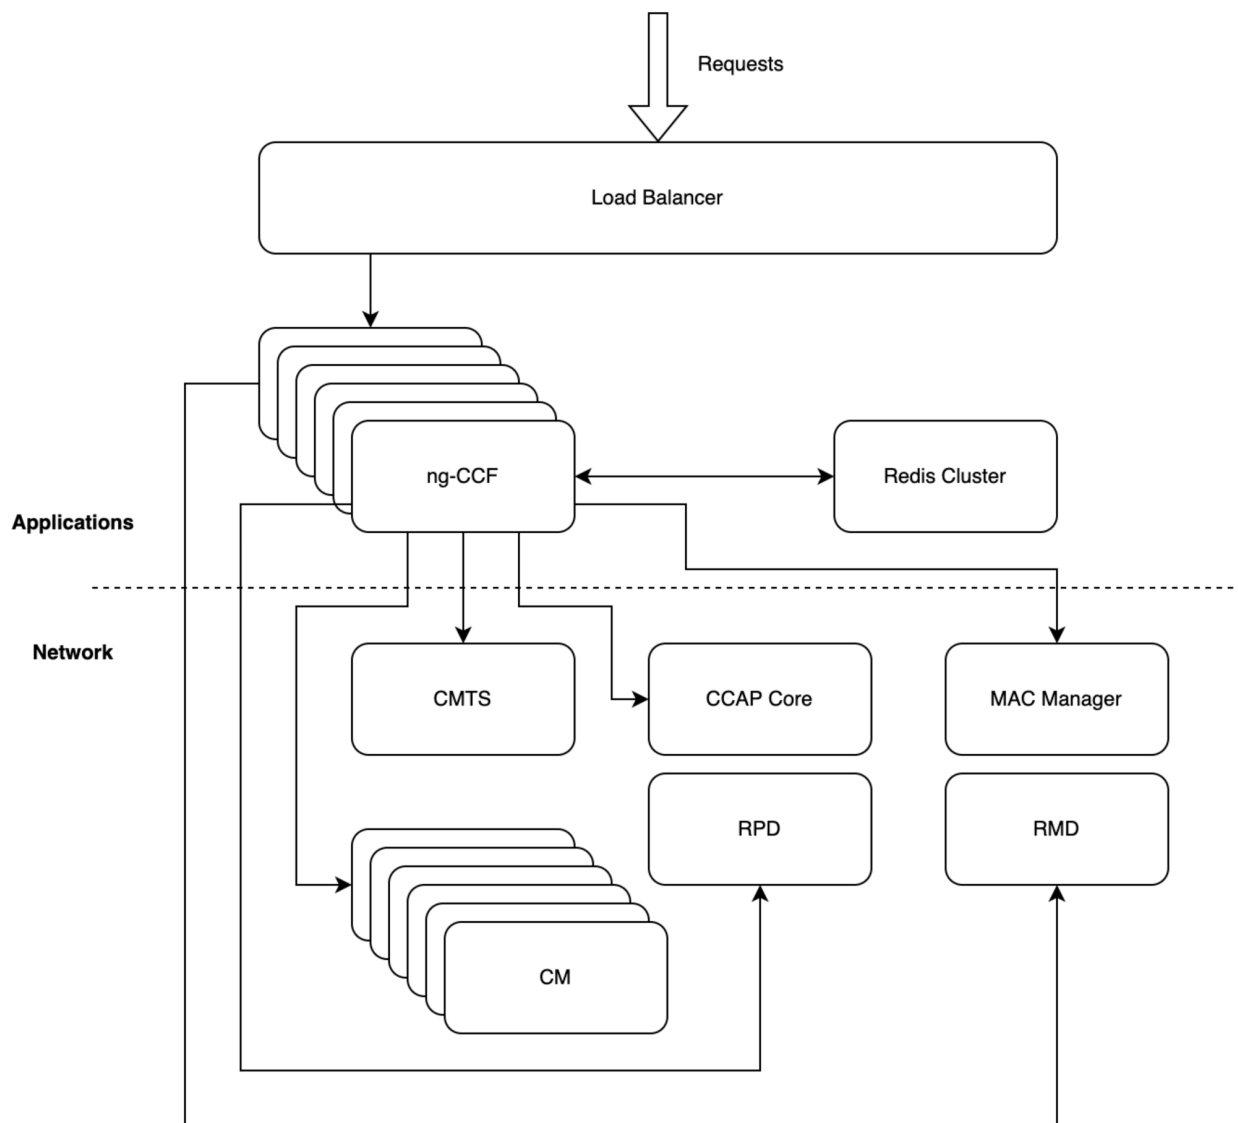

Figure 6 – ng-CCF deployment architecture (horizontal scaling)

5.7. Performance Testing

The performance testing of the ng-CCF focuses on three aspects:

- API calls handled per second,
- API call latency, and
- Mock data collection performance.

The number of API calls handled per second is an indicator of the API performance of the ng-CCF. And the API call latency is the indicator of the API responsiveness of the ng-CCF, which is another aspect of the ng-CCF's API performance. And finally, the mock data collection test uses a mock driver to simulate large scale data collection scenarios and measures the ng-CCF's data collection performance with a reasonable number of concurrent tasks and also pushes the ng-CCF to the limit to see how many concurrent data collection tasks a single ng-CCF instance could handle on a powerful server.

The tests were conducted on an Ubuntu 20.04 VM that's running on a 2021 Macbook Pro with 4 cores of the Apple M1 Pro processor and 8 GB of random-access memory (RAM). We used an open-source HTTP benchmarking tool, called wrk [5] (<https://github.com/wg/wrk>), running on a separate machine to start 12 threads with 400 concurrent connections to send API requests to both the CCF and the ng-CCF instances as fast as possible for 30 seconds. The measurement results are shown in Figure 7, Figure 8, and Figure 9.

12 threads, 400 concurrent connections, 30 second test duration

Figure 7 – ng-CCF and CCF's API performance (requests per second)

The initial version of the CCF only could handle 269.78 requests per second whereas the ng-CCF could handle more than 300,000 API requests per second, thanks to the Apple M1 Pro's high bandwidth memory. On an ordinary VM assigned with 4 heavily shared Xeon cores and a memory with lower bandwidth, the ng-CCF still was able to handle more than 110,000 API requests per second.

12 threads, 400 concurrent connections, 30 second test duration

Figure 8 – ng-CCF and CCF's API performance (request latency)

On the API latency measurement for the CCF and the ng-CCF, the difference is significant. The initial version of the CCF averaged more than 500 ms on API responses due to its usage of the Linux filesystem as its data store, and its API response latency peaked at almost 2 seconds. Whereas the ng-CCF averaged 7.4 ms of API response time and peaked at 137.46 ms which is possibly affected by garbage collection in Golang.

Mock CMs are designed to take 10 seconds to complete the mock PNM measurement. Hence the baseline of collection time is 10 seconds.

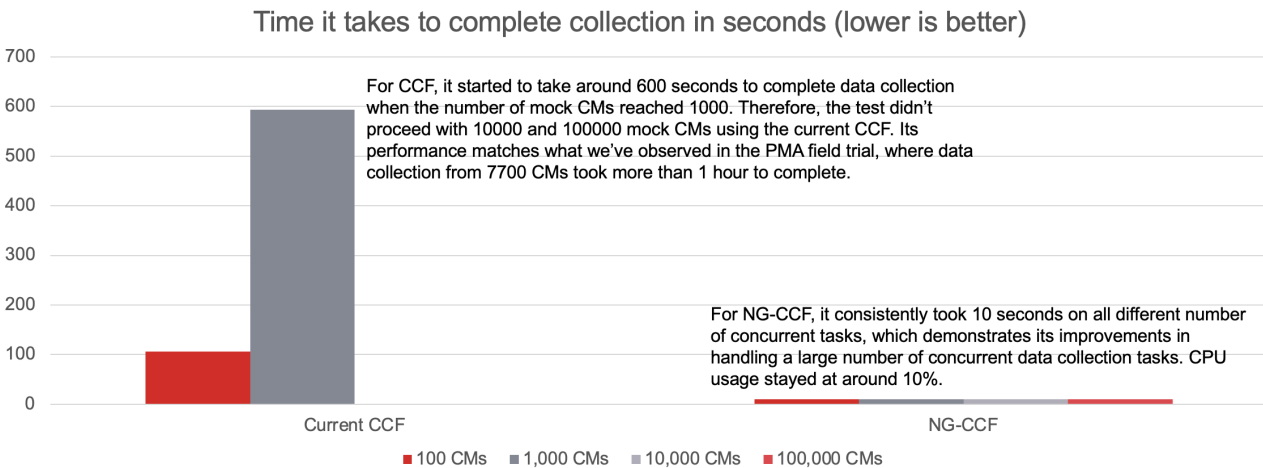

Figure 9 – ng-CCF and CCF's data collection performance

During the simulated data collection testing, we design each measurement to take 10 seconds to complete, most of the time used by the driver waiting for the device to complete the measurement. The initial version of the CCF matched its performance we observed during our first PMA field trial where it took more than an hour to complete measurement from about 7700 CMs. Meanwhile, the ng-CCF effortlessly handled 100,000 concurrent measurements while using only 10% of the 4 core CPU resource, and all tasks completed after the same 10 second wait time.

To find the limit of the ng-CCF for large scale data collection and estimate its requirements for vertical scaling, we conducted another test where one instance of the ng-CCF was hosted on a powerful workstation that has 256 GB of RAM and a 16-core Intel® Xeon® processor (Xeon® Gold 5218 CPU @ 2.30 GHz).

We let the ng-CCF run 0.5 million, 1 million, 2 million, 4 million, 8 million, and 10 million concurrent tasks during the test. Considering heap allocation bottlenecks, each task was designed to run 180 seconds to allow the ng-CCF to complete the allocation of large numbers of tasks.

Figure 10 – ng-CCF's CPU usage (16-core) with different numbers of tasks

Figure 11 – ng-CCF's memory consumption with different numbers of tasks

When the number of tasks surpassed 2 million, we started to observe slowdowns in the ng-CCF's ability to instantiate new tasks quickly. This is likely bound by heap allocation speed as the CPU usage was still low.

When the number of tasks reached 10 million, although the ng-CCF still didn't fully utilize the processing power of 16 CPU cores, the heap allocation delay became significant enough that 10

million was the maximum number of tasks the ng-CCF could allocate during a 180 second window.

When handling 1 million concurrent tasks, the ng-CCF used 9.75% of the 16-core CPU, and used 5.8 GB of RAM, making it promising to handle large scale data collection using only a few servers. When starting 10 million concurrent tasks on the ng-CCF, it used 66.41% of the 16-core CPU and used 68.8 GB of RAM at peak. The heap memory allocation speed could be a limiting factor for vertically scaling the ng-CCF any further. Therefore, it would be recommended to limit the number of concurrent tasks on each ng-CCF instance to less than 10 million.

6. Conclusion

In this paper, we shared the experience of how we identified the pain points and challenges in an existing data collector and analyzed the resource usage for data collection and potential approaches to improve the efficiency of a data collector. And we shared the details of how we designed and developed the Next-Generation Common Collection Framework (ng-CCF) to overcome the issues we've identified and demonstrated improvements in many different aspects such as improved performance and scalability, small and easily deployable executable, enhanced data collection functionalities, and significantly simplified configuration and setup process.

We hope to share our experience with the industry to help others target potential improvements that could be done in their data collectors. And we hope to share the ng-CCF's source code with the industry to help others take advantage of what we've developed. As the data collection continues to grow, a scalable, performant, and reliable data collector is highly desirable to be the foundation of future network maintenance innovations and cost savings.

Abbreviations

API	application programming interface
Bps	bits per second
CCAP	converged cable access platform
CCF	common collection framework
CM	cable modem
CMTS	cable modem termination system
FEC	forward error correction
Gbps	gigabits per second
gNMI	gRPC network management interface
gRPC	Google remote procedure call
HTTP	hypertext transfer protocol
Hz	hertz
JSON	JavaScript object notation
MER	modulation error ratio
OFDM	orthogonal frequency-division multiplexing
OFDMA	orthogonal frequency-division multiple access

1. Introduction

1.1. General Overview of IoT

A new phenomenon is sweeping our lives, involving both small and large devices communicating with each other, and providing rich information that enhances how we live, work, and play. We can tell from miles away if our home is at the right temperature if the porch light is on or if the front door is locked. This is possible because thermostats, bulbs, and door locks can communicate their status, receive commands and act on them. These devices employ a range of network protocols to communicate over the Internet. By using the Internet as the medium, devices can be placed in geographically dispersed locations and still provide near real-time status or environmental reading.

However, this type of convenience comes with a price i.e., how can IoT devices be adequately secured given their constrained nature? How can they fend for themselves in a hostile network environment? These devices are often inexpensive, easy to use, and quick to set up. However, they lack the proper hardware and software security needed to ensure data privacy and integrity.

1.2. Lack of Interoperability - Lack of Open Standards

Lack of standards is manifested in consumer frustration, manufacturer headaches and service provider anxiety. OEM's need to support multiple "stacks" and service providers need to build complex integration models to support thermostats from five different manufacturers. The high-level diagram below (Figure 1.) shows current silos and industry fragmentation in IoT landscape.

The lack of widely adopted IoT application standards is a significant barrier to mass adoption of IoT devices, especially by consumers. The current wall garden approach not only stymies innovation by developers but also acceptance by consumers. The lack of standard results in increased investment by developers because they must develop for multiple application stacks. Similarly, consumers have to invest in new devices every time they switch to a new IoT ecosystem because their current investment in devices will be incompatible.

The disparate protocols create an IoT quilt consisting of a patchwork of communication standards and device models leaving devices unable to interact with each other based on which part of the quilt they belong.

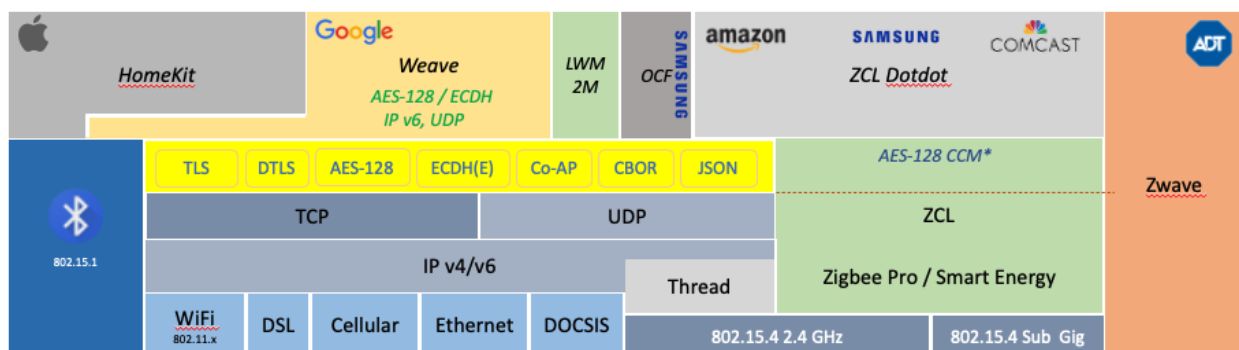

Figure 1: IoT Quilt

What industry needs is a cooperative effort that leads to a widely adopted standard with input from a wide swath of the IoT industry. This is exactly what Matter is. It grew from a need to create a new standard that

brings the best components from prevailing walled gardens in an open effort that guarantees participation from willing participants in drafting the new standard that will have wide acceptability from the launch.

1.3. Consumer Branding/Labeling/Proximal Interoperability

All the industry cooperation in the world will make little difference to the current smart home landscape if consumers do not literally buy in. The Connectivity Standards Alliance, CSA - the standards development organization (SDO) that maintains Matter - recognizes this and has developed marketing materials and a consumer-facing brand to help drive adoption. Starting this fall, consumers will be able to purchase products that contain the Matter logo on their packaging. This logo will signal to consumers that the device they purchase is guaranteed to work with their Matter applications. In the way that users currently associate the Wi-Fi logo with interoperable wireless connectivity, the Matter logo will be associated with guaranteed smart home interoperability.

Manufacturers can only display the Matter logo on their packaging if their devices have been certified. The certification process is run by CSA authorized test labs and is designed to guarantee conformance to the Matter specification. This process is analogous to devices being certified for Wi-Fi, Zigbee, Bluetooth, and many other protocols. With certification, a user can feel confident that the device they purchase will work seamlessly with their Matter application, access point, and other Matter devices. Certification is available to all CSA member companies.

1.4. Lack of Security/Uniform Standard for Security

IoT devices provide a fertile ground for hacking leading to either privacy violation, loss of service or dangerous situations. Two security researchers successfully commandeered a Jeep Cherokee using remote exploit (Greenberg, 2015). Incidents like these demonstrate that today's IoT needs to be empowered so that they can protect themselves in a hostile environment. In September 2016, the website of computer security consultant Brian Krebs was hit with 620 Gbps of traffic emanating from hijacked IoT devices, "many orders of magnitude more traffic than is typically needed to knock most sites offline" Koliass (2017, p.81). This attack exploited IoT devices such as cameras and DVRs that had default passwords to effectively turn thousands of these devices into a bot army. These devices were then used to launch a massive denial of service attack on DNS service provider Dyn, effectively causing an Internet blackout. This malware is dubbed "Mirai". One analysis of the attack showed that the Mirai malware had infected 49,657 unique devices, which included mostly IP based cameras, but also DVRs and routers (Herzberg, Bekerman, & Zeitman, 2016).

Such vulnerabilities are compounded by a lack of common IoT application standards that are created with security and privacy as one of the core principles. With disparate security implementations, IoT devices suffer from multiple possible attack vectors due to different security layers and their implementations.

1.5. Introduction to Matter

Matter is a next gen IoT application protocol designed from the ground up by IoT practitioners of the world. It is designed so that constrained IoT devices, controllers and Apps can interoperate, providing consumers with a rich experience that IoT devices offer. It also provides a standardized, compatible operating environment on which to build amazing experiences for developers. Similarly, retailers will benefit from simplified selling experience. Rather than invent underlying primitives, Matter uses proven technology and contributions from Amazon, Apple, Comcast, Google, Silicon Labs, Samsung, and others who have contributed resources in following key areas.

- Canonical Protocol Specifications
- Standardized SDK that implements the canonical Specification
- Test harness that checks SDK for compliance with the canonical Specification

Matter provides a unified out-of-box commissioning and pairing mechanism that ensures onboarding interoperability and compatibility between IoT devices made by a myriad of manufacturers. In addition to commissioning, included in the Matter stack are following features.

- Flexible device and service discovery
- A certificate-based device attestation process
- A secure end to end mutual authentication and encryption that provides security, privacy, and integrity of inter device communications.
- A unified and flexible interaction layer between data model and routing layer
- A unified data model with a wide range of device types defined

The following diagram depicts different layers of Matter protocol.

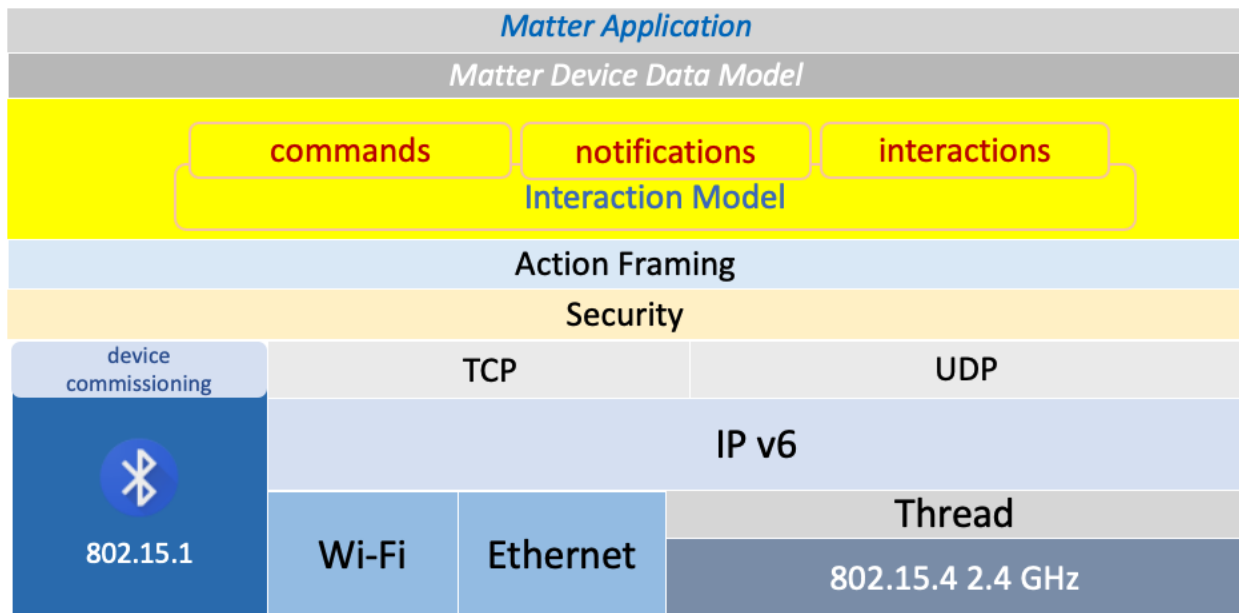

Figure 2: Matter Protocol Layers

1.6. Impact for Cable Operators.

Cable operators will be impacted by the emergence of Matter in several ways. Perhaps the most immediate impact is the introduction of a new wireless protocol, Thread, to the smart home. Over time, more and more low cost, low power, and low bandwidth devices will adopt this protocol and consumers will begin to expect support within their access point. Cable operators that fail to meet this expectation should expect increased call volume due to failed onboarding and lack of end device connectivity. Where Thread connectivity winds up being provided by some other device, such as a smart speaker, cable operators will lack any visibility into the state of the Thread network and have limited tools to support their customers. Matter will also increase the amount of broadcast and unicast traffic on a consumer's local area network. All this traffic will be encrypted leaving cable operators unable to effectively characterize it as malicious or safe. Participation in Matter will provide operators tools to better understand the devices on their customers networks and those devices' expected behavior. Matter also requires support for IPv6 and multicast DNS. Cable operators who do not currently support these technologies should expect increased call volume. Operators must support at least the basic requirements of Matter; Wi-Fi, Thread, IPv6, and mDNS. Failure to do so will risk their current managed access point offerings becoming obsolete, resulting in a lower take rate for this recurring source of revenue.

2. Matter Architecture

2.1. Transports and Network Stack (Wi-Fi, Thread, BLE, IPv6, DNS-SD)

At its core, Matter is a specification that defines a framework for interoperable, local network communication. The Matter specification allows for application layer messages to be transported over any IPv6 bearing network. Version 1.0 explicitly lists three compatible transports: Wi-Fi, Ethernet, and Thread. Wi-Fi and Ethernet are aimed at general purpose or high bandwidth applications and provide access to a local area network, LAN. Thread is aimed at low power and low bandwidth applications and

provides a mesh network topology known as a personal area network, PAN. A device known as a Thread Border Router allows for messages to be transported between the LAN and PAN. Cable companies that currently offer Wi-Fi routers should consider adding Thread support and enabling Border Router functionality. This will increase the range of devices they can currently support, provide access to useful information about the Thread PAN and network topology, and ensure their current connectivity solutions maintain pace with user expectations.

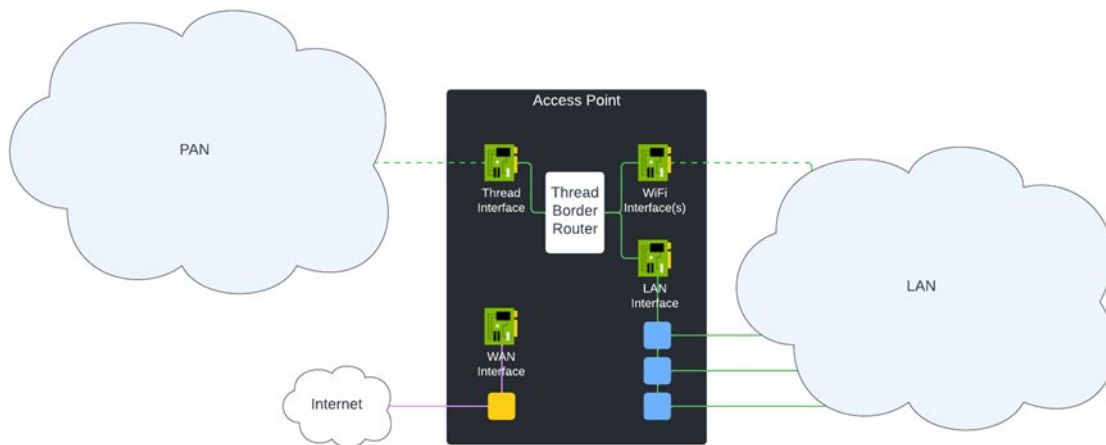

Figure 3: Router Architecture

In addition to IPv6 bearing transports, Matter also utilizes a few additional technologies to enable device discovery and network onboarding. One such technology is Bluetooth Low Energy, BLE. Matter utilizes BLE to enable discovery of commissionable devices and to facilitate a series of messages designed to verify the authenticity of a device, provision the device with Matter credentials, and to transmit credentials needed to connect to the user's Wi-Fi or Thread network. Devices that support BLE, this includes all Matter Thread devices, will initially advertise themselves over BLE when first powered on. Once they have been configured through the Matter commissioning process they will begin to operate over Wi-Fi or Thread.

Matter also makes extensive use of DNS service discovery, DNS-SD. This technology is utilized for device discovery and IP resolution. In the case of device discovery, devices that have already been onboarded to the user's LAN or PAN can publish themselves as commissionable for Matter commissioners to discover. In this situation the commissioning process would occur over IP on the respective transport and not utilize BLE. In the case of IP resolution, DNS-SD is utilized to resolve the IP address of commissioned devices, known in Matter as nodes, on the LAN or PAN. Utilizing DNS-SD to resolve a node's IP address allows for greater flexibility with IP assignment and does not require the node's IP to remain fixed over time. Nodes publish their presence with the `_matter._tcp` service and include an identifier consisting of their Fabric ID and Node ID. This allows the IP address of a Matter device to be resolved to its Fabric scoped Matter node identifier.

2.2. Fabrics

Matter groups collections of devices, Matter nodes, into what are known as Fabrics. Fabrics exist to provide: a common root of trust for this collection, enable encrypted communications between nodes, and

provide a set of scoped access controls. Fabrics exist only at the application layer and are completely decoupled from a user's LAN or PAN. In practice, most Matter users will operate multiple Fabrics, one per application they utilize to control their smart home.

Fabrics are created, or provisioned, by a Trusted Root Certificate Authority, TRCA. A Fabric ultimately consists of a unique 64-bit identifier and the public key certificate of the TRCA. A Matter device may belong to one or more Fabrics and would have a unique Node ID and Node Operational Certificate, NOC, for each Fabric it belongs to. This structure is what allows a Matter device to be controlled from multiple applications, provides users flexibility in granting applications access to Matter devices, and prevents ecosystem lock-in. Cable operators are well positioned to be TRCAs and provide supporting services to businesses that wish to participate in Matter but don't want to manage the required PKI.

Figure 4: Matter Fabrics

Nodes within a Fabric are permitted to communicate with each other based on access controls scoped to that Fabric. Every Matter node must maintain a set of access controls for each Fabric it belongs to. These access controls dictate permissions other nodes on the Fabric have to interact with functionality, exposed through Clusters, that a given node hosts. Communications between nodes are encrypted using the NOC they were provisioned during commissioning into a Fabric. This functionality allows for a secure channel to be established between nodes and is analogous to how communications are secured between modern Internet websites and browsers using HTTPS and PKI.

2.3. Data Model

In Matter, physical devices such as light bulbs, door locks, TVs, and more expose their functionality through the Zigbee Cluster Library, ZCL, data model. This data model enables interoperability between clients that issue commands and servers that accept commands. The highest order element in the Matter data model is a Device Type. Device Types can be things like dimmable light bulbs, thermostats, video players, and Wi-Fi access points. There are two high level Device Type categories in Matter, Utility Device Types and Application Device Types.

These Device Types are exposed through Endpoints that in many ways are akin to IP ports. A single physical device may expose multiple endpoints and therefore functionality of multiple Device Types. However, in practice most physical Matter devices will host two endpoints. One, endpoint 0 in all cases, that is used for administration and one that is used for actual application functionality. More information about Matter device types can be found in Connected Home over IP Device Library.

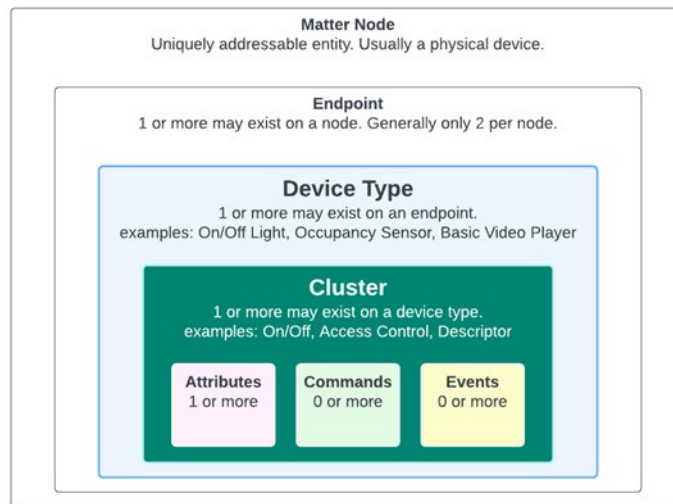

Figure 5: Device Types and Clusters

The functionality that a Matter Device Type exposes is done through implementing Clusters. Clusters are the foundational element of the ZCL data model and describe types of functionality such as the ability to turn something on or off, or adjust the level of something, like in a fan. Clusters are constructed from three lower-level elements: attributes, commands, and events. Attributes store state, such as the on or off state of a light bulb. Commands can be invoked to manipulate state, such as a toggle command to change the on or off state of a light bulb. Events can notify interested parties of updates to an attribute. An example of a complex interaction displaying all three Cluster conventions could involve an update to a thermostat that multiple occupants control from separate applications. In application 1, an occupant can invoke the 'SetpointRaiseLower' command hosted by the 'Thermostat Cluster' to adjust the 'OccupiedCoolingSetpoint' attribute. In a second application, another occupant that had subscribed to events on the 'Thermostat Cluster' could be notified through a Matter Cluster event of the update to the 'OccupiedCoolingSetpoint' attribute.

Clusters are defined as being either an application cluster or a utility cluster. Application clusters describe actual device functionality such as the ability to unlock a door lock. These clusters are generally hosted on endpoint 1 but may exist on multiple endpoints or have unconventional starting indices. Utility clusters are used to configure a Matter device or convey information about it. The functionality and information exposed on these clusters aids in commissioning, setting access controls, configuring bindings, reading logs, and more. In general, these clusters will be exposed through the Root Node device type that is always hosted on endpoint 0 for every Matter device. However, some utility Clusters, such as the Descriptor Cluster, exist on all endpoints that a device hosts. More information about application clusters can be found in Connected Home over IP Application Clusters. More information about utility clusters can be found in sections 9.5 – 9.14 and 11.1 – 11.19 of Connected Home over IP Specification.

2.4. Interaction Model

Matter defines four methods that a controller application can use to interact with the ZCL data model - read, write, invoke, and subscribe. These interactions ultimately allow an application to retrieve the current state of a device or to affect changes to its current state. Reads can be performed on cluster attributes to get their current state. An example would be reading the 'OnOff' attribute of a light bulb to determine if it was currently on or off. Writes can be performed on some cluster attributes to update their state. An example of this would be writing an entry to the 'NodeLabel' attribute to specify a user defined name for the Matter device. Invokes can be performed on cluster commands to affect the state of a cluster attribute. An example would be to invoke the 'Off' command to change the 'OnOff' attribute of a light bulb to off. Subscribes can be performed on many cluster attributes and events to receive notifications of changes to their state. An example would be to subscribe for updates to the 'CurrentLevel' attribute of a light bulb. With the subscription enabled, any time a user updates the level (brightness) of the bulb, all applications with active subscriptions would receive a message with the updated state.

2.5. Bridging - Current Networks and Legacy Devices

Bridges allow non-Matter IoT devices to participate in a Matter Fabric. This will allow consumers to continue to use some of their current (legacy) devices and will allow for a gradual transition to newer Matter-enabled devices. Bridges act as a translator between non-Matter protocols and Matter Fabrics. Similar to other Matter devices, a bridge can participate in many Matter Fabrics and must have at least one node on each Fabric. From that node the bridge will expose any number of endpoints through a specific device called an Aggregator. This device type has a cluster attribute that contains a list of all the bridged devices called a PartsList. Bridged endpoints are not full Matter nodes, they do not have their own Matter operational credential and all access control decisions for bridged devices will use the operational credential associated with the bridge. Access control entries can be specified using a set of targets that contain bridged device entries and bridged device types. For example, an ACL on a Matter lock could allow bridged device types of Window Sensor to read its state using the Node credential of the bridge.

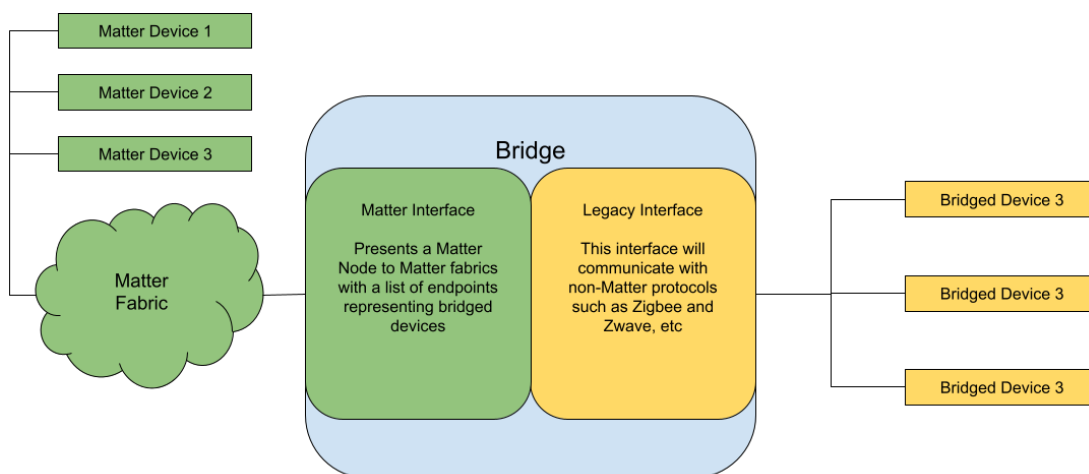

Figure 6: Bridging Architecture

3. Commissioning

The commissioning refers to a process of bootstrapping a network (aka a Fabric in Matter parlance) consisting of devices (including apps) that communicate with each other using Matter protocol. The commissioning process is designed to address following critical security principles.

- a. User Intent - user is explicit in the intention to commission the device
- b. Proof of Possession - the user is known to physically have and control the device
- c. Initial Secure Channel - all communications to commission and configure are secure and encrypted
- d. Device Authenticity - the user can be confident that the device is what it says it is

Figure 7: Matter Commissioning

In Figure X above the commissioning process ① is started by first scanning the QR code on the device or its packaging, this is usually done with an app on a smartphone referred to in Matter as a commissioner. The QR code contains among other things the product ID, the vendor ID and a passcode that is used to establish the initial secure connection with the device. This passcode can be manually entered by the user and even spoken into a smart speaker.

Next the commissioner will search for and connect to the device ②. This connection can be done over BLE, a temporary Wi-Fi connection to the device (SoftAP), or directly via IP. In this step the commissioner will check the device attestation certificate (DAC) and the certification declaration (CD) to establish that the device is authentic and has been tested and certified. The commissioner and the device will then establish a strong encrypted communication path with which to configure the device.

In ③ the commissioner configures the device with credentials for the Wi-Fi network as well as operational credentials that the device will use to connect to devices on the same fabric. Additionally, this step will often be used to set up access control lists so that the device will allow connections from other devices and applications.

Finally, in ④ the device will connect to the access point and begin normal operations.

The commissioning of a device can be done several times to add the device to new fabrics and to add administrators of the device.

4. Distributed Compliance Ledger

The Distributed Compliance Ledger (DCL) is a cryptographically secure, distributed network that allows device manufacturers (vendors), official test houses and Alliance certification centers to publish public information about a given device. Based on blockchain technology, it allows participants to update relevant device information that is cryptographically signed.

Connectivity Standards Alliance's (Alliance's) Distributed Compliance Ledger (DCL) is an industry-wide initiative to provide a cryptographically secure, distributed ledger of certified IoT devices and their roots of trust, without one company or an entity in charge of the ledger. By using an underlying permissioned blockchain framework, the DCL benefits from the following properties:

- Multi-node network that is run by the Alliance member companies
- Individually signed transactions using pre-approved keys
- Non-repudiation
- Distribution of data in different geographical locations
- Consensus protocol to ensure majority approval
- Public reads with available cryptographic proofs attached
- Transparency and auditability

4.1. Architecture

Conceptually, the DCL is a network of authorized "Validator Nodes" that comprise the consensus pool of the underlying blockchain framework. It works on the basis of a "Permissioned Ledger" where all write transactions are individually validated by the distributed validator nodes using the enrolled public keys. The CSA provides a public facing "Node" for full public access (Read Only). CSA members run their own nodes in their protected networks.

DCL 1.0 Topologies

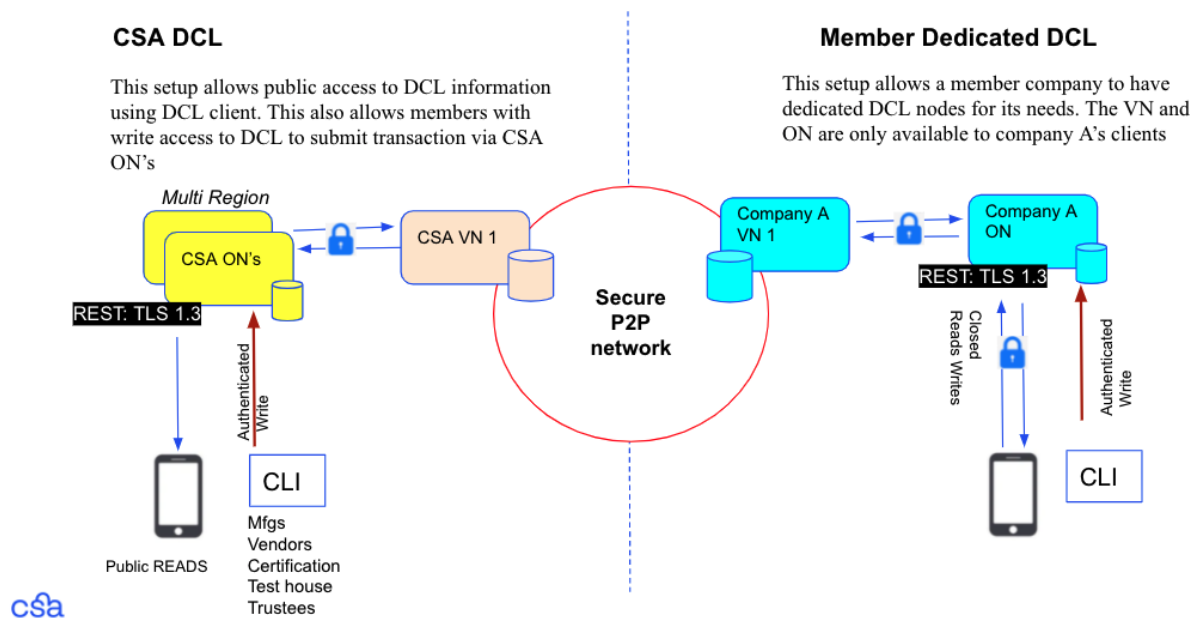

Figure 8: DCL Architecture

4.2. DCL Schema

DCL contains the following standard information, securely uploaded by individual members and validated using their public keys to provide nonrepudiation.

- **Vendor Info**, for example, company name, legal and preferred name, URL, etc.
- **Models and Model Software Versions**: models are identified by a unique combination of 'VID' (vendor ID) and 'PID' (product ID).
- **Model Certification**: DCL can be used as a source of information if certain Model Software versions are certified by a Certification Center. Certifications may be revoked.
- **PAA Certificates**: DCL can distribute authorized X509 Certificates (PAA and non-root).
- **Auxiliary Information**: DCL has an array of required auxiliary transactions:
 - **Validator Node** transactions define the current set of VNs participating in consensus.
 - **Account** transactions contain a role and a public key for every user wanting to write to the ledger and must be signed by the private key associated with the account.

- **Upgrade** transactions contain information about scheduled and completed updates of the DCL software.

4.3. DCL Nodes

The DCL network consists of a peer-to-peer network of Validator Nodes that communicate with each other using a secure and authenticated protocol.

- **Validator Node (VN)** is a full node that participates in the consensus protocol utilizing an authorized cryptographic key. A VN is responsible for validating new records. In order to run a VN, an organization must have an approved account with a Node Admin role - Access to VNs should be restricted by means of Sentry nodes and private networks. A better way to accept requests from the user is via Observer nodes.

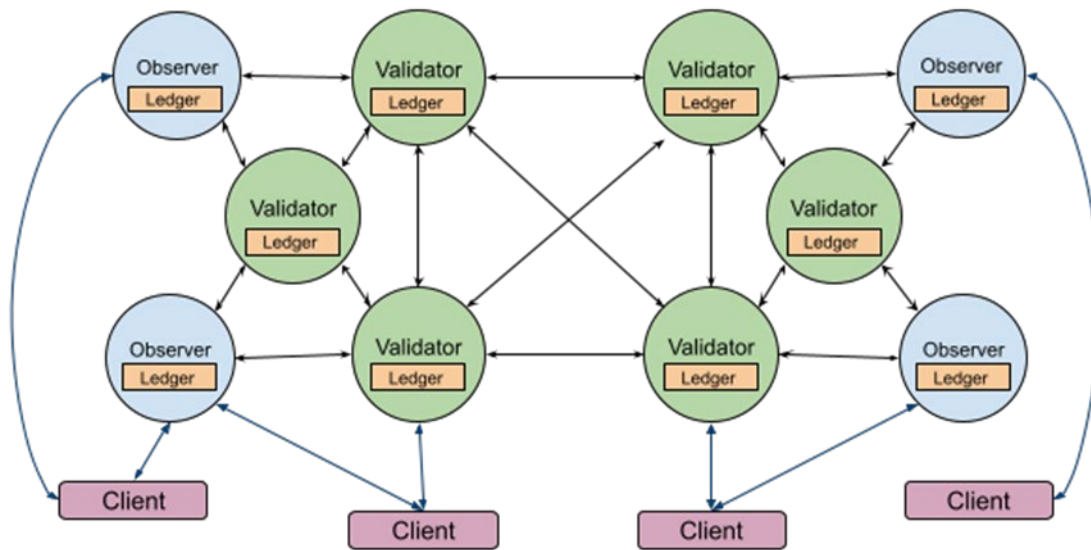

Figure 9: DCL Network

- **Observer Node (ON)** is a full node that does not participate in the consensus. ONs do not require an account with a Node Admin role to be created and member companies can govern their access to their ONs.

4.3.1.PKI Overview (PAA/PAI)

Matter specifies a three tier certificate chain for device attestation certificates to ensure device authenticity during commissioning. The top-level root is called “Product Attestation Authority” or PAA.

Each PAA can have one or more Intermediate known as ``Product Attestation Intermediate” or PAI. The PAI is responsible for issuing a unique device attestation certificate or DAC to each Matter device. The authorized pool of PAAs is entered in DCL so that they can be downloaded using the public DCL read interface to all Matter commissioners.

The Matter specification allows CSA members to operate their device PKI chain as long as the PAA and PAI adhere to the Matter Certificate Policy. Therefore, due care and best practice should be followed in setting up both a root and intermediate certificate authority and certain requirements must be met according to the Matter certificate policy for establishing and running a PAA/PAI. Several public PKI providers who are also CSA members can also provide PKI as a service by hosting PAA and PAI chains on behalf of Matter device manufacturers.

4.4. Running a DCL node

DCL consists of a pool of validator nodes that provide consensus based cryptographic integrity checks on the DCL entries. This provides blockchain level security and integrity for all the device data that is entered by authorized companies. Since DCL is a permissioned ledger, CSA and trustees of the DCL authorize each Validator node individually to become part of the DCL consensus pool.

CSA members can also run Observer Nodes which do not participate in the DCL consensus pool and therefore do not need to be authorized individually. CSA members can run Observer Nodes so that they have a full database of certified Matter devices in their network to enable individual company’s use cases.

5. Security

Matter takes a comprehensive approach to security that involves securely onboarding the device to the Matter Fabric, encrypted mutually authenticated connections between devices, fine-grained access control between devices and users, and a software update mechanism for issuing patches and new firmware to devices.

5.1. Secure Communications

The set of protocols used in Matter assures that all unicast communications are secured (encrypted and integrity checks), authenticated and provide builtin replay protection.

There are two methods of establishing a secure session in Matter and their use depends on if the device is being commissioned or is in normal operation. Both methods set up a shared symmetric session key for fast data encryption.

Passcode-Authenticated Session Establishment (PASE) is used when a device is being commissioned. PASE uses a password or passcode communicated through an out-of-band channel such as Bluetooth Low Energy (BLE), scanning a QR code, or Near Field Communication (NFC). Once both the device and the commissioner have the passcode they use it to calculate a common symmetric key on both sides. This key is then used to establish AES-CCM session keys to provide confidentiality and integrity of communications between devices. PASE is used to set up connections that establish operational credentials between devices.

Certificate-Authenticated Session Establishment (CASE) is used once a device is configured. It uses operational credentials in the form of certificates that are established at the time the device is

commissioned. These operational credentials are used to authenticate both ends of the communication and set up shared session keys. These shared symmetric session keys are used by the devices to encrypt traffic using the AES-CCM cipher suite.

5.2. Replay Prevention

Matter nodes use sessions as a way to quickly setup previously authenticated channels between two nodes. Sessions provide a mechanism to pause and resume a connection between devices as long as the session keys remain valid. Sessions also provide the Matter protocol a way to keep track of messages as they traverse two nodes. A randomly initialized message counter is established with each session that serves a two-fold purpose. First, it acts as an encryption nonce to ensure that every message is encrypted in a unique manner. Second, it acts as a replay and duplicate message detection mechanism.

Message duplication can be caused by network latency and errors where the sender did not receive an acknowledgement. Unhandled duplicate messages present problems if control messages are sent multiple times and can change the state of the device in unpredictable ways. Threat actors, while they are incapable of decrypting the message, can intercept encrypted messages and re-send them or “re-play” them. This can cause an unintended state in a device. A common example of this is a legitimate unlock command that is captured by an attacker and resent to a door lock later allowing the attacker to gain physical access. Matter prevents these issues by maintaining a history window of message counts from a sender to determine if the message is a duplicate. Duplicate messages are dropped by devices before they reach the application layer.

5.3. Secure Group Communications

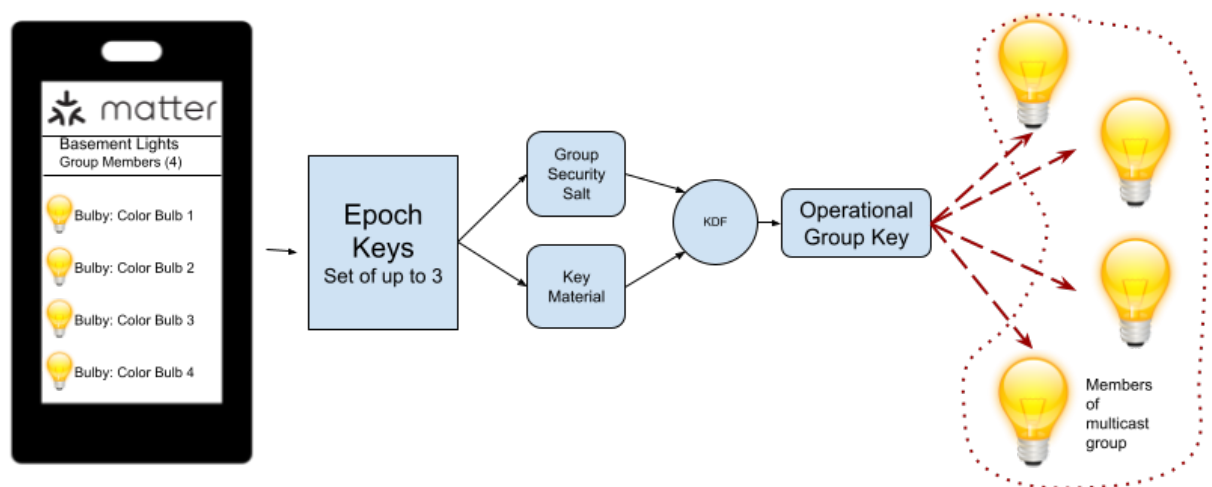

Figure 10: Secure Group Communications

Group communications in Matter take advantage of multicast networking. Multicast allows a single sender to send a message to a specific destination group and it is received by several devices simultaneously, relying on the network to replicate the message. An example use-case of this in the smart home is to send an “ON/OFF” command to a group of lights. Using multicast, a single command can be sent to a large group of devices instead of having to send individual unicast messages to each

device. This is both more efficient and faster than unicast as it requires fewer messages from the sender and can be done in parallel.

Because secure group communications is a one-to-many relationship i.e one sender and many recipients, securing this communication must be done in a way that provides three things:

1. All devices can prove that they are members of the associated group
2. All messages are encrypted and confidential.
3. Messages can only be decrypted by other members of the group

To accomplish the above goals Matter distributes through an Administrator Node a set of 1-3 keys to each device in the group called epoch keys. Devices use these epoch keys to derive an operational key that is used to encrypt and decrypt messages for the group.

5.4. Access Control

Access control provides fine grained access to devices. For example, your front door lock can be set up to allow one family member's phone (i.e., a parent) to manage who can change access settings on the lock (what other devices can view and perform actions on the lock), and another family member's phone (i.e., child) to operate (lock/unlock) the door.

Access control lists consist of the following attributes:

- Fabric Index: ID scoped to the associated Fabric
- Privilege Level: View, Proxy View, Operate, Manage, and Administer
- Targets: List of clusters (data model elements e.g DoorLock, temperature sensor)
- Subjects: List of sources of an action to which the ACL applies, often this will be the Node ID
- Authentication Mode: Type of secure channel (PASE, CASE)

An example of an ACL on a Matter device is shown below. The first entry gives "Administrator" privilege to a Matter node with ID "0xAABD65DF76230b54" over CASE authentication.

The second entry allows all devices on Fabric 1 to have "View" privilege on all target devices endpoint 1.

The last entry provides "Manage" privilege to subject 0x0000000000000001 on End Point 1 and Endpoint 3 of cluster ID 0x0000_0202.

```
ACL: [
  {FABRIC: 1, PRIVILEGE: ADMIN, AUTHMODE: CASE, SUBJECTS: [0xAABD65DF76230b54],
  TARGETS: []},
  {FABRIC: 1, PRIVILEGE: VIEW, AUTHMODE: CASE, SUBJECTS: [], TARGETS: [ENDPOINT: 1]},
  {FABRIC: 1, PRIVILEGE: MANAGE, AUTHMODE: GROUP, SUBJECTS: [0x0000000000000001],
  TARGETS: [{ENDPOINT: 1}, {ENDPOINT: 3, CLUSTER: 0x0000_0202}]}
]
```

5.5. Software Update

All devices will need to be updated at some point in their life cycle either to provide new functionality or to patch a vulnerability. Matter mandates that all Matter certified devices support over-the-air (OTA) software update. Software images must be signed by the vendor using a private key dedicated to signing images. Firmware images are transferred over a Matter specific Bulk Data Exchange (BDX) protocol that treats images as a collection of bytes with metadata. BDX is modeled after TFTP and can use either TCP or UDP as an underlying transport.

The software update process in Matter involves two nodes:

- OTA Requestor is any node that requires updating of software.
- OTA Provider is a Node that fulfills software update requests. The OTA Provider downloads the image from the vendor and stores a copy or alternatively can act as a proxy through which the OTA Requestor can download the firmware image.

Software updates must be checked for authenticity and integrity by the device prior to being installed. Additionally, devices will not install version numbers that are lower than their current running firmware version to prevent downgrade attacks.

6. Administration

6.1. Operational PKI

Devices are permitted access to a Matter Fabric through the provisioning of a Node Operational Certificate, NOC. The NOC uniquely identifies a particular node within the scope of a particular Fabric. This certificate is also used to establish secure communication channels with other nodes belonging to the same Fabric. NOCs may be directly issued by a Trusted Root Certificate Authority or an Intermediate Certificate Authority and are provisioned during Matter commissioning. A Matter device will have exactly one NOC for every Fabric that it belongs to.

6.2. Configuring Access Control

Matter provides a flexible fine grained access control list for participating devices. The rule-based ACL defines no implicit access by default. Therefore, it works on the principle of implicit “deny” unless an explicit rule defined on a device grants access to a requesting device, further fine grained to a given endpoint (service) on the target device.

An access list is created on a device during its commissioning so that when it is put on the network, it has proper security in place. During the commissioning phase, the access control module on a device grants implicit “Administrative” access to a Commissioner over PASE session which entails creating a secure channel using SPAKE2+ protocol between the device and commissioner using a passcode for that device. Further updates to Access Control lists can be made over the network on a CASE session as long as the source device has “Administrator privilege” defined in the target device ACL.

6.3. Fabric Management

There are two roles that are necessary to fully manage a Fabric. The commissioner role is used to provision new nodes into the Fabric and provide them with operational credentials that chain up to an operational root of trust. The administrator role is used to change access control lists within their respective Fabrics. Additionally, administrators can remove a Fabric that is not directly under their control. This is an important feature of Matter as it allows a device owner to remove a Fabric from the device that they may no longer control or a Fabric they no longer wish to control the device.

6.4. Group Management

It is expected that groups of devices will change. For example, you may wish to add or remove a light from a group. Adding a device is as simple as commissioning a new device and adding it to the group along with the required group operational key so that it can decrypt signals sent to the multicast address of the group. Removing a device from the group requires a re-key of the remaining devices in the group with new operational keys.

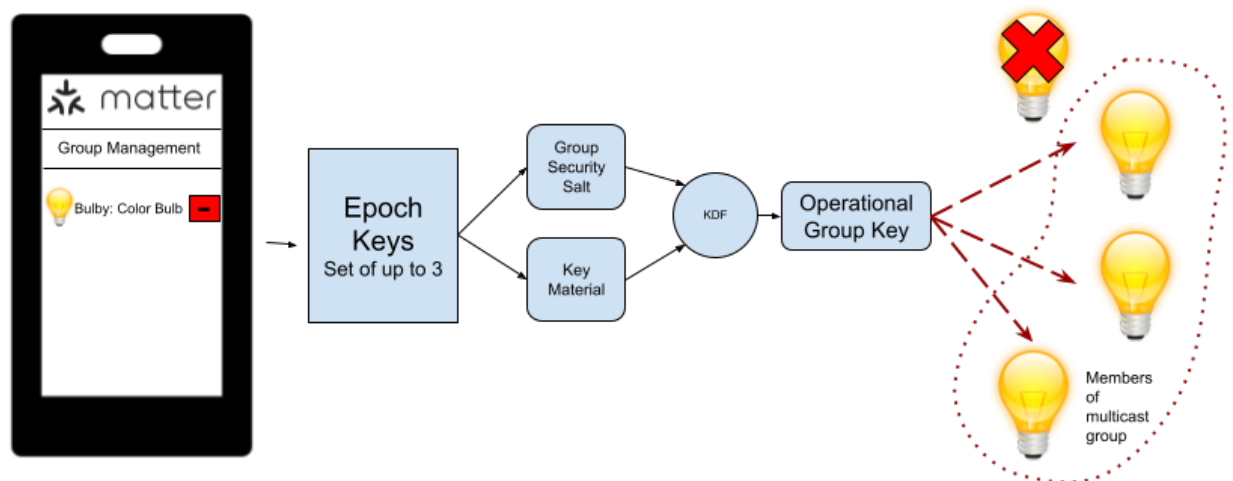

Figure 11: Group Management

6.5. Software Update

Software update announcements and notifications are automatic and happen in the background. To assure that the update does not disrupt the user, downloading and applying updates should be done after obtaining user consent. User consent can be stored for future use and is an optional process in Matter.

6.6. Multi-Admin

Matter has standardized simultaneous command and control of a device by multiple ecosystems. This key feature allows consumers to “commission” i.e. securely add control of their Matter devices by multiple ecosystems ensuring they are not locked into using a single vendor or ecosystem. For example, a door lock can be opened with multiple apps through multiple ecosystems if provided the initial owner intends to set it up in such a way.

The sequence diagram below depicts the steps initial Ecosystem (Eco A) takes to pair an already commissioned “bulb” to add it to the second ecosystem (Eco B). The process involves the user (Alice) instructing the device (Bulb) to go into commissioning mode using a new onboarding passcode and go into discovery mode. The commissioning window is open for a specified time in seconds. Alice conveys the new PIN to Bob who is connecting to the bulb using a different ecosystem. Bob discovers the bulb using “dns-sd” and completes commissioning using the new passcode.

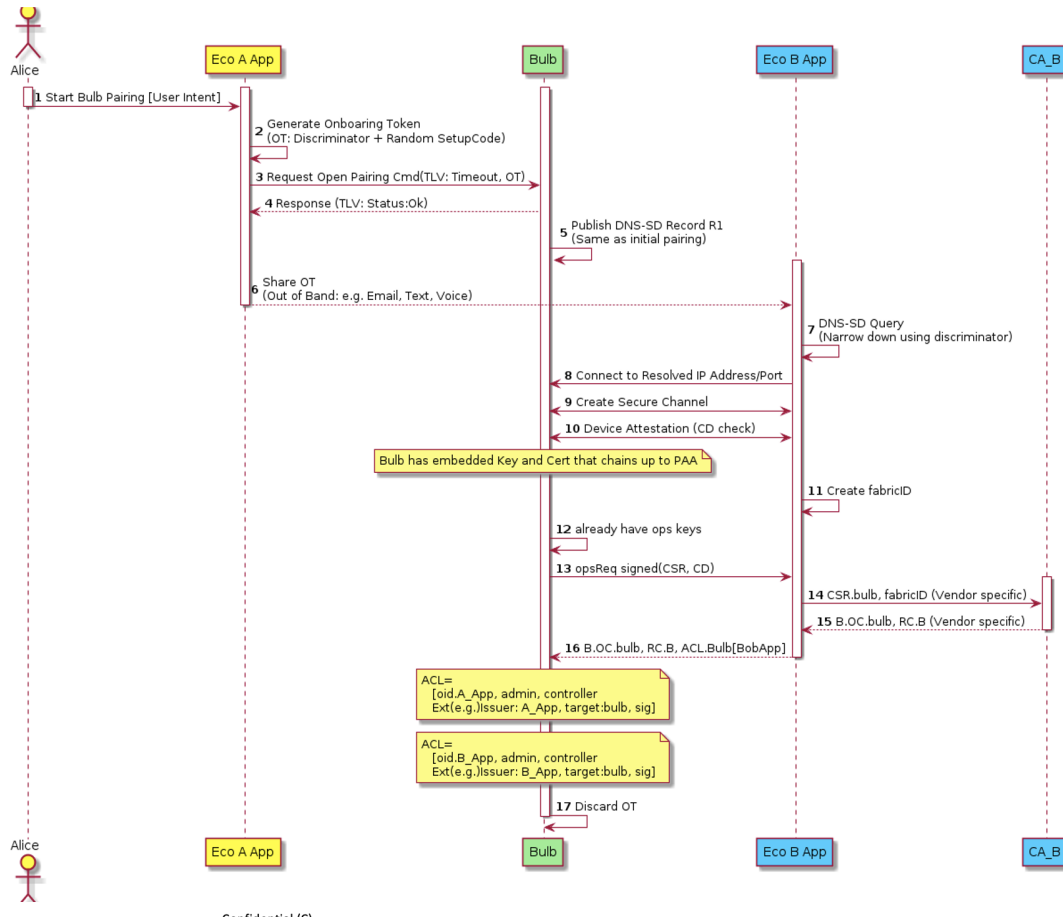

Figure 12: Multi-Admin Sequence

7. Matter and Operators

Matter represents a paradigm shift in traditional smart home management. This new specification simplifies the way applications and devices communicate by utilizing IP, the language of the Internet. It decouples the networking stack from the application stack, allowing for flexibility in use cases that require differing bandwidth and energy constraints. Matter is also open source and provides full access to specifications and reference SDKs. Given the unique relationship that Cable operators have as Internet and local connectivity providers to the smart home, they have a great opportunity to both add value to and derive value from Matter.

As wireless connectivity providers, Cable operators have a goal of ensuring their customer's devices seamlessly and consistently connect to their access points. Fundamentally, all that is needed to support the basic connectivity requirements of Matter is to provide Wi-Fi Access Points, Thread Border Routers, and IPv6 and multicast DNS support. Most operators already support many of these requirements and simply need to add Thread capable radios to their access points. Ensuring all Matter supported wireless transports, Wi-Fi and Thread, are present in customer's homes will reduce the potential for failed device connections and user confusion. This in turn will drive down customer service calls and improve user satisfaction. Cable operators should also consider certifying their access points as Matter certified Wi-Fi access points and Thread Border Routers. These additional device certifications are currently being defined and will be available in a future release of Matter.

As Internet Service Providers, Cable operators have a responsibility to help safeguard their customer's home networks and the broader Internet as a whole. The tools that allow this oversight often rely on the ability to uniquely identify network devices and to understand the applications they expose or interact with. In the evolving world of Internet security and privacy practices that encourage use of randomized MAC addresses and encrypted communication channels, the ability to acquire this information is becoming increasingly difficult. With Matter, Cable operators can directly query devices to uniquely identify them and understand what type of device they are. Additional helpful information such as a device's software version, hardware version, manufacturer, product ID, and serial number are also made available. Devices can be further vetted against the Matter Distributed Compliance Ledger to verify their authenticity and certification status. All of this represents a suite of tools that can be used to uniquely identify devices on a customer's network, understand the expected behavior of those devices, and provide a rich set of data to direct customers to appropriate support resources.

As customer premise equipment providers, Cable operators are well positioned to add value to Matter by proxying Matter communications from the Internet to a customer's local network. Matter is designed as a local network communication stack and does not define how the smart home may be interacted with when a user is not at home. Control of Matter devices while away from a user's local network will require routing messages through a locally connected device. Cable companies offer a range of devices including Wi-Fi routers, cable modems, and set-top-boxes that can act as proxies to relay these messages. Having a locally connected device that is always listening and addressable from the Internet provides Cable operators the ability to address this existing gap. Further value can be added by simplifying the device onboarding process. Cable's scale, access to the home, and ability to forge business to business relationships place it in a unique position to improve this area. Through arrangements with retailers, device onboarding information could be transferred to a customer's router at time of purchase so that the onboarding process automatically happens in the background when the device is first powered on. These are just a few of many potential value propositions the Cable industry can provide to Matter.

Matter is poised to transform the way that users, device manufacturers, and ecosystem providers approach the smart home market. Users will benefit from a recognizable brand that simplifies the purchasing process and ensures interoperability. Device manufacturers will be able to offer a reduced set of SKUs and take advantage of open-source SDKs. Ecosystem providers will be able to seamlessly connect to a range of devices with improved onboarding flows and enhanced security. With all these benefits in place, Cable operators must embrace Matter in order to meet their customer's evolving expectations and usher in the next generation of the smart home.

1. Introduction

To measure IP Video Playback Quality of Experience (QoE) there are several distinct metrics available that need to be reviewed individually to determine the overall playback quality. These may include rebuffering, startup latency, video bitrate, errors, and downshifts. This paper presents a novel approach to objectively predict the IP video playback quality as perceived by the end-user by calculating a single, final overall metric referred to as Video Viewing Quality (VVQ). VVQ factors in several distinct metrics such as rebuffering, playback errors, video quality, downshifts, startup latency, and recency. Inherent in some of these metrics are the impact from audio issues such as dropouts, missing audio. VVQ scores are currently being utilized to determine IP video playback QoE on various IP video devices and to troubleshoot playback issues. We will also discuss how this single metric, or score can further be leveraged to enhance IP Video playback experience by performing bandwidth and network optimizations. Measuring IP video playback quality is an important aspect of the transition to the delivery of video over IP from legacy QAM.

2. IP Video Architecture

At a high level, the IP video architecture is as shown in the Figure 1 below. In this figure, the compressed or uncompressed video stream is transcoded into several streams (variants), each at different fixed bitrate, to accommodate the varying network bandwidth available between IP video consumer devices and the content delivery network, and the various consumer devices. The transcoded streams might be encoded using one of the MPEG compression codecs (MPEG-2[4], MPEG-4/AVC [2], HEVC [3]). This is then packaged into one of the many streaming formats, for example MPEG-DASH [5] or HLS [6], where they are typically split into time-aligned segments of a few seconds duration. These are then placed on the Origin Server and IP CDN for delivery to IP video clients. This would apply to both linear and on-demand IP video. Consumer devices will typically try to download the highest bitrate video that they can support, with the intent of providing higher video quality to the viewer.

Figure 1 – IP Video Architecture

2.1. Playback Artifacts

During IP video playback several customer impacting issues could arise; some of them are listed below.

- Stalling of video playback due to rebuffering or errors in the stream
- Playback of low-quality video for extended durations

- Bad quality of encoded video/audio, causing video issues like macroblocking, blurry images, noisy, out of lip sync, flashing, video buffering errors (underflow, overflow), or missing audio
- Large startup latency
- Media playback failures (playback start fails or leads to ending playback)
- Playback control failures (for example, while pausing or exercising trick modes)
- Live latency
- Multiple and frequent occurrences of playback issues during a session

2.2. Measuring IP Video Playback QoE

Measuring IP Video playback QoE is important for numerous reasons including:

- To allow for the seamless transition to delivery of video over IP from legacy QAM; customers should not experience a degradation in video playback experience when they are switched to IP video
- Early detection of IP video infrastructure issues and enable self-healing
- Validation of new streaming technologies (for example content adaptive streaming, new players, codec)
- Facilitating IP video system component upgrades
- For the retention of video customers in a highly competitive marketplace
- To provide an entry point for identifying streaming video issues and assist in their resolution

3. Video Viewing Quality(VVQ)

As described earlier, there is a need to measure IP video playback QoE. There are several distinct metrics that can be reviewed individually to determine the overall IP video playback QoE including average video bitrate, startup latency, rebuffering duration, rebuffering count, top errors/failures, encoded video quality, and others. Viewing these distinct metrics one at a time to detect bad user experience is not feasible, especially with large-scale deployments. One option is to look at only a subset of them, but because customer experience can be impacted by any one of them, all need to be taken into consideration.

What is needed is a holistic metric for measuring IP Video Playback Quality of Experience (QoE) and the VVQ score meets that need. It objectively determines the IP video playback quality as perceived by the end-user and is expressed as a single, final overall score. VVQ would be applicable to any IP video playback use cases such as IP linear, VOD, and time-shifted streams.

3.1. VVQ Model

The VVQ model uses several metrics to compute the single final overall score. They are listed below.

- Video quality (as a result of lossy encoding)
In this model, variants/segments in the ABR ladder are classified into three video quality categories Low, Medium, High. There are several classification options that may include:
 - Video bitrates
 - Complex video analysis
 - Video quality metric from Peak Signal to Noise Ratio (PSNR), Structural Similarity Index (SSIM) based tools
 - Quantization values
- Quality switching (Downshift to Low/Medium video quality segments)

Considered in the quality switching are peak frequency value and number of downshifts (High to Medium, Medium to Low, High to Low)

- Low/medium video segments playback
Considered here are
 - The total playback duration of these lower quality segments during the entire measurement period
 - Continuous playback duration: duration of low/medium video playback before switching to optimal quality segment
- Rebuffering events
 - Total duration of rebuffering during the entire measurement period
 - Peak frequency value for these events
 - Continuous duration of rebuffering event
 - Number of rebuffering events
- Startup latency (Primacy)
- Last bad video quality impact (Recency)
Elapsed time since the last bad video quality event such as low-quality video or rebuffering
- Playback failures/errors
Considered here are failures and errors that disrupt video playback like frozen video, loss of audio, or error messages displayed to the user. During these types of errors/failures the following are determined
 - Total duration of error events during the entire measurement period
 - Peak Error frequency
 - Continuous duration of error event
 - Number of failures/error events
- End-user actions
Latency when executing trick mode commands like Pause, Seek, Fast Forward, Rewind
- Display dimensions

3.2. VVQ Formula

The formula to calculate VVQ score is shown next. It is an equation that factors in several IP video playback artifacts. From the customer point of view the main artifacts impacting them are quality of video and audio, rebuffering, startup latency, playback failures, quality switching, and time between bad video quality events.

Video Viewing Quality Score = 100 - Impact from Low Quality Video Playback - Impact from Medium Quality Video Playback - Rebuffering impact – Impact from the time interval between bad quality events - Playback startup times impact - Impact from Playback Errors - Impact from trick play latency

Expanding this to the actual terms used in the formula we would have,

VideoViewingQualityScore = 100 – (LowQualVideoImpact + ContinuousLowQualityImpact + DownshiftToLowQualImpact + MediumQualVideoImpact + ContinuousMediumQualityImpact + DownshiftToMediumQualImpact + ContinuousRebufferingImpact + RebufferingFrequencyImpact + OverallRebufferingImpact + LastBadQualityEventImpact + StartupTimeImpact + PlaybackFailureImpact + ContinuousErrorImpact + ErrorPeakFrequencyImpact + OverallErrorImpact + SeekLatencyImpact)

The terms in the above equation are further detailed below.

1. Low-quality video impact computation: This measures the overall impact from the playback of low-quality video at certain times or during the entire measurement period.

$$\text{LowQualVideoImpact} = A1 * \frac{m1}{n1}$$

$A1 = \text{Low Quality Video Impact Coefficient}$

$m1 = \text{Total Duration of low quality video playback}$

$n1 = \text{Total Duration of video playback}$

2. Medium-quality video impact computation: This measures the overall impact from the playback of medium-quality video at certain times or during the entire measurement period.

$$\text{MediumQualVideoImpact} = A2 * \frac{m2}{n1}$$

$A2 = \text{Medium Quality Video Impact Coefficient}$

$m2 = \text{Total Duration of medium quality video playback}$

3. Continuous low video quality impact computation: Computes impact based on how long the user client device is playing low-quality video before it switches to either medium or optimal quality video.

$$\text{ContinuousLowQualityImpact} = \sum_{l=0}^{m3} A3 * e^{A4 * t(l)}$$

$A3 = \text{Continuous Low Quality Impact Coefficient}$

$A4 = \text{Continuous Low Quality Impact Exponent Coefficient, } < 1$

$t(l) = \text{Low quality continuous duration,}$

$l = 0 \text{ to } m3. m3 - \text{Total number of continuous low video quality events}$

4. Continuous medium-video quality impact computation: Computes impact based on how long the user client device is playing medium-quality video before it switches to optimal or low-quality video.

$$\text{ContinuousMediumQualityImpact} = \sum_{l=0}^{m5} A5 * e^{A6 * t(m)}$$

$A5$ = Continuous Medium Quality Impact Coefficient

$A6$ = Continuous Medium Quality Impact Exponent Coefficient, < 1

$t(m)$ = Medium quality continuous duration

$l = 0$ to $m5.m5$ – Total number of continuous medium video quality events

5. Downshift to low video quality impact computation: Computes impact when user client device is downshifting to low-quality video during playback; uses peak downshift frequency and total number of downshift events

$$\text{DownshiftToLowQualImpact} = A7 * m7 + m4 * C1$$

$A7$ = Downshift to Low Quality Impact Coefficient

$m7$ = Peak frequency of downshift to low quality events

$m4$ = Total number of downshift to low quality events

$C1$ = Impact to score from downshift to low quality

6. Downshift to medium-video quality impact computation: Computes impact when user client device is downshifting to medium-quality video during playback; uses peak downshift frequency and total number of downshift events

$$\text{DownshiftToMediumQualImpact} = A8 * m8 + m6 * C2$$

$A8$ = Downshift to Medium Quality Impact Coefficient

$m8$ = Peak frequency of downshift to medium quality events

$m6$ = Total number of downshift to medium quality events

$C2$ = Impact to score from downshift to medium quality

7. Continuous rebuffering impact computation: Computes impact based on how long the user client device is rebuffering before it restarts video playout.

$$\text{ContinuousRebufferingImpact} = \sum_{p=0}^{m9} A9 * e^{A10*t(p)}$$

$A9$ = Continuous Rebuffering Impact Coefficient

$A10$ = Continuous Rebuffering Impact Exponent Coefficient, < 1

$t(p)$ = Continuous Rebuffering duration,

$p = 0$ to $m9$. $m9$ – Total number of rebuffering events

8. Rebuffering frequency impact computation: Computes impact based on how often the user client device is rebuffering.

$$\text{RebufferingFrequencyImpact} = A11 * m15$$

$A11$ = Rebuffering Frequency Coefficient

$m11$ = Peak frequency of Rebuffering events

9. Overall rebuffering impact computation: Computes the overall impact from rebuffering during the entire video playback.

$$\text{OverallRebufferingImpact} = A12 * \frac{m12}{n1}$$

$A12$ = Overall Rebuffering Impact Coefficient

$m12$ = Total Duration of video rebuffering

$n1$ = Total Duration of video playback

10. Last bad video quality event impact: A logarithmic curve is used to compute the impact to user viewing experience for the time intervals between bad video quality events such as a downshift to a low-quality video, rebuffering but then recovers after a certain time. Therefore, this impact is dependent on the time between the bad video quality events.

$$\text{LastBadQualityEventImpact} = \sum_{k=0}^{m10} C1 + A14 * \log_{m11} t(k)/A15$$

$C1$ = Last Bad Quality Event Impact Constant

$A14$ = Last Bad Quality Event Impact Coefficient

$m11 = \text{Last Bad Quality Event Impact Base} < 1$

$t(k) = \text{Time since last bad video quality event,}$

$k = 0 \text{ to } m10.m10 - \text{Total number of bad video quality events}$

$A15 = \text{Time scale factor}$

The time of occurrences of low-quality video, rebuffering, failure events are used to determine $t(k)$, the time since last bad video quality event.

11. Playback failure impact: This would be applicable to failures such as unable to playback video due to inability to retrieve video segments or unable to decode video or corrupt video without recovery.

$\text{PlaybackFailureImpact} = A16$

$A16 = \text{Playback Failure Constant}$

12. Startup time impact: Computes impact based on how long it takes for video playback to start after the user has initiated it. An exponential growth curve is used to compute the impact.

$\text{StartupTimeImpact} = A20 * e^{A21*t(z)}$

$A20 = \text{Startup time Impact Coefficient}$

$A21 = \text{Startup time Impact Exponent Coefficient,} < 1$

$t(z) = \text{Startup time}$

13. Seek latency impact: Computes impact based on how long it takes for video playback to start after the user has initiated a seek or trick mode operation like FFWD or RWD. An exponential growth curve is used to compute the impact.

$$\text{SeekLatencyImpact} = \sum_{p=0}^{m14} A22 * e^{A23*t(w)}$$

$A22 = \text{Seek Latency Impact Coefficient}$

$A23 = \text{Seek Latency Impact Exponent Coefficient,} < 1$

$t(w) = \text{Seek Latency}$

$p = 0 \text{ to } m14.m14 - \text{Total number of seek events}$

14. Continuous error impact computation: Computes impact based on how long the user client device is in error state before it restarts video playout.

$$\text{ContinuousErrorImpact} = \sum_{p=0}^{m15} A24 * e^{A25*t(p)}$$

A24 = Continuous Error Impact Coefficient

A25 = Continuous Error Impact Exponent Coefficient, < 1

t(p) = Error state duration,

p = 0 to m15. m15 – Total number of error events

15. Error frequency impact computation: Computes impact when the player runs into error events, uses peak error frequency and total number of error events.

$$\text{ErrorPeakFrequencyImpact} = A26 * m16 + m17 * C3$$

A26 = Error Peak Frequency Impact Coefficient

m16 = Peak frequency of error events

m17 = Total number of error events

C3 = Impact to score from all error events

16. Overall error impact computation: Computes the overall impact from errors during the entire video playback.

$$\text{OverallErrorImpact} = A27 * \frac{m18}{n1}$$

A27 = Overall Error Impact Coefficient

m18 = Total Duration of Error events

n1 = Total Duration of video playback

3.3. VVQ Coefficients Calibration

Calibration of VVQ coefficients in the above formula involved analyzing IP video playback data from production, publicly available Mean Opinion Score (MOS) data, and technical documents specifying the customer thresholds for various IP video playback issues.

In particular, the publicly available University of Waterloo QoE database test samples with MOS scores using 25 subjects was utilized [1].

4. VVQ Implementation

VVQ scoring implementation could be done either in IP Video Players or remote monitoring system/analytics engine as shown in the Figure 2. In the case of the VVQ scoring in analytics engine, the players are expected to emit playback data such as timestamps for bitrate changes, rebuffering start and stop times, and other events, to the analytics engine to permit VVQ scoring there. In the case of VVQ scoring in the IP video players, the calculated score is communicated to the remote monitoring system. The remote monitoring system analyzes the VVQ scores and determines the measures that need to be taken to address issues resulting in low scores.

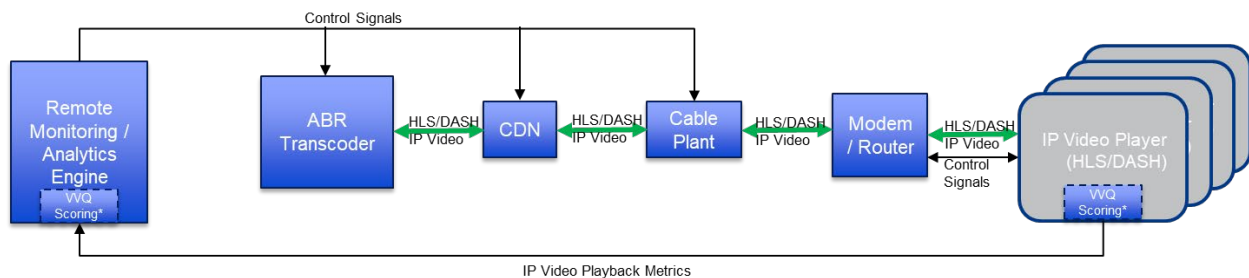

Figure 2 – Scoring in Analytics Engine or IP Video Player for Video QoE Management

4.1. VVQ in Analytics Engine Reference Architecture

Figure 3 below shows one implementation of VVQ in Analytics Engine. The IP video players in Set Top Boxes (STBs), Connected TVs, Mobile Devices and Desktops send player analytics data to Headwater 3 during IP video playback. Details on the Headwaters is available here [7]. Data in Headwaters is then stored in a Data Lake and ingested by ETL AWS Glue VVQ code to generate the scores. These scores are plotted using QuickSight user interface considering various parameters such as device type, application type, time of occurrence, and others.

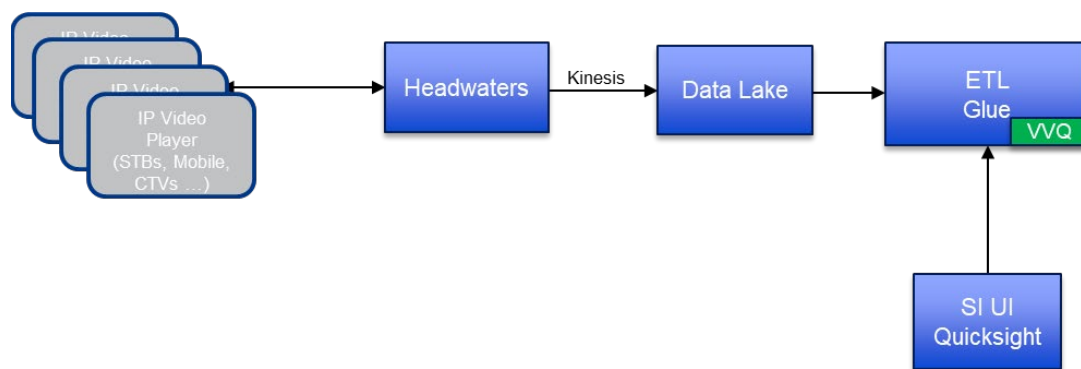

Figure 3 – VVQ Implementation in Analytics Engine

Variants/Segments in the ABR ladder are classified into three video quality categories - Low, Medium, High. The classification could be done via several approaches such as no reference or reference video encoding quality measurement tools, or simply based on video bitrates. The approach chosen here is using the video bitrates and their assignments to the three quality categories is predetermined.

The VVQ scores can be computed at various points in time during video playback. Some of the options are:

- At the end of video playback sessions, for example at the end of a movie playback, end of linear channel viewing session
- At predetermined fixed intervals during VOD or linear playback session
- Continuously as, and when, new playback data is available
- At the end of a program during linear channel viewing utilizing program metadata from Gracenote

In the architecture here the VVQ is computed at the end of video playback session.

Figure 4 below shows the screenshot of the VVQ scores generated from an implementation of this reference architecture for Linear IP Video Playback sessions.

Figure 4 – VVQ Average Scores Linear

Figure 5 below displays the VVQ score components average values for Linear IP Playback sessions. The components are the various terms detailed in the section 3.2 VVQ Formula.

Linear Sessions: Daily Average of VVQ Components

Figure 5 – VVQ Score Components Average values

4.2. Sample VVQ Scores

Listed in the table below are sample VVQ scores generated from IP video playback sessions across various devices.

Table 1 – Sample VVQ Scores

Device	VVQ Score	Description
STB	0	Total Linear playback duration: 88 mins 2 Rebuffering events, Max duration 7 mins 6 downshifts to bitrate 0.8Mbps (34s on low bitrate video*) 26 downshifts from 6 to 2Mbps (4mins on medium bitrate video*) In home issue, attributed to packet loss and Wi-Fi latency
STB	73.34	Total Recorded content playback duration: 51 mins 5 downshifts to 2.1Mbps Video (13mins on medium bitrate video*)
iPhone	0	Total VOD playback duration: 35 mins 9 mins on low bitrate video**
iPhone	82	Total VOD playback duration: 36 mins 3 Rebuffering events, Max duration 8s 2 downshifts to bitrate 0.7Mbps (31s on low bitrate video**)

Device	VVQ Score	Description
Desktop Edge	0	Total Linear playback duration: 48 mins 2 downshifts to low bitrate video (20mins on low bitrate video**) 3 downshifts to medium bitrate video (28mins on medium bitrate video**) 1 Rebuffering event, Max duration 3s
Android	20	Total Linear playback duration: 19 mins 17 downshifts to bitrate 0.5Mbps (3 mins on low bitrate video**) 56 downshifts to medium bitrate video 2Mbps (7mins on medium bitrate video**)

* Low bitrate video < 1.8Mbps, Medium bitrate video < 3Mbps, Video compression – AVC

** Low bitrate video < 0.75Mbps, Medium bitrate video < 1.5Mbps, Video compression - AVC

Please note that “We collect, store, and use all data in accordance with our privacy disclosures to users and applicable laws”.

5. IP Video Playback QoE Management – Self healing

One important objective of this scoring is to drive a self-healing feature of IP video playback issues. In the Figure 2 above the remote monitoring system based on the VVQ scores calculated interacts with ABR transcoder, CDN, cable plant, and with the client to control changes that will lead to better playback video experience (higher VVQ score). The client interacts with modem/router, for example, to switch to channels with less interference.

Possible self-healing scenarios are listed below,

- If the score is low due to in home Wi-Fi issues, automatically switch channels with less interference; also recommend upsell to better routers. This is made possible when the Wi-Fi Gateway and routers network analytics data is accessible by the IP Video playback device and is also controllable by it.
- If the in-home network bandwidth is maxed out causing low scores, automatically increase bandwidth and display upsell packages for higher BW product to customer
- If unable to fix occasional network issues via configuring in-home Wi-Fi equipment, display error messages for users to troubleshoot and identify possible sources of interference
- Detect low scores with new deployments and pull back releases/upgrades without manual intervention
- Detect low scores from all clients in a plant attributable to a plant DOCSIS channels outages and/or incorrect configuration and switch to redundant paths
- Detect CDN delivery issues (e.g., network connectivity failures) and allocate additional resources on the existing CDN or switch to alternate CDNs. If the issue is with an external CDN then potentially interface with their control interface to address these issues and indicate so to the customer.
- Switch to alternate transcoder delivery lanes when consistent media failures are detected, for example on linear channels.
- If most IP video players in a region are reporting low scores due to network BW capacity saturation, the remote monitoring system could instruct the transcoder to generate the highest profile stream in the ABR ladder at a lower bitrate that would reduce the saturation
- If the score is low due to out-of-home Wi-Fi/Carrier signal issues, provide scores to carriers for alternate solutions and recommend upgrades
- Proactively inform users of upcoming IP video outages

6. Conclusion

Measuring IP Video Playback Quality of Experience is important for several reasons including transition to all IP video, early detection of IP video infrastructure issues, enable self-healing, and video customer retention. VVQ meets these needs by presenting one final overall score that holistically measures IP Video Playback QoE rather than looking at several distinct metrics individually.

The VVQ model utilizes several playback metrics such as rebuffering, playback errors, video quality, downshifts, startup latency, recency, and others to compute the score and was validated with production data and publicly available MOS scores. VVQ is flexible and conducive to implementation either in analytics engine or IP Video Player. One such reference architecture implementation and its results are shown in this paper. VVQ is actively being utilized to gauge IP video playback QoE on various IP video devices and troubleshoot playback issues.

One another key benefit is self-healing of issues in the IP video eco system utilizing VVQ scores.

Author would like to thank several Comcast Video research and engineering teams that assisted with this work.

1. Introduction

Network device provisioning (NDP) is a key component of the end-to-end system for service order fulfillment and activation. NDP is responsible for the configuration and service provisioning of subscriber's network devices. The DOCSIS network devices are the D2.0, D3.0, D3.1 and soon D4.0 modems, and their derivatives, such as set-top-box (STB) with embedded cable modem, media terminal adaptor with embedded cable modem (eMTA), eRouter, and more.

The number of device types, along with the number of available services applies a multiplication factor in the number of configuration files needed to provision. In the process of supporting tens of millions of individual devices and hundreds of services, the NDP of today is managing millions of DOCSIS configuration files. As network operators continue to invest in the roadmap to 10G, expanded network capabilities will add to the number of permutations of service and the number of device types involved. In addition, customers are expecting greater service agility in terms of faster development, deployment, and support for these innovative products and services offerings.

Although the DOCSIS subscriber management term is used extensively, currently the provisioning and management are done at the device level. This paper discusses an approach to modernizing today's device management and introduces new management systems with the goal of maintaining backward compatibility, employing network automation with dynamic service assurance, and increasing service activation velocity in support of the 10G technology roadmap. Use cases for current and possible future services are also covered towards a real subscriber management system.

2. Current Service Fulfillment Architecture

The service fulfillment architecture features a number of components that are vital to providing and implementing the customer's desired services (Figure 1).

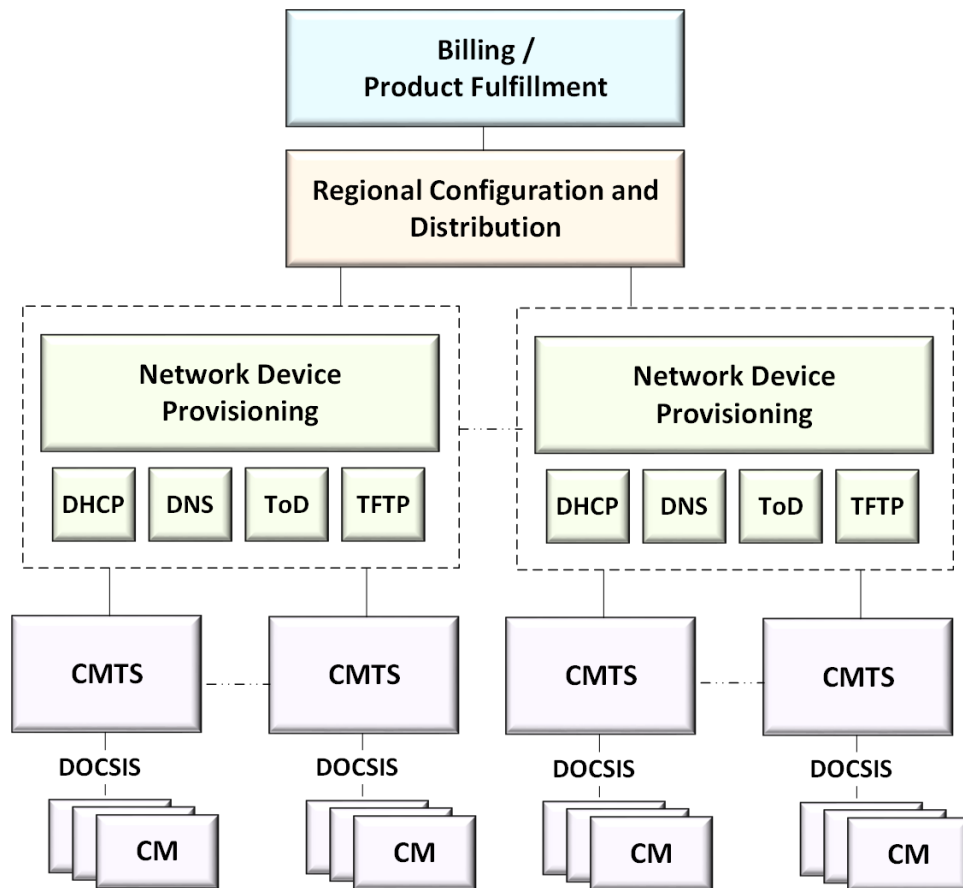

Figure 1 - Cable Service Fulfillment Architecture

As shown in Figure 1, a central provisioning and distribution system configures the servers and routers and distributes Dynamic Host Configuration Protocol (DHCP) instructions and device configuration files to the Device Provisioning Servers. These servers are integrated with the Network Registrar DHCP server to control the assignment of IP addresses for each device.

The devices supported by this architecture are the DOCSIS cable modems (CM) and embedded devices such as set-top-box (STB), media terminal adaptor (eMTA), eRouter, and more. The modem establishes DOCSIS data link layer connection to the cable modem termination system (CMTS), which in turn provides the L2 or L3 path to reach the NDP for its service provision and device configuration.

Figure 2 illustrates the main steps for CM initialization and registration. After ranging with CMTS and optional early authentication and encryption initialization, the IP initialization step takes place. The CM acquires an IP address in the cable operator address space, the current time-of-day, and a binary configuration file. The configuration files are delivered to the devices via the Trivial File Transfer Protocol (TFTP) server whose address is provided through DHCP information. During the registration step, the CMTS validates the configuration file contents sent by the CM, activates Medium Access Control (MAC) layer resources accordingly and sends MAC layer identities to the CM, as described in detail in CableLabs MULPI specifications. Services are defined statically in the configuration file except for dynamic services

that support eMTA voice service configuration file. Different service flows (SF) including High Speed Data, Voice Signal, Video data and signal, Community Wi-Fi and Business Services over DOCSIS (BSoD) services are defined with corresponding classifiers and QoS settings. Operators often use Service Class Names (SCN) that are defined in the CMTS and mapped to SFs in the configuration files but may include explicit service definition TLVs as well. A variety of other service attributes such as number of IP addresses, packet classifiers, and even diplexer settings may be included in the configuration files further expanding the unique sets of service attributes.

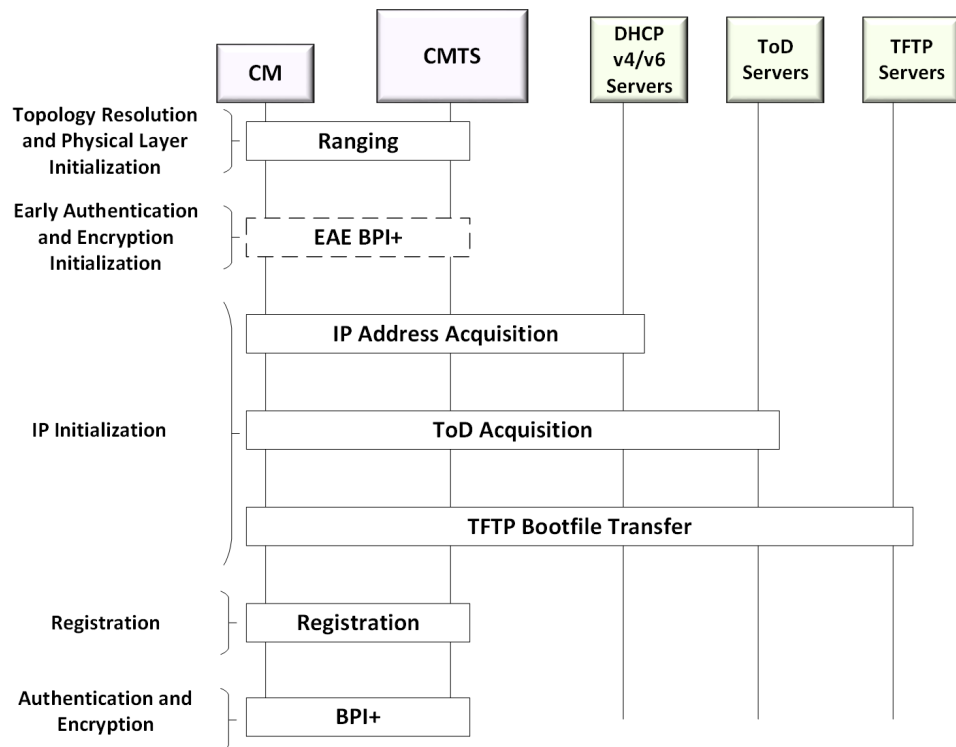

Figure 2 - Cable Modem Initialization and Provisioning

An SCN provides a set of Quality of Service (QoS) parameters for the SFs associated with it. At least two default SFs known as Primary Service Flows must be defined. As described in detail in the CableLabs OSSI specifications, the SCN also identifies the SF service characteristics to billing or customer service systems. Therefore, both SF identifier (SFID) and SCNs are used by the billing system. For most operators, the creation and integration of SCNs is a manual process.

Voice calls are established using PacketCable MultiMedia (PCMM) as shown in Figure 3. For eMTA voice calls, the SIP messages are delivered to P-CSCF that provides the reservation information to Policy Server (PS) for CMTS gate instructions. The Gate settings include classifiers and QoS settings defined for Upstream Unsolicited grant service (US UGS) and Downstream Best Effort (DS BE) calls. The PCMM architecture can also be used for non-voice SFs such as HSD SFs. All HSD dynamic SFs must be created using an SCN defined in the CMTS if the service is processed by the billing system with the current

architecture. The details on the PCMM architecture and OpenDayLight implementation of a Policy Server can be found in [6].

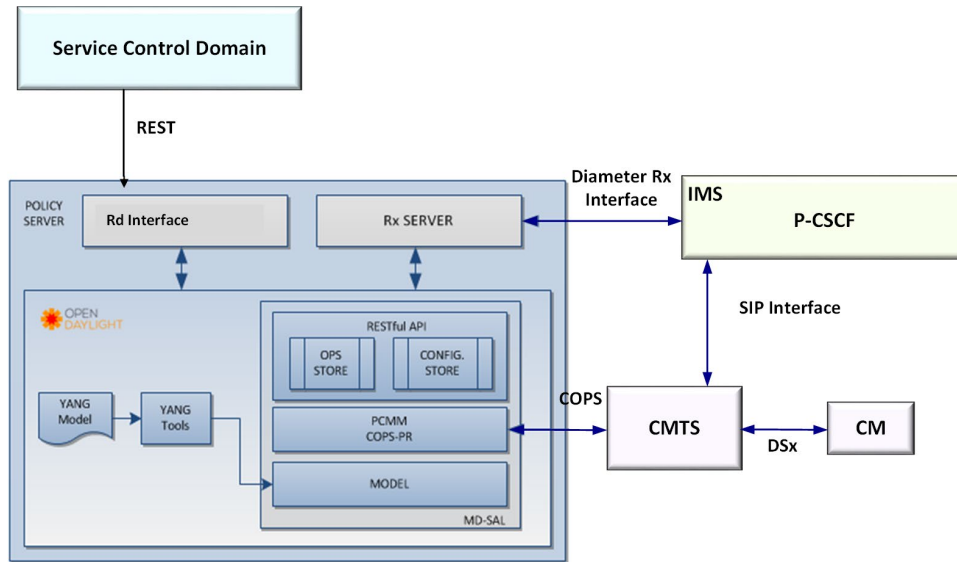

Figure 3 - PacketCable MultiMedia Architecture

2.1. Challenges

This section covers the challenges operators face with traditional network provisioning systems with the focus on DOCSIS CM and service provisioning.

2.1.1. Scaling

New configuration files are introduced for new speed tier rates and CM models and versions. Different number of CPE IP addresses and security attributes also require new configuration files. Furthermore EOL devices that are not swapped but required to support additional speed tier rates increase this number. If the configuration file management is not effective, e.g. not fully automated, many unused configuration files may exist within the operator's active database. In the process of supporting tens of millions of individual devices and hundreds of services, the NDP of today may be required to manage millions of DOCSIS configuration files.

Manual processing steps in the creation, update and deletion of a high number of configuration files may create issues in the existing deployments and new service launch.

2.1.2. Service Agility

Service agility for the 4As to have “Any content, Anywhere, Anytime and on Any device” is the ultimate goal for the ISPs. The key points of service agility are:

- Fast development of innovative products and services
- Configuring the services according to changing customer behaviors and requests
- Deploying new products and services without breaking existing systems and creating new issues
- Operating the services and underlying networks through proactive management techniques

A survey conducted by the TM Forum in October 2018 [1] shows that legacy Operations and Business Support Systems (OSS/BSS) remain the biggest challenge to network transformation causing slow progress. However, more recent TM Forum research [2] shows that 80% of ISPs have started to implement or benefit from digital transformation programs during the Covid-19 pandemic, which shifted the focus to customer experience and operations digitalization. Modular and configurable BSS are being adopted to reduce customization costs.

To achieve optimized service lifecycle management [3], some existing MSO systems, which have not been changed for more than two decades, must be replaced by a new design with automated service workflows and microservices. Today, the workflows for a new service and subscriber activation include manual steps for device and resource provisioning. The system is prone to human error, not suitable for fast activation and deployment and hard to operate and provide service assurance. These systems require customer equipment to be staged and configured initially in the warehouse and then shipped to the customer premises for installation. It also creates more need for dispatching technicians to activate services.

In these systems, initial estimations of the service group size and traffic load are used to project current and future scaling requirements. Therefore, service to resource mapping is not adaptable to more granular service and network changes. Traditional polling-based monitoring of data and manual troubleshooting create obstacles for automation and scaling.

To mitigate these issues, operators have started to automate the workflows gradually. A critical workflow that needs automation is the network infrastructure and device configuration.

2.1.3. Network Programmability

Service agility requires dynamic mapping of services to underlying network resources and automated provisioning based on traffic characteristics and service policies. The network resources may be physical or virtual function components and can be located in customer premises, the field, edge network, core network or in the cloud. The same network functionality may be distributed in different locations and scales.

Today, MSO networks consist of different access networks such as HFC, PON, Carrier Ethernet and Wireless. Redundant access networks and multi-path technologies are also being deployed with new service requirements. Although access networks have different resources and functionalities, the service to resource mapping and automated provisioning of workflows must be unified for effective service deployments and operations [3,4]. This can be achieved through microservices that can be reused by

different technologies. In this case, the services may be defined without requiring specific knowledge on the underlying technology. Such abstraction is crucial for both service agility and network programmability.

As an example of the current obstacles, today in most Cable operators' networks, configuration file TLV settings and SCN settings are provisioned separately. This creates an obstacle to change the network and device settings for customer needs without requiring a reset and interruption of the services. If a combination of SCN and explicit TLVs is used for modem provisioning, having a TLV value to be optimized based on an SCN parameter may not be feasible in this case. Optimization may require a vendor or the operator to introduce a new firmware code. This approach also makes network functionality upgrades impossible or very hard for early versions of the network components. For instance, a new optimization defined in the specifications can be applicable for both D3.0 and D3.1 modems but the operator may choose to apply it only for D3.1 since the code upgrades by the vendor for D3.0 may not be active.

Another example is the introduction of new speed tiers in the upstream direction. Mid-split and High-Split Enablement use cases involve CMs to range to OFDMA channels. This process has the following issues:

- It requires reconciliation among different tools and settings (SCNs and per CM Configuration file CoS)
- Backward compatible solutions must exist for iCMTS/iOLT but allow for more flexible solutions for vCMTS/vOLT
- Some of the new systems like FDX and PON do not use diplexers, requiring different provisioning
- Each new system must support different new modem models which require new configuration files

Not having programmable systems, e.g. requiring more configuration files also has direct scaling consequences.

One gradual step MSOs may take is to use PCMM based Dynamic Service Flow management for non-voice services. The current deployments are mostly for voice calls that are based on RSVP type resource allocation and management. This system may not be optimal for general dynamic service flow management and many ISPs have to pay license to a third party due to implementation and management complexities. Gradually, open source and APIs should be developed and adopted for all SF types.

2.1.4. Operations

Today manual and siloed workflows and resource management systems create obstacles for lighter operations and automated processes. Functionalities common to multiple access technologies such as subscriber management filters are implemented and managed differently depending on the access network. Therefore, multiple components with the same functionality are configured and operated for different implementations and APIs.

Services and network components are intertwined. Service definitions still include access network attributes, and they are not access technology agnostic. The billing system must know the SCNs defined in the access network provisioning system. The lack of abstraction is a challenge on the road to automated

service operations. Therefore, a unified service chaining over digitized network components cannot be deployed over multiple access technologies.

Having operational parameters of a CM provisioned using configuration files creates obstacles for a self-optimizing system without service disruption.

Therefore, there is a need for new network provisioning and subscriber management systems. The next section describes a solution that can be implemented as a first step towards completely agile service and automated network management.

3. Proposed Solution

3.1. Device Management Application

The proposed solution must be backward compatible, interoperable, and incremental because the existing back-end system is vast and impossible to replace as a single unit. Backward compatibility and interoperability are required for the front-end facing interfaces to cable modems and backend facing interfaces to the existing Billing-Production Fulfillments and NDP components.

The proposed solution is to introduce the device management application (DMA) component to proxy the interfaces between NDP, CMTS and modem devices. The DMA provides a light-weight API interface as an alternative, programmatic provisioning interface that enables a path toward modernizing the backend systems. Figure 4 illustrates the end-to-end (E2E) system model view.

The DMA has the following components (Figure 5):

- TFTP Client for downloading modem configuration file from NDP on behalf of modem devices,
- TFTP Server for modem devices to download their configuration file,
- Configuration File Manager (CFM) for managing the DOCSIS modem configuration file,
- API server for external orchestration application to programmatically managing modem devices provisioning,
- Device Database for modem devices configuration and provisioning attributes

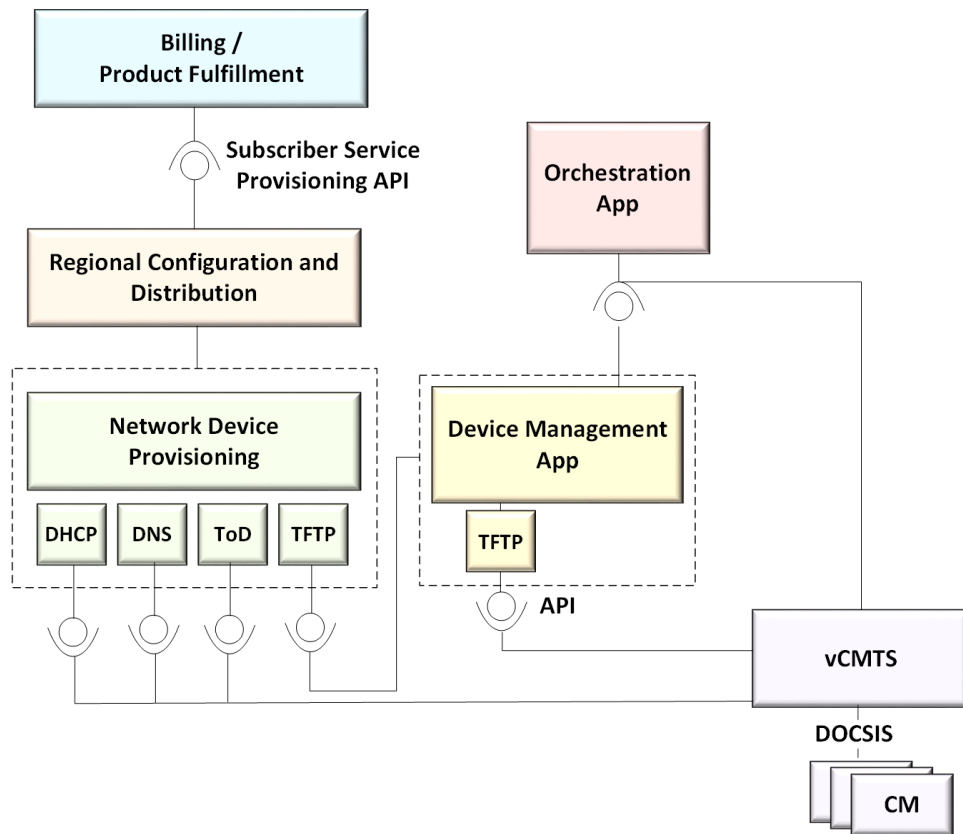

Figure 4 - E2E System Model

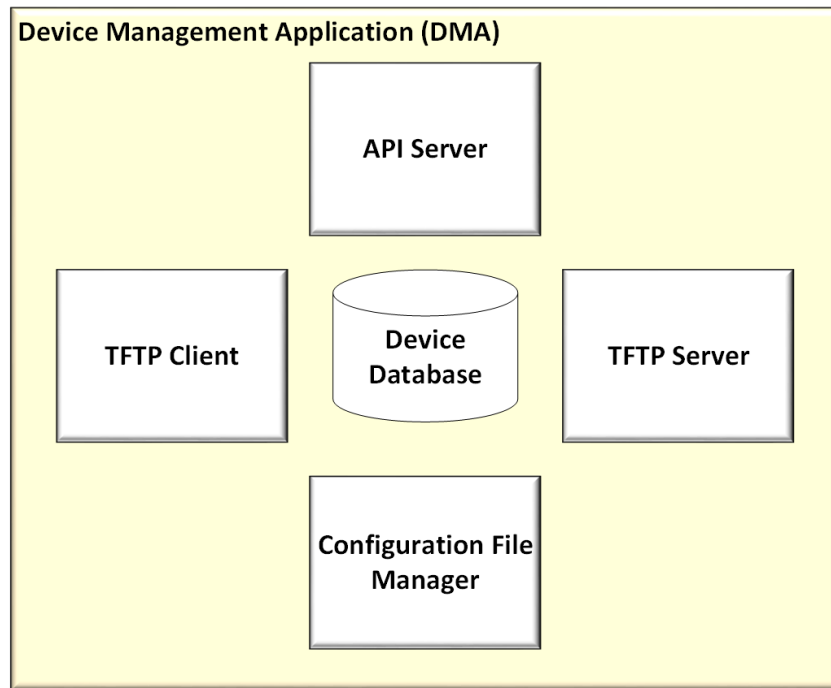

Figure 5 - DMA Component View

In the following subsections, the key functions and concepts are described.

3.2. Device Database

The device database must be persistent and highly available. Its database schema must support all objects and attributes in the DOCSIS modem configuration file. The schema must be extensible to support devices such as ONU for PON. The schema could support classifiers, policy rules and intent objects.

Automated database management without manual processes is needed to reduce errors and increase the speed of introducing new devices and services. Otherwise, increased number of device configurations may not be manageable and create scale and maintenance issues.

3.3. TFTP Proxy

DMA is the TFTP proxy server, consisting of TFTP client, TFTP server and configuration file manager (CFM) components. The configuration file manager downloads the configuration file on behalf of the cable modem. The configuration file is parsed, and the provisioned objects and their attributes are stored in the device database. At a high level, the sequence of events is:

- When modem sends DHCP request, CMTS DHCP relay agent would replace DHCP options 66 (TFTP server name) and 150 (TFTP server IP address) to DMA's internal TFTP server FQDN and IP address.
- CMTS then notifies the CFM.
- CFM initiates the TFTP client to download the modem configuration file from the NDP on behalf of the cable modems.
- CFM parses, validates, and updates the device database.
- CFM finally regenerates a new configuration file for the modem to TFTP download.

The DMA enables the combination of NDP provided configuration file and locally inserted device configuration attributes by regenerating a new configuration file and offering it to the cable modem.

3.4. Lightweight REST API

As an alternative to NDP, the API server provides REST interface for other orchestration applications to programmatically provision a modem. The API provides access to the provisioned objects and the attributes in the device database.

As described earlier, the device database schema is extensible to support objects such as:

- Policy, Rules, and Intents
- Device Classifiers
- New Service Offerings

These objects will be newly defined, beyond the scope of the existing DOCSIS configuration file. The objects are meant to be consumed by the CMTS or OLT at the core side for the active management of the device devices.

3.5. Deployment

The distributed access architecture (DAA) specification was introduced to evolve and modernize access network performance. This split allowed the core functions to run on a cloud computing platform. As such, virtualized CMTS (vCMTS) is a collection of software applications for the core functions. It is built upon a microservice architectural pattern and targeted for cloud computing platforms.

Here, vCMTS as platform is referring to the deployment of vCMTS core function software in MSO private cloud. In contrast, the integrated CMTS (iCMTS) represents the traditional custom hardware CMTS platform.

During the MSO roll out of the vCMTS platform, the production environment will have a mix of vCMTS and iCMTS components. It is essential for DMA to support new service offering across all iCMTS and vCMTS systems in the footprint. With that in mind, the DMA application can be deployed either in the MSO regional data center or public clouds.

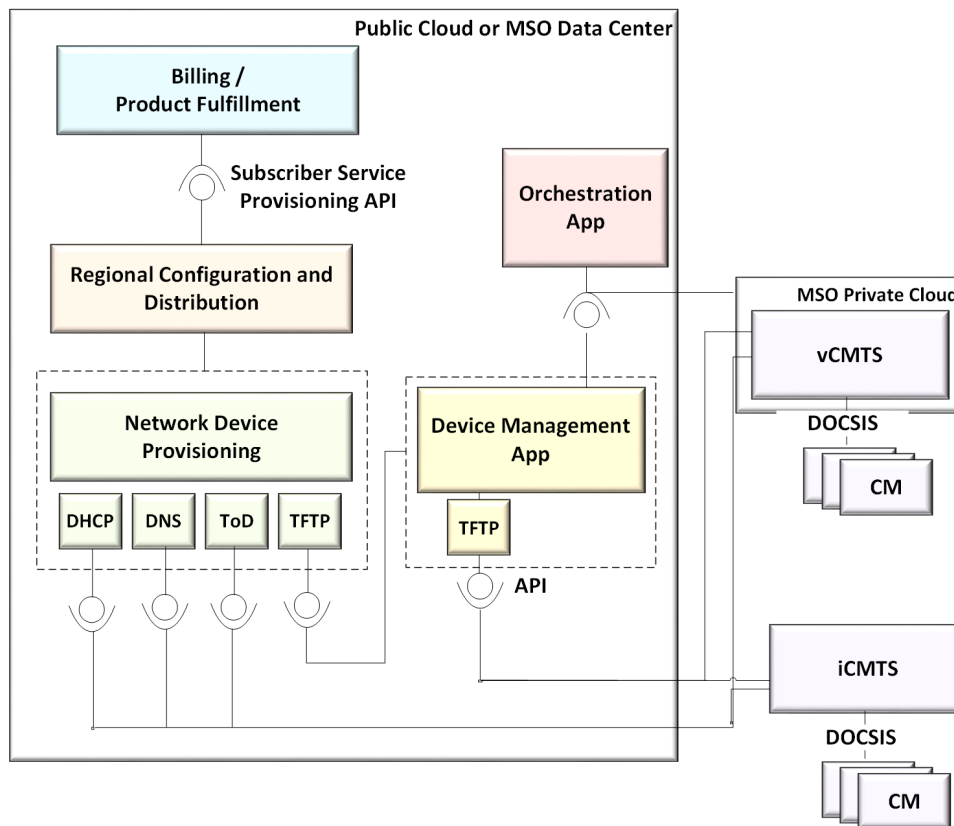

Figure 6 - DMA Deployment Diagram

4. Use Cases

4.1. Mid-Split Enablement

The benefits and challenges to Mid-split deployment are well documented in [5]. The obvious benefit is that a mid-split plant doubles the upstream bandwidth of the standard-split (aka low-split) plant. The challenges are:

- Coexistence of Mid-split (MS) and Standard-split (SS) CPE, where the MS-CPE and SS-CPE share the cable feed through a splitter. With imperfect isolation, the MS-CPE's upstream OFDMA signal may leak into the SS-CPE's downstream RF front end.
- Old infrastructure components such as drop-amps and splitter that makes MS-CPE inoperable on the OFDMA channel.

A detection and mitigation mechanism is proposed in [5] to address the above challenges. The mitigation mechanism is to steer the modem via the configuration file or DBC. Customizing modem configuration file at per device level is operationally challenging. The mechanism to DBC the modem requires external application to be developed, CMTS to expose its DBC API, and re-apply whenever the modem re-registers.

The management and mitigation mechanism can be simplified by utilizing the device management application. The interference detection tool would invoke the DMA API to update modem having SS-CPE interference or drop-amp. CMTS queries the DMA during modem registration. If the device database has

the interference attributes set, then the CMTS would enforce the OFDMA channel exclusion as part of the transmit channel set assignment process. Reports of modems having these types of interference can be easily obtained by querying the device database.

4.2. New Service Offerings

Operators are interested in providing personalized solutions for their subscribers without the need to have custom solutions for their network and service platforms. For example, services to support low latency applications, speed boost and continuation of speed rates over wireless (home and on-the go use cases) can be supported per subscriber's status and preference.

These services can be turned on and off by the subscriber or service options may be available to subscribers. In this case, an agile service platform can support runtime changes without interruption and resets. An example is provided in Figure 7 where Low Latency and Speed-Boost requests can be fulfilled dynamically using a PCMM based system. A REST API may provide the request to the PCMM that in turn opens or deletes gates for the vCMTS. As an alternative, PCMM gates may be integrated with Device Management App to facilitate future architectures (Figure 7).

Current PCMM specifications, at the time of publishing this paper, do not include Aggregate SF cases as defined in Low Latency DOCSIS specifications. However there is an increasing interest to extend PCMM SF definitions and have Policy Server implementations that are based on open source code and standard APIs.

This architecture can be further extended to use DMA only at the first initialization of subscriber devices and services or to remove it completely. In the former case, a basic common configuration file may be used to initialize the CM with primary SFs. Then, actual SFs can be dynamically provisioned using Orchestration app and PCMM. When backward compatibility is not needed and standard APIs may be used directly to configure the CMs, DMA may be replaced. This architecture is also a first step to have automated subscriber management by provisioning network and device components per subscriber service status and preferences.

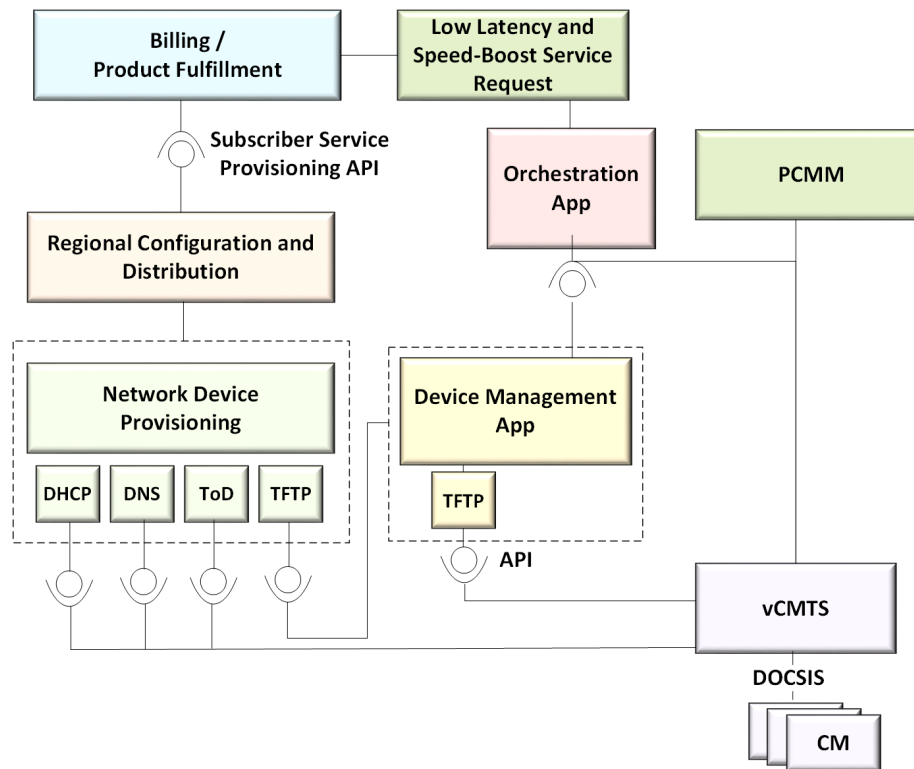

Figure 7 - New Service Use Cases

4.3. vBNG

CableLabs' DOCSIS Provisioning of EPON (DPoE) specification enables MSO to deploy EPON technology using the existing DOCSIS based backend systems. As shown in Figure 8 the ONU is emulated as virtual cable modem (vCM).

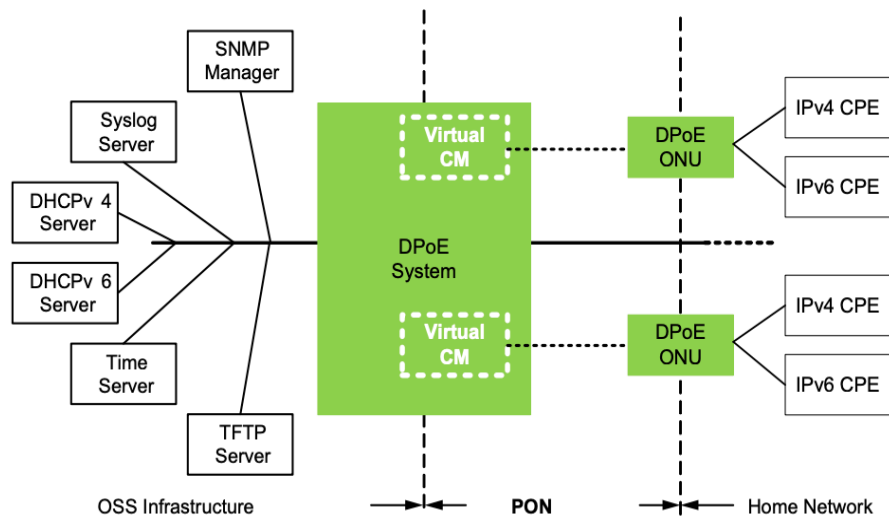

Figure 8 - DPoE-SP-MULPIv2.0 vCM Model

As MSOs are rolling out vCMTS platforms, the same private cloud can host virtual broadband network gateway (vBNG) [4] application to support EPON technology.

vBNG can be developed to utilize DOCSIS based NDP. In this case, vBNG invokes DMA provided API to initiate the download of the vCM configuration file and to query for the ONU device and service provisioning objects as shown in Figure 9.

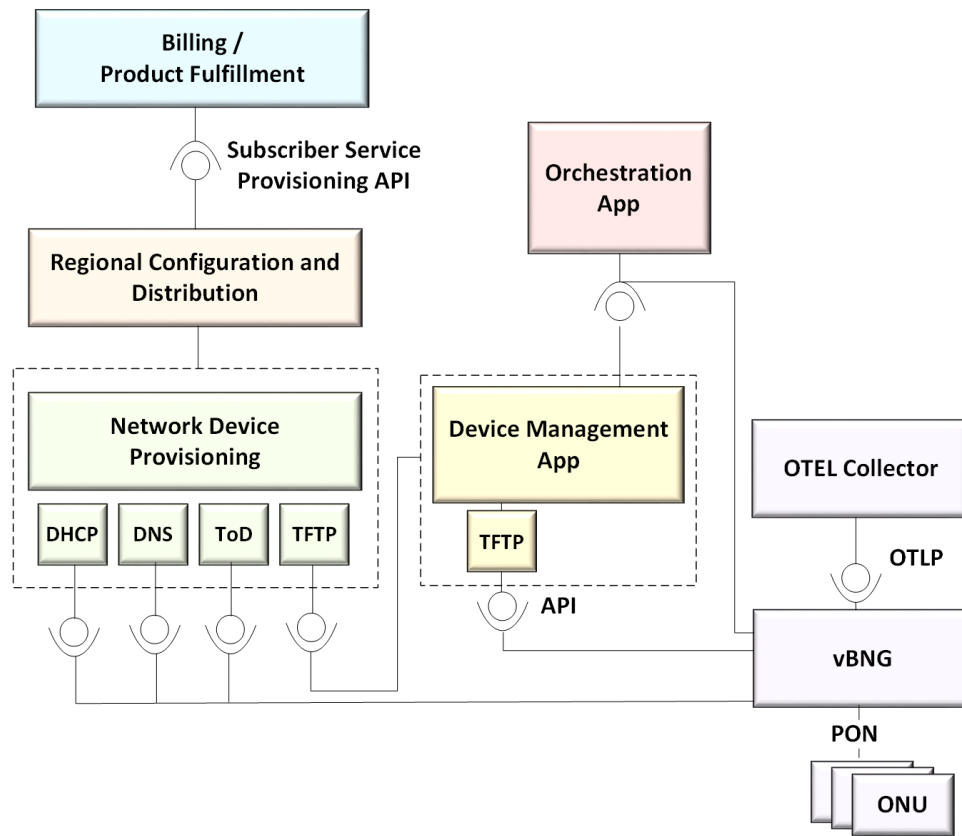

Figure 9 - vBNG System Components Utilizing DOCSIS Based NDP

The observability aspect of the operational support systems (OSS) for vBNG can be modernized by utilizing vendor-neutral open-source observability framework such as OpenTelemetry (OTEL).

5. Conclusion

The proposed DMA provides a path forward for modernizing the device management systems. It maintains backward compatibility and interoperability with the existing NDP systems. At the same time, it enables steps toward agile service deployments with programmable and automated networks. The DMA provides a programmatic interface to external applications to access the device database. The external application can be a CMTS, utilizing the DMA for the active management of subscriber services.

The proposed device management systems enable the operator to meet the goals of maintaining backward compatibility, employing network automation with dynamic service assurance, and increasing service activation velocity in support of the scalable 10G technology roadmap. The solution can be extended to unify management of access networks and introduce dynamic services with low latency and speed-boost support. These new services can be personalized based on the subscriber's status and preferences using dynamic SF provisioning. This architecture enables MSOs to integrate device, subscriber and service management as a unified system.

This is a crucial step to achieve optimized service lifecycle management. Operators started to transition to automated service workflows and microservices and have been deploying SDN, NFV and cloud enabled access networks [3]. The new system supports existing services while being upgraded for new services such as Gig Symmetric (Mid-Split, High-Split and FDX), MVNO and Low Latency services. As more services are being introduced at a faster pace and service personalization is becoming more crucial, a fully automated system as illustrated in Figure 10 is needed. The orchestrator and controllers use telemetry data and system knowledge to map services to resources, instantiate and manage the service and network microflows, and program and configure resource components. Once such a system is adopted, it can support dynamic changes to support customer runtime requests or network needs. Abstraction between services and resources can help to support multiple access technologies in a harmonized way, either as single or simultaneous technologies serving the same subscriber.

The following list describes the steps needed for modernizing device, service and subscriber management systems:

- Abstracted service and digitized resource management independent of underlying technologies
- Data and knowledge center based on cloud-enabled and push-based telemetry with standard APIs
- Data-driven orchestration for self-optimizing and scaling systems
- Microservices instead of monolithic functionalities and meshed service chains
- Containerized SW for faster initiation, efficient execution, and better isolation
- Automated inventory and topology management
- Zero touch installation and self-activation systems
- Customer centric personalization without requiring customized designs and operations

1. Introduction

Hybrid fiber cable (HFC) or data over cable service interface specifications (DOCSIS) networks are the most widely deployed technology for delivering Internet data services to the consumers. Cable operators today have variety of choices in front of them, in terms of upgrading and evolving their HFC networks. The upgrade choices with the current DOCSIS 3.1 technology includes Mid-split, High Split and distributed access architecture (DAA) and extending the downstream to 1.2 Gigahertz (GHz). With DOCSIS 4.0 technology there are even more plant upgrade options, from Full Duplex DOCSIS to the four new Ultra High Split upstream options (up to 684 Megahertz (MHz)) and the Extended spectrum to 1.8 GHz for the downstream. For each of these scenarios, operators are interested in knowing what are the data capacities that the system can realize from each of these plant upgrades. Also, for a consumer service, what are the potential service tiers that could be realized within each of these technology options. This paper gives a detailed analysis on each of these scenarios and layout the possible spectrum options for an operator given the different types of plant conditions. Understanding these options is a very important tool in figuring out what services can be reliably deployed. The cost benefit analysis for each of these options will help answer various for tactical and strategic network planning questions.

1.1. DOCSIS Evolution

DOCSIS 3.1 uses orthogonal frequency-division multiplexing (OFDM) for downstream modulation. In the downstream direction, the cable system is assumed to have a pass band with a lower edge of either 54 MHz, 87.5 MHz, 108 MHz or 258 MHz, and an upper edge that is implementation-dependent but is typically in the range of 550 to 1002 MHz. Upper frequency edges extending to 1218 MHz, 1794 MHz and others are expected in the upcoming DOCSIS 4.0 technology deployments in the plant. Within that pass band, digital television signals in 6 MHz channels are assumed present on the standard, as well as other narrowband and wideband digital signals.

The cable modem (CM) supports a minimum of two independently configurable OFDM channels each occupying a spectrum of up to 192 MHz in the downstream. The demodulator in the CM supports receiving downstream transmissions up to at least 1.218 GHz and optionally support receiving downstream transmissions up to at least one or more of the following downstream upper band edges: 1.002 GHz, 1.218 GHz, 1.794 GHz.

1.2. Technology Evolution

Allocating more spectrum to broadband is a priority for cable operators. Initially all of the downstream spectrum was allocated for carrying video programming. Over the past ~25 years, the downstream has transitioned by migrating the spectrum from video to broadband. In addition to transitioning the existing spectrum to broadband, there are several scenarios where additional downstream spectrum can be added and used for broadband service. Analyzing downstream DOCSIS capacity is different than analyzing upstream DOCSIS capacity. For the initial evolution from DOCSIS 1.0 to 2.0 to 3.0, the upstream spectrum allocation was fairly straightforward because the spectrum was mostly unused and could be allocated to broadband. In the last many years, upstream has become the bottleneck for cable networks, and is now driven by shifts in user behavior and symmetrical competition. Ultimately this became the primary driver for today's capacity upgrades, be it mid-split or DOCSIS 4.0. Downstream spectrum is much wider than upstream spectrum, and it also carries video signals. The table below shows the evolution in the spectrum supported by a cable modem for each DOCSIS version.

Table 1 – CM Spectrum Support

DOCSIS Version	Downstream Spectrum (usable)	Upstream Spectrum (usable)
DOCSIS 1.0	6 MHz	6.4 MHz
DOCSIS 1.1	6 MHz	6.4 MHz
DOCSIS 2.0	6 MHz	6.4 MHz
DOCSIS 3.0	24 to 192 MHz	25.6 (to 51.2) MHz
DOCSIS 3.1	576 MHz	192 MHz
DOCSIS 4.0	1152 MHz	Frequency Division Duplex (FDD) CMs 272/ 368/ 464/ 656 MHz Full Duplex DOCSIS (FDX) CMs 272/ 464/ 656 MHz

As shown by Table above the trend has been for each DOCSIS version to require more downstream and upstream spectrum support on the modem. The DOCSIS 3.0 specifications was a seminal moment when channel bonding was introduced. Early DOCSIS 3.0 modems would support up to 24 MHz of downstream spectrum, and the last DOCSIS 3.0 modems supported up to 192 MHz of downstream spectrum (256 MHz of downstream spectrum if Annex A quadrature amplitude modulation (QAMs) were used).

1.3. Spectrum Evolution

The cable modem termination system (CMTS) has more variability—it can support the minimum requirements as described above or it can support additional DOCSIS spectrum when there is spectrum available in the cable plant. With the move to both more broadband and Internet Protocol television (IPTV), and a recent trend is for a CMTS to support more downstream spectrum than a modem.

About 20 years ago, cable plants were carrying analog television (TV) signals. In North America, this equated to allocating 6 MHz of spectrum, one Consumer Technology Association (CTA) channel, to carry one analog TV channel in the National Television System Committee (NTSC) format. A sub-split 750-MHz system can carry about 115 CTA channels (each 6 MHz) for a total of 690 MHz of downstream spectrum.

Digital video technology was already on the rise to pack more television programming into a single CTA channel. MPEG-2 encoding allowed a single 6-MHz CTA channel to carry up to 10 standard-definition NTSC or 3 high-definition NTSC channels. MPEG-4 encoding allowed up to 17 standard-definition and about 9 high-definition NTSC channels to be put into a single 6-MHz channel.

Today, the coaxial cable is assumed to carry around 300 MHz of video programming. The amount of spectrum allocated to video programming varies widely, and 300 MHz is chosen as a "nominal" number. There are numerous solutions that can raise or lower that number, including the use of MPEG-4 encoding, switched digital video, and migration to IPTV. This number is assumed to go down as video switches to IPTV solutions.

Before 2008, the DOCSIS 1.0, 1.1, and 2.0 systems used only one downstream channel, a 6-MHz CTA channel. Since 2009, the DOCSIS 3.0 deployments allowed more downstream spectrum to be used for broadband, starting with four DOCSIS downstream channels (24 MHz) and, eventually, products that supported up to 32 downstream channels (192 MHz). The rise of digital video coincided with the availability of DOCSIS 3.0 technology, all around 2008, and spectrum that previously carried analog TV channels could now be reclaimed to carry both digital TV and broadband. As the internet bandwidth

consumption continued to rise, the need for additional spectrum for broadband became apparent. Around 2016, DOCSIS 3.1 technology was made available, resulting in the downstream needing additional spectrum for the new OFDM technology.

1.4. Modem peak speeds and service Tiers.

An old rule of thumb which multi system operators (MSOs) use is to offer a service tier which is about half of the CM's peak throughput capacity. (CM Capacity/Service Tier = 2/1) As service group bandwidth capacity increases with CMTSs providing more channels than the modem can handle, this ratio is slowly edging closer to the modem's peak capacity. We are now starting to see ratios of 1.5/1 or lower, as the higher network bandwidth capacity allows operators to take better advantage of the statistical multiplexing inherent in a medium like the DOCSIS network.

The throughput numbers described in this paper is peak broadband capacity per modem. As will be seen in the cases, the coaxial cable/CMTS can support more broadband capacity than a D3.1 CM or D4.0 CM can use, which can be used for load balancing and increasing service tiers. For purposes of this paper, the channel conditions are assumed to be good enough to get to the better/top modulation orders. All the capacity numbers are calculated as described in our previous paper [D3.1 Capacity]. Numbers will need to be adjusted if the actual channel conditions are lower than expected in certain deployments.

2. D3.1 Technology Options

This section talks about the various configurations which in operator can implement when deploying DOCSIS 3.1 technology and the capacities for each setting. An operator typically has one of the following types of networks in which they can deploy D3.1 technology. The first (and most common in the past), is a low split network with the upstream ranging from 5 to 42 MHz and the downstream ranging up to 750 or 860 MHz. The next is a mid-split network with the upstream ranging from 5 to 85 MHz and the downstream ranging up from 108MHz up to 1 GHz. The third is a high split network with the upstream ranging from 5 to 204 megahertz and the downstream ranging from 258Mhz to 1.2 GHz. Some operators may have networks with different combinations of the downstream with the upstream depending on when those plant upgrades were done.

2.1. Legacy Low Split with 750 MHz

Let's start with the legacy DOCSIS 3.0 plant with a low split for the upstream (42 MHz), and a 750 MHz plant for the downstream. The typical configuration used by MSOs has been 4 SC-QAM upstream channels and anywhere from 8 to 32 SC-QAM downstream channels. An operator would use 6.4 MHz channels upstream carriers and placing them directly adjacent to each other and using the modulation orders to 64 QAM for the upstream SC-QAM carriers.

Figure 1 – Legacy D3.0 Plant

With four 6.4-MHz-wide channels operating at 64 QAM, the aggregate throughput of the CMs is about **106 Mbps**. With 32 x 6 MHz-wide channels operating at 256 QAM, the aggregate throughput of this CM on the downstream is about **1.2 Gbps**.

2.1.1. Legacy Low split with 750 MHz, Adding OFDM, Adding 5th SC-QAM

Here we stay on to the legacy low split plant with the upstream still at 42 MHz, and a 750 MHz plant for the downstream. The downstream has the 32 SC-QAM downstream channels and with the DOCSIS 3.1 technology being introduced, we now have a new additional 96 MHz OFDM channel deployed, typically at the higher band edge of the downstream spectrum.

As a final step for the upstream in a sub-split network, operators could try adding one or more additional upstream SC-QAM carriers, up high or down low, as shown in Figure. The paper [Bandwidth Growth] draws the conclusion that even adding 10% additional upstream capacity can help alleviate upstream congestion. Operators have been successful in adding new carriers, which is a testament to maintaining the plant more diligently over the last decade. So, in many operator networks, the upstream configuration now adds a 5th SC-QAM channel.

The number of homes passed has decreased, which lowers the effect of noise funneling at low frequencies, and cascades have shortened, which lessens the impact of group delay close to the duplex filter cutoff frequency. Operators have been successfully running narrow carriers (typically with lower order modulation) both down to 10 MHz and closer to the duplex filter.

With 5 x 6.4-MHz-wide channels operating at 64 QAM, the aggregate upstream throughput of the CMs is about **133 Mbps**. With 32 x 6 MHz-wide channels operating at 256 QAM, and an additional 96 MHz OFDM channel (at 4096 QAM) the aggregate throughput of this CM on the downstream is ~ **2.1 Gbps**.

Figure 2 – D3.1 Deployment on a Low Split Plant

2.1.2. Legacy Low Split with 750 MHz, with OFDMA

Here we stay on the legacy low split plant with the upstream still at 42 MHz, and a 750 MHz plant for the downstream. For the upstream configuration, an operator could bring the number of SC-QAM upstream channels down to 1 and add a 25.6 MHz orthogonal frequency-division multiple access (OFDMA) channel. While this may not be a realistic scenario, due to the number of D3.0 CMs that may need to be supported, this is an interesting thought exercise on the capacity increase on the upstream for a low split plant. The downstream stays at 32 SC-QAM downstream channels and the 96 OFDM channel.

With a 25.6 MHz OFDMA channel operating at the max of 2048 QAM, along with the 1 SC-QAM channel, the aggregate upstream throughput of the CMs is about **267 Mbps**. With 32 x 6 MHz-wide channels operating at 256 QAM, and an additional 96 MHz OFDM channel the aggregate throughput of this CM on the downstream is about **2.1 Gbps**.

Figure 3 – D3.1 Deployment on a Low Split Plant w OFDMA

2.1.3. D3.1 Low Split Upstream and 860Hz Downstream

If the sub-split deployment cannot be changed and there are enough DOCSIS 3.1 modems on the network, operators can consider replacing SC-QAM channels with an OFDMA channel. OFDMA technology makes better use of spectrum because it can operate nominally at 1024 QAM, whereas an upstream SC-QAM channel is limited to 64 QAM.

In this scenario, the legacy low split plant stays with the upstream at 42 MHz, and an 860MHz plant for the downstream. For the upstream configuration, an operator could bring the number of SC-QAM upstream channels to 3 and add a 12.8 MHz OFDMA channel. The downstream has 32 SC-QAM downstream channels and two 192 MHz OFDM channel. (Leaving about 226 MHz for about 37 CTA/video channels)

With a 12.8 MHz OFDMA channel operating at the max of 2048 QAM, along with the 3 SC-QAM channels, the aggregate upstream throughput of the CMs is about **200 Mbps**. With 32 SC-QAM channels operating at 256 QAM, and an additional 2 x 192 MHz OFDM channel the aggregate throughput of this CM on the downstream is about **5 Gbps**.

Figure 4 – D3.1 Deployment on a Low Split Plant and 860 MHz

When there is a higher percentage of DOCSIS 3.0 modems on the network, as those modems cannot use the DOCSIS 3.1 spectrum, it may make sense to replace the second OFDM channel with 32 SC-QAM channels. When there is a higher percentage of DOCSIS 3.1 modems on the network, the 2 OFDM channels will provide more OFDM capacity for those modems to use. Because this case has more spectrum allocated to DOCSIS 3.1 technology, the aggregate throughput is 5 Gbps.

2.2. D3.1 Mid-Split

A mid-split HFC network has a return path of up to 85 MHz, or two times the spectrum of a sub-split network. With a mid-split, the forward path begins around 108 MHz; therefore, set top box (STB) based video services should be able to be maintained because the forward data channel can be up to 130 MHz. The additional upstream spectrum provided by a mid-split network can provide about 500 Mbps of capacity. Per the [PHYv4.0] specifications upstream SNR must increase from 22 dB for 64 QAM to 35 dB for 1024 QAM. An upgrade to mid-split offers the MSO an opportunity to access cleaner upstream spectrum to achieve this improvement. The SC-QAM channels depicted here may need to operate below 64 QAM if the mid-split upgrade does not also improve upstream SNR at the lowest frequencies. The downstream extends to a 1GHz plant but allows the same number of channels tunable by the CM as in the above scenarios. With 32 SC-QAM channels operating at 256 QAM, and an additional 2 x 192 MHz OFDM channel the aggregate throughput of these CMs on the downstream is about **5 Gbps**.

2.2.1. Start with SC-QAMs

In terms of additional upstream spectrum, a mid-split can be configured in several ways. As shown in the figure, a mid-split can fit 10 traditional upstream SC-QAM carriers of 6.4-MHz width (for a total of 64 MHz of upstream spectrum allocated to broadband).

Figure 5 – D3.1 Deployment on a Mid-Split Plant

This configuration can yield up to **265 Mbps** of aggregate upstream capacity. Note that DOCSIS technology allows SC-QAM to be modulated up to 256 QAM and no higher. That is, with SC-QAM, 512 QAM and 1024 QAM are not available. However, the newer DOCSIS 3.1 technology does allow higher order QAM modulation.

2.2.2. Add an OFDMA Channel

Figure shows another configuration of the traditional 4 upstream SC-QAM channels along with a 49.5 MHz OFDMA running at 2048 QAM up to 85 MHz.

Figure 6 – D3.1 Deployment on a Mid-Split Plant with SC-QAM and OFDMA Channels

This configuration can yield up to **572 Mbps** of aggregate upstream capacity and an increase of ~300 Mbps using the same spectrum because the OFDMA carrier can operate at a higher order of QAM modulation than single-carrier QAMs.

2.2.3. Replace with OFDMA

The next step for an operator could be to use 75 MHz of OFDMA, which can offer **708 Mbps** of upstream capacity, an increase of ~443 Mbps using the same spectrum. It may be necessary, however, to retain a single SC-QAM upstream channel for DOCSIS 3.0 modems.

Figure 7 – D3.1 Deployment on a Mid-Split Plant with OFDMA Channel

2.3. D3.1 High Split Deployments

A high-split HFC network has a return path of up to 204 MHz, or more than 4 times the spectrum of a sub-split network. With a high-split, the forward path begins around 258 MHz, so STB-based video services cannot be maintained because the forward data channel can only be moved as high as 130 MHz, as described in the SCTE-55 standards. However, the additional upstream spectrum provided by a high-split network can provide more than 1.8 Gbps of capacity.

An interesting observation is that a high-split 1.2-GHz system supports about the same amount of downstream spectrum as a sub-split 1-GHz system (12 MHz more downstream spectrum). The benefit of the high-split system is the additional upstream broadband capacity, though this additional 12 MHz of downstream spectrum can be used in a downstream OFDM channel. As a result, the approximate downstream throughputs for the 1.2-GHz system are only slightly higher than the sub-split 1-GHz system.

Though this system supports up to 1.2 GHz, many older CPE only support a lower top frequency. For example, early DOCSIS 3.0 modems were required to support only up to 870 MHz, though later DOCSIS 3.0 modems supported up to 1002 MHz. Similarly, different models of video CPE will also have different top ends. These constraints on CPE should be considered while laying out services on the coaxial cable.

2.3.1. SC-QAM and OFDMA

In the High-split plant, the upstream spectrum is up to 204 MHz, and a 1218 MHz plant for the downstream. The downstream configuration still remains about the same and can have 32 SC-QAM downstream channels and 2 x 192 MHz OFDM channels.

In the upstream spectrum, an operator can retain the 4 SC-QAM channels for DOCSIS 3.0 (and earlier) CMs and then expand the first OFDMA channel up to 108 MHz. Now the operator can add a second

OFDMA channel to the mix. This second OFDMA channel will start from 108 MHz and span up to 204 MHz.

This configuration can yield up to **1764 Mbps** of aggregate upstream capacity. With 32 SC-QAM channels operating at 256 QAM, and the 2 x 192 MHz OFDM channel the aggregate throughput of this CM on the downstream is about **5 Gbps**.

Figure 8 – D3.1 Deployment on a High-Split Plant with SCQAM & OFDMA Channels

2.3.2. Full OFDMA

In the scenario where there are no more D3.0 CMs in the plant, an operator can remove the 4 SC-QAM channels for DOCSIS 3.0 (and earlier) CMs and then expand the OFDMA channels to span from 12 MHz to 204 MHz.

Figure 9 – D3.1 Deployment on a High-Split Plant with Full OFDMA Channels

This configuration can yield up to **1988 Mbps** of aggregate upstream capacity. With 32 SC-QAM channels operating at 256 QAM, and the 2 x 192 MHz OFDM channel the aggregate throughput of this CM on the downstream remains at about **5 Gbps**. If the Operator can free up more downstream bandwidth, the CMTS can source more downstream channels, but a D3.1 CM can only use the 32 SC-QAM and 2 OFDM channels worth of bandwidth, but these additional channels will allow an operator to load balance the different CMs on the network better across the available DOCSIS channels.

3. DOCSIS 4.0 ESD/FDX Technology Options

The DOCSIS 4.0 specifications builds upon the previous generations of DOCSIS specifications. It includes backward compatibility for the existing physical (PHY) layers in order to enable a seamless migration to the new technology. The DOCSIS 4.0 specifications introduces Full Duplex (FDX) DOCSIS PHY layer technology as an expansion of the OFDM/A PHY layer introduced in the DOCSIS 3.1 specification to increase upstream capacity without significant loss of downstream capacity within the same available spectrum. The DOCSIS 4.0 specification also builds upon DOCSIS 3.1 OFDM and OFDMA technology with an extended Frequency Division Duplex (FDD)

DOCSIS alternative. DOCSIS 4.0 FDD supports legacy high-split and also provides extended upstream splits up to 684 MHz in an operational band plan which is referred to as Ultra-high Split (UHS). DOCSIS 4.0 FDD also introduces expansion of usable downstream spectrum up to 1794 MHz (Extended spectrum DOCSIS). Both the FDX and FDD DOCSIS 4.0 alternatives based on the OFDM/A PHY carry the cable networks into the 10G space.

3.1. D4.0 ESD/FDD Technology Options

The 1.8-GHz systems are intended for DOCSIS 4.0 equipment where the CMTS is specifically designed to place more broadband spectrum on the coax, both upstream and downstream. However, these systems need to be backward compatible with DOCSIS 3.1, DOCSIS 3.0, and perhaps DOCSIS 2.0 modems. The DOCSIS 4.0 specification builds upon DOCSIS 3.1 OFDM and OFDMA technology with an extended frequency division duplex (FDD) DOCSIS alternative. DOCSIS 4.0 FDD supports both mid-split and high-split and provides extended upstream splits up to 300/396/492/684 MHz in an operational band plan referred to as ultra-high split (UHS).

DOCSIS 4.0 FDD also introduces the expansion of usable downstream spectrum up to 1794 MHz to support higher upstream splits. An FDD CM supports at least two or more of the following upstream upper band edges: 204 MHz; 300 MHz; 396 MHz; 492 MHz; and/or 684 MHz. The FDD CM supports a minimum of 5 independently configurable OFDM channels each occupying a spectrum of up to 192 MHz in the downstream, while the FDD node/CMTS supports 6 OFDM channels

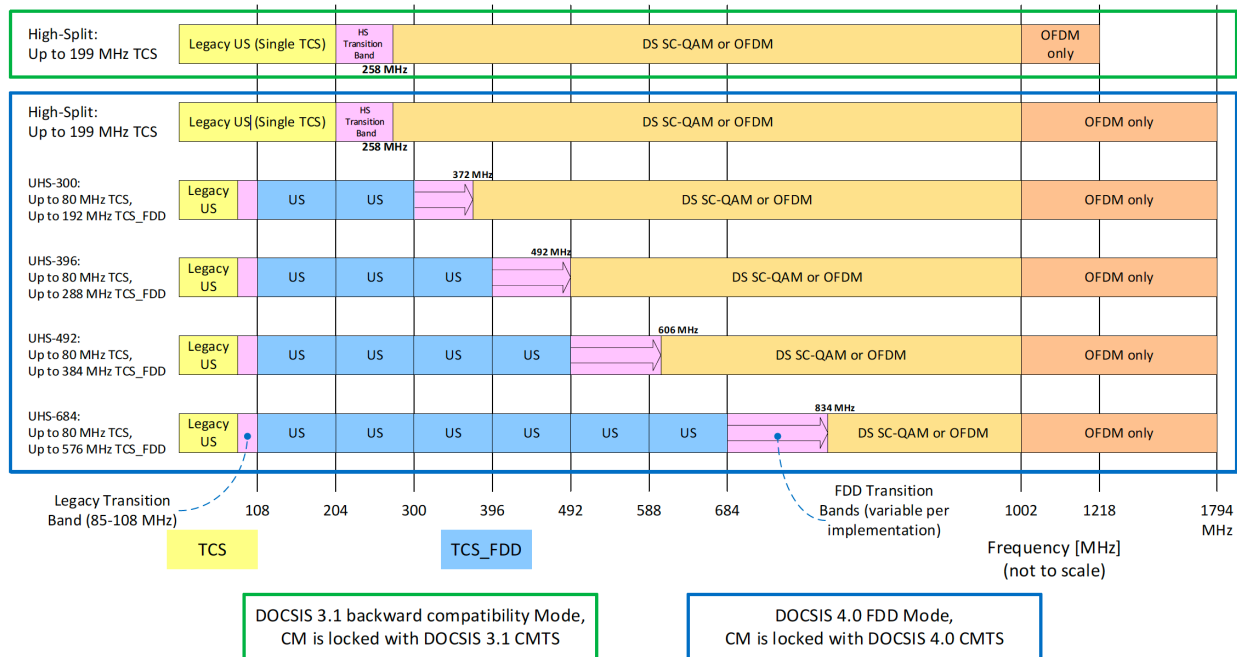

Figure 10 – D4.0 FDD Spectrum Options

Figure Source: [PHYv4.0] spec

3.1.1. D3.1 High Split with D4.0 CM

In the High split plant, the upstream spectrum is up until at 204 MHz, and the downstream up to 1218 Mhz. The downstream configuration can have 32-SC-QAM downstream channels and since the D4.0

CMs can support it, up to 4 x 192 MHz OFDM channels. In the upstream spectrum, an operator can retain the legacy 4 SC-QAM upstream channels and can have 2 OFDMA channels (70 and 96 MHz each)

This configuration can yield up to **1764 Mbps** of aggregate upstream capacity. The 32 SC-QAMs and the 4 x 192 MHz OFDM channel the aggregate throughput of this CM on the downstream is about **8.8 Gbps**.

Figure 11 – D4.0 FDD CM on a High Split Network

3.1.2. D4.0 FDD 300 MHz Split

In the UHS-300 plant the upstream spectrum is up until at 300 MHz, and downstream extends up to 1794 Mhz. The downstream configuration can have 32 SC-QAM downstream channels and now 5 x 192 MHz OFDM channels. In the upstream spectrum, an operator can simply have 2 OFDMA channels from 108 to 300 MHz and one 75MHz OFDMA below 85 MHz. At this scenario and onwards, we are assuming the SC-QAM Channels are no longer needed, if they are the upstream numbers will need to be adjusted slightly lower, as seen in previous examples.

This configuration can yield up to **2696 Mbps** of aggregate upstream capacity. With 32 SC-QAM channels operating at 256 QAM, and the 5 x 192 MHz OFDM channel the aggregate throughput of this CM on the downstream is about **10.7 Gbps**.

Figure 12 – D4.0 FDD CM on UHS-300 MHz Split Plant

3.1.3. D4.0 FDD 396 MHz Split

In the UHS-396 plant, the upstream spectrum is up until at 396 MHz, and downstream starts at 492 and extends up to 1794 Mhz. This makes a total of 1302 MHz of downstream spectrum, and the figure shows 1152 MHz for downstream DOCSIS channels. The downstream configuration can have 32 SC-QAM downstream channels and 5 x 192 MHz OFDM channels. In the upstream spectrum, an operator can simply have 3 OFDMA channels from 108 to 396 MHz and one 75MHz OFDMA below 85 MHz.

This configuration can yield up to **3690 Mbps** of aggregate upstream capacity. With 32 SC-QAM channels operating at 256 QAM, and the 5 x 192 MHz OFDM channel the aggregate throughput of this CM on the downstream is about **10.7 Gbps**.

Figure 13 – D4.0 FDD CM on UHS-396 MHz Split Plant

3.1.4. D4.0 FDD 492 MHz Split

In the UHS-492 plant the upstream spectrum is up until at 492 MHz, and downstream starts at 606 and extends up to 1794 Mhz. This makes a total of 1188 MHz of downstream spectrum, and the figure shows 1152 MHz for downstream DOCSIS channels. The downstream configuration can have 32 SC-QAM downstream channels and 5 x 192 MHz OFDM channels. In the upstream spectrum, an operator can simply have 4 OFDMA channels from 108 to 492 MHz and one 75MHz OFDMA below 85 MHz.

This configuration can yield up to **4684 Mbps** of aggregate upstream capacity. With 32 SC-QAM channels and the 5 x 192 MHz OFDM channel the aggregate throughput of this CM on the downstream is about **10.7 Gbps**.

This is an interesting case; in case an operator decides to keep video services and D3.0 CMs. With the downstream starting at 606 MHz, and if an operator decides to keep some amount of video spectrum, the DOCSIS 3.0 spectrum needs to be below 870 MHz (The top end for some early DOCSIS 3.0 modems). Also, no DOCSIS 3.0 modem is specified to use spectrum above 1002 MHz; hence, the DOCSIS 3.0 spectrum ends at 1002 MHz. Further, because video CPE possibly cannot tune above 1002 MHz either, the spectrum below 1002 MHz would need to be allocated such that both the video CPE and the DOCSIS 3.0 and earlier modems can best utilize the downstream according to service plans.

Figure 14 – D4.0 FDD CM on UHS-492 MHz Plant

3.1.5. D4.0 FDD 684 MHz Split

In the UHS-684 plant the upstream spectrum is up until at 684 MHz, and downstream starts at 834 MHz and extends up to 1794 Mhz. This makes a total of 960 MHz of downstream spectrum The downstream configuration can simply have 5 x 192 MHz OFDM channels. In the upstream spectrum, an operator can simply have 6 OFDMA channels from 108 to 684 MHz and one 75MHz OFDMA below 85 MHz.

This configuration can yield up to **6672 Mbps** of aggregate upstream capacity. the 5 x 192 MHz OFDM channel the aggregate throughput of this CM on the downstream is about **9.5 Gbps**.

Figure 15 – D4.0 FDD CM on UHS-684 MHz Plant

3.2. D4.0 FDX Technology Options

DOCSIS 4.0 FDX functionality significantly increases upstream capacity by using the spectrum currently used for downstream transmission for simultaneous upstream and downstream communications via full duplex communications. The FDX Allocated Spectrum is subdivided into FDX sub-bands each with a single FDX Downstream Channel and the associated FDX Upstream Channel(s) that can be assigned to modems according to system requirements. In the full FDX spectrum, the 3 resource blocks (each 192 MHz wide) will fit 6 FDX OFDMA upstream channels and 3 FDX OFDM downstream channels. The FDX node will simultaneously transmit and receive data on these channels with the Echo cancellation technology while the FDX CM either receives or transmits within a channel in a given sub-band. The CMTS assignment of FDX channels within the FDX band for Full Duplex DOCSIS operation can be done incrementally over time as a transition strategy, from existing DOCSIS networks to Full Duplex DOCSIS networks, as FDX-capable CMTSs and modems become available. The figure below shows the FDX allocated spectrum within the cable plant.

Figure 16 – FDX Allocated Spectrum

3.2.1. D4.0 FDX 1.0 GHz with SCQAMs or OFDM

In the initial FDX scenario, in a FDX plant the upstream-only spectrum is up until 85 MHz, and the downstream-only spectrum is from 804 MHz to 1002 MHz plant, and the FDX-Spectrum (simultaneous Upstream and Downstream) is from 108 MHz to 684 MHz. Staying at 1GHz downstream plant is a realistic initial scenario as it helps with not replacing all the taps at the start to 1.2 GHz.

In the spectrum between 684 and 804 is the as this is in the FDX transition band, to prevent any interference between the FDX bands and the downstream only region. An operator could choose to deploy video QAM channels here, and these channels can be used by other devices (STBs), but this spectrum cannot be used by the FDX CM itself

As regards a FDX CM's data capacity, in this type of a FDX plant, an operator can choose one of two options: to retain in the downstream-only spectrum (804 to 1002 MHz region) the 32 SC-QAMs or deploy a single 192 MHz OFDM channel and a single SC-QAM channel. In the upstream-only spectrum (5-85MHz), an operator can retain the 4 SC-QAM channels for DOCSIS 3.0 (and earlier) CMs or and cover the rest of the spectrum below 85 MHz with an OFDMA channel.

Figure 17 – D4.0 FDX (1.0 GHz) Channel Allocations with SCQAMs

In the FDX spectrum, the 3 resource blocks (each 192 MHz wide) will fit 6 FDX OFDMA upstream channels and 3 FDX OFDM downstream channels.

This configuration can yield up to **6537 Mbps** of peak aggregate upstream capacity. The peak aggregate throughput of this CM on the downstream, is **6937 Mbps**, if the 32 SCQAM option is chosen and **7666 Mbps**, if the 1 OFDM + 1 SC-QAM channel option is chosen.

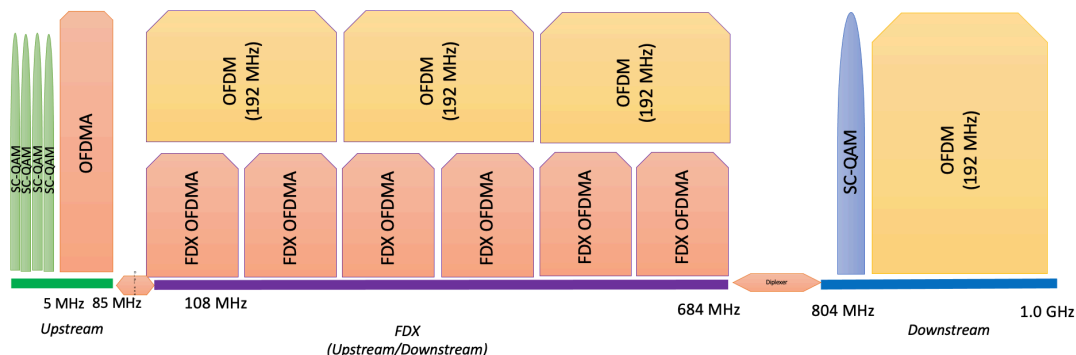

Figure 18 – D4.0 FDX (1.0 GHz) Channel Allocations with an OFDM

3.2.2. D4.0 FDX 1.2 GHz with SCQAMs

In the initial FDX scenario, in a FDX plant the upstream-only spectrum is up until 85 MHz, and the downstream-only spectrum is from 804 MHz to 1218 MHz plant, and the FDX-Spectrum (simultaneous Upstream and Downstream) is from 108 MHz to 684 MHz.

In this type of a FDX plant, an operator can choose to retain in the downstream-only spectrum (804 to 1218 MHz region), the 32 SC-QAMs and then deploy a 192 MHz OFDM channel and a second smaller 30 MHz OFDM channel. In the upstream-only spectrum (5-85MHz), an operator can retain the 4 SC-QAM channels for DOCSIS 3.0 (and earlier) CMs or and cover the rest of the spectrum below 85 MHz with an OFDMA channel.

The FDX spectrum, will fit 6 FDX OFDMA upstream channels and 3 FDX OFDM downstream channels.

This configuration can yield up to **6537 Mbps** of peak aggregate upstream capacity and **9141 Mbps** of the peak aggregate throughput of this CM on the downstream.

Figure 19 – D4.0 FDX 1.2 GHz Channel Allocations with SCQAMs and OFDM

3.2.1. D4.0 FDX 1.2 GHz with OFDMA and 2 OFDMs

Building on the FDX plant as described above, now the operator can remove the 4 SC-QAM channels for DOCSIS 3.0 (or earlier) CMs and expand the OFDMA channel to cover the spectrum below 85 MHz. Similarly for the downstream an operator could reduce the 32 SC-QAM channels to 4 and add an OFDM channel for more efficiency, for a total of 2 OFDM channels. The FDX band remains the same with 6 x 96MHz OFDMA upstream channels and 3 x 192 MHz OFDM downstream channels

This configuration can yield up to **6672 Mbps** of peak aggregate upstream capacity. The peak aggregate throughput of this CM on the downstream is about **9687 Mbps**.

One additional use case to consider would be FDX in a N+x configuration. While spectrum plans will likely remain quite similar, if we assume a lower RxMER (say 3-4 dB) or one modulation order lower for the FDX channels, the peak capacity will adjust lower to 6144 Mbps on the upstream and 9144 Mbps. Depending on the performance from the FDX amplifiers the modulation orders possible on the OFDM/A channels will change and the capacity calculation will also vary.

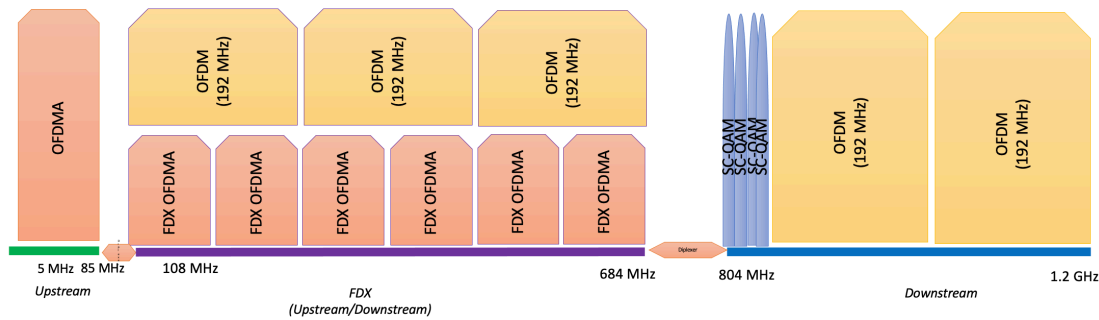

Figure 20 – D4.0 FDX Channel Allocations with OFDM/A and 2 OFDMs

3.3. Comparison to FTTP/PON Technology Options

Most FTTH networks are based on passive optical network architectures, simply as it is usually the lowest cost way to design a FTTH network. Many operators are deploying passive optical networks (PON) in many of their market segments

Per *[Broadband Pie]*, one operator's investigations and analysis has concluded that the overall cost of deploying FTTP to their residential footprint would be about 5 to 6 times the cost of rolling out DOCSIS 4.0 with DAA.

3.3.1. 10 G EPON

10G Ethernet PON (EPON) is the current and widely available generation of EPON technology, although the Nx25G EPON specifications have also recently been published. This technology is defined by Institute of Electrical and Electronics Engineers (IEEE) 802.3 standard and offers asymmetrical (10/1Gbps) and symmetrical (10/10 Gbps) rates for downstream and upstream.

The peak user throughput to an optical network unit (ONU) is around 8.6 Gbps upstream and 8.65 Gbps downstream

3.3.1. XGS PON

XGS-PON the current and widely available generation of gigabit PON (GPON) technology, although the 50G higher speed PON (G.HSP) specifications are now available. XGSPON is defined by the ITU-T G.9807.1. standard and offers asymmetrical (10/1Gbps) and symmetrical (10/10 Gbps) rates for downstream and upstream.

The peak user throughput to an ONU is around 8.55 Gbps upstream and 8.6 Gbps downstream

4. Conclusion

The table below offers a summary of the scenarios that we reviewed in this paper. It documents the number of downstream/upstream channels and the theoretical (best conditions) peak capacity that would be obtained in each of those configurations. (Do keep in mind that changing the underlying assumptions e.g., channel conditions, number of channels, spectrum allocated will change the numbers appropriately.)

Table 2 – Summary of Peak Speeds on the Path to 10G

Plant Config	Technology	DS Channels			US Channels				Theoretical Peak Capacity	
		SC QAM DS	DS-192-OFDM	FDX DS-192	SCQAM US	OFDMA-US-75	OFDMA-US-96	FDX US-96	Max DS Mbps	Max US Mbps
42 split / 750 MHz	D3.0	32			4				1216	106
42 split/ 860 MHz	D3.1	32	0.5		5	0	0		2170	133
42 split/ 860 MHz	D3.1	32	0.5		1	0.34	0		2170	267
42 split/ 860 MHz	D3.1	32	2		3	0.17	0		5030	200
85 split/ 1.2 GHz	D3.1	32	2		10	0	0		5030	265
85 split/ 1.2 GHz	D3.1	32	2		4	0.66	0		5030	572

The figures below summarize the information in the table above in a graph, to get a feel for the differences in technology. The first figure shows the various downstream and upstream peak capacities, while the second figure shows the amount of actual usable spectrum (upstream versus downstream versus FDX) at the CM based on the number of channels in each of these configurations.

Figure 21 – DOCSIS CM DS/US capacity across technologies

Figure 22 – DOCSIS CM DS/US Usable spectrum usage

As seen in the table/figures above and in the example scenarios in this paper cable operators have many useful and cost-effective choices to increase the service speeds to their customers. Both DOCSIS 3.1 and DOCSIS 4.0 technologies give the operators plenty of options in both the upstream and downstream network design. The speeds provided by these technologies are more than capable to meet the competitive pressures in each of their respective markets. D3.1 can provide up to 5 Gbps downstream and almost 2 Gbps upstream peak speeds, ultimately enabling high service tier speeds to the customers. D4.0 FDD and FDX technologies take those peak downstream speeds to the 10 Gbps level and 6.6 Gbps in the upstream. This paper walks through the various channel planning scenarios that operator would need to go through to figure out which of these options they choose in each of their markets for scale, reliability, and cost for the benefit of speeds offered.

1. Introduction

Network fingerprinting is an emerging classification and filtering process that utilizes standard flow protocols to extract and enrich traffic records for analytics purposes. The process utilizes both public and private enrichment resources to create a modular, templated framework for use by automated machine learning (ML) and artificial intelligence (AI) systems. The goal, to create a predictive, proactive and forecast ready system for network traffic analysis, including the evolving diversity of traffic.

Through flexible templating, network fingerprinting enables a system to rapidly identify destination bottlenecks, detect anomalies within traffic flows and even recommend package adjustments. This approach has no deep packet inspection requirement and leverages flow record and packet metadata to store and enrich existing flow sources. The separation of enrichment from machine and AI techniques supports the use of homegrown solutions such as forecasting or monitoring while also allowing the use of additional open-source models for quick deployment and rapid time to value. This flexibility is designed to enable use cases across a variety of network, threat assessment and quality of service spaces and includes models to address proactive network management, self-healing actions (platform to network connections), anomaly detection, traffic monitoring, customer churn and capacity management.

The proceeding sections introduce the basic elements needed to achieve network fingerprinting and classification processes and demonstrate possible outcomes when leveraging those resources in traffic flow environments. The processes outlined focus on enrichment and augmentation, leveraging standard traffic flow protocols at a software layer without the need for specific network inspection hardware.

2. Enrichment Templating

Enrichment templating is essential for fingerprinting exercises and begins with defining the resources, business and technical requirements necessary to augment traffic flow data from a specific system or process. Defining enrichment sources in a modular and easily parsed format provides flexibility for automation, continuous updates and analytics reuse. Aligning traffic protocol fields to enrichment sources is key and ensures accurate data discovery and analysis.

2.1. Augmenting Traffic Protocol Fields

Before beginning the enrichment templating process, it is necessary to understand the traffic flow protocol and associated fields of the system being analyzed. While there are many common fields and properties between the various traffic flow exporters, identifying and understanding both the nuances and similarities of traffic protocols such as: NetFlow, Internet Protocol Flow Information Export (IPFIX), sampled flow (sFlow) etc. will greatly expedite the templating and alignment processes. Fields available to augment and enrich may vary slightly by traffic protocol so it is important to understand availability and alignment to any specific analysis use cases.

With the traffic protocol identified, assessment of the available fields and their key properties can begin. Developing valuable enrichment templates begins with understanding the consistency of fields and data within the traffic export a system will be receiving. This consistency will be critical to the application of enrichment via systematic lookups, joining of data via common fields or similar methods used by the traffic analysis system. Examples of common fields include private Internet Protocol (IP) addresses, public IP addresses, network type, network protocols, network ports and even traffic direction.

Flow Record Field Enrichment Source Fields derived from Client IP and Destination IP Addresses

client.ip	client.publicip	client.mac	client.package	client.monthusage	client.networkelement	org.name	application
10.0.0.1	192.168.0.1	00:00:00:00	GIGABIT PLUS - 1G	1.10 TB	CMTS-A01	MICROSOFT-CORP-MSN-AS-BLOCK	MS-Teams-Skype

10.0.0.5	192.168.0.1	00:00:00:00	GIGABIT PLUS - 1G	2.37 TB	CMTS-B01	FASTLY	Disney Plus

Figure 1 - Example flow record and enrichment source fields

Defining enrichment sources depends on analysis, modeling or automation requirements (see sections [4.2](#) and [5.1](#) for examples). Sources are normally qualified as either public or private. Public being sources or definitions broadly available or published openly by companies and individuals. While private sources normally represent internal network systems, purchased products or resources not publicly accessible.

The table below provides example definitions of several common enrichment sources, their classification type (public or private) and a brief description of their purpose in analysis systems.

Table 1 – Example enrichment source definitions

Enrichment Source	Type	Purpose
Autonomous Systems	Public	Align servers and destinations to known systems
Geographical IP Details	Public	Geographical data for public IP addresses
Application Identification	Private	IP address and protocol lookup for application enrichment
Cache Systems	Private	Internal network resource list for video or third-party service caching

When reviewing external enrichment sources, it is important to reference key fields and traffic flow protocol support to clearly decipher dependencies and alignment to protocol fields. Understanding how selected sources will impact and ultimately enrich the existing traffic flow data is crucial and plays a large role in defining not just data discovery but enrichment timing and performance. Identifying not just the fields but relevant aggregations required for analysis, can assist in preparation of the system and necessary classifications.

2.2. Leveraging Additional Network Resources

Enhancing a library of enrichment sources, begins by understanding the additional network resources capable of being leveraged for broader traffic intelligence. In some environments, traffic flow data may be the sole source of collection and in that case alternative public or private sources may be used for enrichment. However, in many network environments additional resources may be available or accessible through a variety of methods including Simple Network Management Protocol (SNMP) polling, Optical Line Termination (OLT) hardware or even Cable Modem Termination Systems (CMTS) via Internet Protocol Detail Records (IPDR). Additionally, Domain Name Systems (DNS) can provide insight into both local network destinations as well as public Internet resources, providing additional depth when analyzing traffic flow destinations.

Depending on policies and local regulations, another flexible and valuable resource for enrichment is billing system data. Even when anonymized or utilized only for subscriber package analysis, it can provide powerful insights into network health and ultimately customer experience within a network.

Billing systems may also include device and network resource details specific to subscribers, often simplifying the alignment process with traffic flow data.

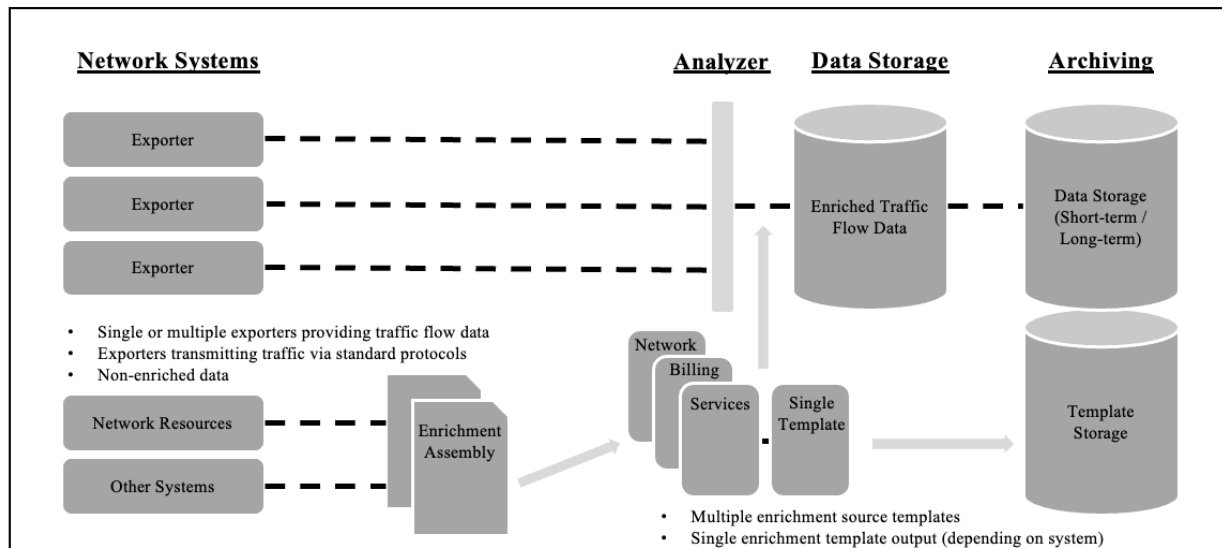

Successfully leveraging the various formats and outputs of network resources normally requires a series of crafted templates. Depending on the volume of data desired for analysis and presentation, templates can be either individually constructed or merged to a single network enrichment source. The latter normally only being preferred if continuous updating of resources is not anticipated.

2.3. Aligning Template Sources

Template alignment begins with identifying fields capable of being joined together through common keys or via the fields present within traffic records. The exact method of enrichment may be dictated by the system or application being utilized for traffic flow inspection and analysis. While many traffic analysis systems support enrichment from multiple sources, some require a single formatted file. The alignment processes described assume a multi-templated approach but with the option to join to a single file location if required.

When initially developing a solution for enrichment alignment, one commonality is IP address information. While originating IP addresses can exist in traffic records in either public or private form (depending on network settings, environment), it is normally one of the simplest and most consistent origin identifiers. When combined with subscriber enrichment sources it can provide the basis for numerous enrichment field additions. Before selecting a single origin field such as IP address, it is important to understand network behavior that can contribute to field consistency, including client/server protocol behavior and Dynamic Host Configuration Protocol (DHCP) settings within the network. Since not all enrichment sources may be leveraging IP address as a primary method of joining data, various combinations of ports, protocols and network service information can also be used. When facing more complex or non-IP address enrichment scenarios, defining unique combinations of enrichment source elements that are aligned to flow record data can assist in rapid lookups at time of application.

Aligning application specific enrichment sources within templates is sometimes a broader challenge, as the variation and combination of server or destination ports and IP addresses can require continuous enrichment from both public and private locations. This continuous enrichment is critical for the effectiveness and accuracy of application specific details (see section [3.3](#) for additional context). However, introducing the results of more complicated enrichment sources to traffic flow data remains a clearer task when adhering to described IP address or unique string combination solutions.

2.4. Defining Enrichment Timing

There a variety of traffic analysis systems and solutions available in the market and defining when to perform enrichment of traffic flow data may depend on the solution deployed. Timing selection may also depend on the use cases and type of analysis being constructed. While real-time performance is desired or required for many scenarios, such as threat analysis or capacity monitoring, it is not always necessary for point-in-time analytics or broader experience measurements. Depending on the flexibility of the solution this can lead to other alternative time considerations for analysis that may be focused on past outcomes, point-in-time comparisons or historical grading. The templating process is an ideal time to assess when enrichment should occur and whether it is necessary for enrichment updates to be applied only to newly collected (ingested) data or whether all historical datasets should be updated.

Many enrichment sources that include IP address, service or application focused details are most valuable remaining real-time. Simply meaning that at the moment enrichment sources are updated, all traffic record data from that point forward is enriched with the source details, until the source is updated again. Network fingerprinting and classification is often the most valuable when there is a clear history of events. Whether it is IP addresses dynamically changing and being associated to a new subscriber, a content delivery network (CDN) change occurring for a particular site or application and even location based internal resources such as cache systems becoming visible in the network.

This does not mean that there are no scenarios where historical collection updates should not be planned. Adjustments due to billing, subscriber, network resources or other field classification changes are often common to ensure that analysis done for historical or trending purposes, remains accurate. When assessing historical data adjustment, it is important to understand the timing and impact on the system, volume of data that is required to be queried and ultimately updated. For scenarios where an enrichment source may only be updated weekly or monthly, planning for historical reconciliation or adjustment on a set schedule will likely be the most practical option. For further timing considerations and tradeoffs when applying enrichment to traffic flow records, see section 3.1 for additional context.

2.5. Retaining Templated Sources

Enrichment sources can be a valuable commodity over time. Depending on the source, having historical references of enriched values can aid other analysis efforts, metrics or grading. Determining an optimal process for storage, access and use within additional data lake or analysis systems can depend on the enrichment source types. Leveraging long-term or cold storage options may make sense for enrichment snapshots that are continuously refreshed while more accessible storage may assist sources that will be more commonly reused. When deciding on retention strategies for enrichment templates it is often valuable to define how often each enrichment source is updated by underlying code or processes. Sources that are refreshed on a daily or more often basis may be more desirable for short-term storage options where the data can remain accessible if required.

Example retention timeframes for templated sources, including possible storage classes and conditions can be referenced in the table below.

Table 2 – Template retention example

Archive Description	Archive Timeframe	Storage Conditions	Storage Class	Details
Autonomous Systems	On Update	Past two versions	Standard / Short-term	Two versions of the complete source stored
Application Identification	Daily	7 days	Standard / Short-term	Saved daily and stored for 7 days
Billing System	On Update	Past two versions	Standard / Short-term	Two versions of the complete source stored

When designing an effective templating process, it is important to plan for the unexpected. In a real-time system, what happens if an enrichment source becomes populated with incorrect information? Having a plan to not only rollback to a previous enrichment source but also knowing the optimal method for updating historical data to a very specific point-in-time is invaluable during a production event. While the actual restoration and historical update process remains specific to the application or system deployed for traffic analysis, ensuring that a standard set of processes accompanies enrichment retention plans will ensure enrichment accuracy or adjustment is always a possibility.

3. Applying Enrichment

The art of enrichment application begins with determining the frequency for updating traffic records and ends with the aggregation and storage of the combined flow data (original record plus enrichment, if desired). Understanding the impact that sampling rates can have on specific use cases, enrichment actions and ultimately flow record storage will help ensure required modeling, analysis or presentation function as desired. The ability to successfully enrich traffic flow records accurately and at scale depends on the consistency and quality of enrichment sources and their field alignment. This makes previous planning and templating efforts key to a performant system, capable of supporting detailed network fingerprinting and classification.

3.1. Approaches to Traffic Protocol Enrichment

As previously noted, real-time traffic enrichment is not always a reality. Sometimes the volume of data or complexity of an enrichment source requires a point-in-time or scheduled update. When the time comes to apply enrichment sources to traffic flow data, each of these three: real-time, point-in-time and scheduled,

time-based scenarios is important to consider and apply within enrichment and flow record data collection.

Real-time is normally representative of enrichment that occurs as flow records are ingested and processed by the traffic analysis system. Relevant enrichment sources are leveraged to populate supplemental traffic record fields and augment the existing traffic flow data. In a real-time enrichment scenario, historical data is not updated. Depending on collection and fps rates, the actual moment an enrichment source is updated, collected data is supplemented. Real-time enrichment allows for supplemental traffic fields to be used for immediate visualization, presentation and modeling as records are ingested by the system.

Point-in-time enrichment occurs after flow records are ingested and processed by the traffic analysis system. Relevant enrichment sources are leveraged to populate supplemental traffic record fields and augment the existing traffic flow data. In a point-in-time enrichment scenario, data updates are made to historical traffic flow records only. Supplemental fields are added or updated after collection and only a dependency on system ability, performance is needed to make the updates. Point-in-time enrichment allows for supplemental traffic fields to be used for visualization, presentation and modeling between two time periods and after records are ingested by the system.

Scheduled enrichment is similar to point-in-time and occurs only after flow records are ingested and processed by the traffic analysis system. Relevant enrichment sources are leveraged to populate supplemental traffic record fields and augment the existing traffic flow data. In a scheduled enrichment scenario, data updates are made to historical traffic flow records only but are done so on a consistent frequency in order to align or aggregate key fields. Supplemental fields are added or updated after collection and only a dependency on system ability, performance is needed to make the updates. Scheduled enrichment allows for supplemental traffic fields to be used for visualization, presentation and modeling between two time periods and after records are ingested by the system.

Understanding tradeoffs that need to be made for the performant function of the traffic analysis system will save time and may help simplify the approaches selected for specific enrichment sources. When combined with sampling and continuous refinement processes, these approaches assist in the overall accuracy and classification capabilities of the system.

3.2. Traffic Flow Sampling and Enrichment Impact

Sampling rates of exported traffic flows can have an impact on the type of enrichment being performed. The level of sampling often pertains to specific use cases or automated actions being taken. When assessing traffic flow collection and enrichment, it is important to understand the volume of devices, flows per second (fps) and even internal or external traversal of the network element being collected. Each of these factors represent considerations and influence use cases for network fingerprinting and classification exercises. For example, in threat analysis and security spaces, no to extremely low sampling rates are often preferred to ensure that malicious traffic is not missed and can be cataloged and actioned effectively. While higher sampling rates can provide adequate intelligence for prime time and capacity planning use cases. While there is a wide variation in collection and enrichment use cases for traffic analysis systems, there are a few common scenarios that can help guide enrichment planning.

Determining an optimal sampling rate is often dependent on business, network and retention requirements. The network device itself may also dictate maximum sampling levels based on protocol or vendor defined parameters. The scenarios and use case recommendations provided in the table below may not apply to all customer environments. Threat analysis with low or no sampling scenarios should be reviewed on a case-by-case basis to ensure optimal experience and data retention.

Table 3 – Traffic flow sampling scenario use case examples

Use Case	Sampling
Capture and aggregate detailed traffic patterns across device base. Monitoring of key internal cache resources for capacity management, alerting and team response.	1:512
Detailed traffic flows for client/server, protocol and application analysis. Determine traffic locations and key server destinations for capacity planning and design.	1:2048
Develop overall network insights particularly during peak/primetime hours without retaining larger quantities of traffic data. Analyze and aggregate with network usage and performance metrics.	1:10000

Sampling rate is an incredibly important consideration when designing and setting up the actual platform where traffic flow record and enrichment will take place. It cannot only determine the effectiveness of the overall solution but also influence enrichment value, modeling and analysis.

3.3. Continuous Refinement and Update

Many enrichment sources require continuous care and feeding to ensure accurate results. As part of the templating process, enrichment sources should be clearly planned and defined. Once these sources are put to work enriching traffic flow records, keeping them up to date is critical to accurate fingerprinting of network resources. For certain enrichment templates, even a short lapse in updates can create data inaccuracy which may then require an adjustment to historical data. The complexity of continuous refinement within a traffic analysis system depends largely on the deployment and the context of the enrichment source. Enrichment sources focused on specific services classification, applications, CDNs and IP address ranges normally represent the highest risk for inaccuracy given change volatility. When finalizing enrichment application activities: documenting, alerting and implementing self-healing capabilities are often seen as best practices for these process critical sources.

Examples of refinement timing and associated enrichment sources are briefly described in the table below.

Table 4 – Enrichment source automated refinement example

Enrichment Source	Type	Timing	Details
Autonomous Systems	Public	Real-time	Align servers and destinations to known systems
Application Identification	Private	Real-time	IP address and protocol lookup for application enrichment
Billing System	Private	Weekly / Historical	Billing system reference and broadband package details

Leveraging built in functions of the traffic analysis system deployed or integrating surrounding scripts or functions to perform continuous enrichment on sources with the most risk, is always a recommended practice. Introducing more complex modeling, analysis and AI to enriched traffic flow data requires a high degree of refinement and accuracy.

3.4. Aggregation and Storage

A clear aggregation and storage strategy is necessary to ensure data remains accessible and retained for critical analysis and reuse. When considering aggregation and storage options it is often best to refer to enrichment template planning processes to guide decisions on what fields may require aggregation. Storing enriched traffic flow field data is not only valuable for historical purposes but often leads to an accelerated path for training AI models. Having aggregated data sets readily available to test or pilot various service techniques, can reduce time to value for analysis and modeling.

While simply storing all data, all the time, forever seems like the most ideal method for long-term historical reference, it is not always feasible for large traffic volumes. This means that for many traffic flow record scenarios, an approach that uses time-based aggregation can be considered a valuable alternative. Selecting the most ideal aggregate will depend on the use cases and traffic analysis system being utilized (support or performance of aggregation). There are many options for field aggregation in a traffic flow system, a time-based approach helps to ensure data can still be introduced to more advanced analysis models quickly. There any number of aggregate storage options based on roll-ups by minutes, hours, days etc. Choosing the right timeframe may also depend on audit scenarios, archive requirements and simply cost.

The table below introduces several timeframes and possible storage class options based on the type of aggregate data being stored.

Table 5 – Aggregate storage options and timing example

Archive Description	Data Timeframe	Storage Timeframe	Storage Class	Details
Enriched flow records	7 days	7 days	Standard / Short-term	Raw traffic and enriched records flow records available for 1 week
Raw flow records	7 days	7 days	Standard / Short-term	Saved for re-processing or comparison purposes
Enriched flow records aggregated	1 day	120 days	Cold / Long-term	Aggregated to a 24-hour period and stored
Enriched flow records aggregated	7 days	365 days	Cold / Long-term	Aggregated to a 168-hour period and stored

4. Introducing AI Service Models

Following an introduction to some of the techniques and processes needed to enrich and augment traffic flow records, it is time to leverage the available data for more advanced modeling and use cases. Introducing AI techniques to enriched traffic flow data enables network fingerprinting and associated classifications to take shape. The advent of numerous open data models as well as commercial solutions to assist with visualization and presentation can make detailed levels of classification a reality for almost any network. The success of each model and use case depends on the volume of data collected, availability of enriched fields and overall dependencies for the analysis being performed. Diligent and consistent enrichment processes help to ensure that the data is viable and more suitable for training and modeling processes. The process of data discovery and AI model selection normally begins with identifying key fields or aggregated points of interest within the enriched traffic flow data. These key data points will be used for model classification and training development activities. Assessing and preparing

enriched traffic flow data for modeling may require exporting or saving data sets for analysis and testing prior to production implementation.

4.1. Fingerprinting Use Cases

While the use cases for fingerprinting the network is ever widening and can even be system specific, there are now a variety of paths supported by readily available market and open solutions. Building and maintaining accurate fingerprints for the network normally means having a system and templating process that is adaptable and capable of growing with the network analysis and classification needs of the environment. This section provides several use cases and attempts to provide insight into specific enrichment templates, fields and techniques utilized to achieve the results. These use cases require various forms of network or traffic enrichment to be successful and are provided as examples. Detailed analysis and response as described throughout the scenarios, may depend on a variety of business and system configurations.

Scenario 1: Internal resource optimization via network system enrichment

In this scenario, the goal is to understand how external video service traffic is traversing the network over a specified period. During this primetime window, a series of internal video cache servers is being observed along with the primary external video service server destination. The video cache servers should be inclusive of the relevant markets being observed and therefore should carry most of the traffic from client systems. However, during the observed window there is still a large quantity of traffic, preferring the external destination vs. internal caches. Leveraging real-time traffic flow enrichment, the capacity and network systems adjust network configurations, re-shaping the traffic and ensuring cache usage. This scenario leverages several enrichment templates: autonomous systems, application identification and internal network resources (video cache systems).

Figure 3 - Internal resource optimization via network system enrichment

Scenario 2: Capacity planning, analyzing past trends and known events to predict future growth

In this scenario, the goal is to understand how streaming video service traffic is traversing the network and how that traffic may take shape based on historical references. During this primetime window, streaming services traffic is being monitored and a forecast view overlaid on the typical chart to indicate expected traffic patterns beyond the current time. To accomplish this both application specific enrichment along with processed, historical traffic data is combined to provide a forecast of usage for the upcoming hours. Leveraging a multi-week baseline of the exact time, day of the week and allowing for any specific events or conditions, the data is then constructed and appended to applicable charting metrics. The accessibility of processed, historical traffic data enables the system to make continual refinements and updates increasing the accuracy of forecasted usage over time. This scenario leverages several enrichment templates: autonomous systems, application identification and processed, historical traffic data.

Figure 4 - Capacity planning, analyzing past trends and known events

Scenario 3: Anomaly detection across selected classifications

In this scenario, the goal is to identify traffic anomalies early and enable rapid response through either manual or automated intervention. The visualization represents a series of connections across sets of classified traffic. This includes traffic that is categorized as gaming, CDNs, streaming services etc. The anomaly detection process is examining the enriched traffic classifications for deviation at either the upper or lower bounds. In a real-time system, as soon as enriched traffic flow data is made available to the detection process, anomalies are identified and can be actioned. In this case, the classification is a particular CDN that has been categorized by the system and is no longer receiving connections. This scenario leverages several enrichment templates: autonomous systems and application identification.

Figure 5 - Anomaly detection across selected classifications

Scenario 4: Identifying the potential for customer churn

In this scenario, the goal is to understand how a combination of traffic data, enrichment sources and network utilization information can help determine the potential for customer churn. This scenario provides a unique visualization, aggregating the various enriched data sources to plot client level data based on numerous activity conditions. These conditions include activity during peak and non-peak times, speed test usage and even references to supplemental customer support system resources. This provides a unique visualization of potential customers with activity that may represent the potential for churn. Drilling into the individual points of the data then provide inspection at the client level including all relevant enrichment detail available. This scenario leverages several enrichment templates: autonomous systems, application identification, internal network resources and customer support system data.

- **Big Consumers:** Power-users, routinely outside of assigned package
- **Baseline Consumers:** Consistent and expected activity based on assigned package
- **Limited Consumers:** Consistently below baseline activity of assigned package
- **Churn Potential:** Measurable decrease in activity, increased speed test usage and/or increased support interaction

Figure 6 - Identifying the potential for customer churn

5. Proactive Monitoring and Network Management

Proactive response remains one of the most powerful elements of network fingerprinting and classification. Leveraging enriched traffic flow data, modeling and analysis methods to enable proactive actions in many forms, should be the goal of any traffic analysis system. Whether those actions are designed to be fully automated, with intervention or in the form of customer experience metrics, there are any number of alerting and automation scenarios that can be developed.

5.1. Monitoring, Automation and Grading

Deploying monitors and automation within the network environment requires a functional traffic system with enrichment and/or deployed analysis use cases described in section [4.2](#). With an optimized traffic analysis system and with clear understanding of any sampling limits that may exist, a wide range of monitoring and automation use cases can be developed. Many of these use cases are made ever more powerful when combined with real-time monitoring and alerting functionality. This can include

automated dispatch of notifications, reports and information via team communication platforms, internal systems and devices. The ability to proactively tune and adjust devices based on analyzed data, either through internal processes or automated services, can assist in reducing manual intervention and drive self-healing abilities in the network. Example use cases for monitoring and automation range from capacity alerts to detailed threat assessments.

The table below provides several examples and includes common internal system dependencies.

Table 6 – Monitoring and automation use case examples

Use Case	Example Enrichment Dependency
Internal network capacity utilization (caches)	Internal network resources
Outage condition detection based on traffic and usage	Usage data, billing, IPDR
Outage detection for popular services / systems	Autonomous systems
Primetime or peak hour monitors	Applications
Congestion and network bottleneck visibility	Usage data, billing, IPDR
Top client / server monitors	Autonomous systems, Applications
Application and service optimization	Autonomous systems, Applications
Threat conditions and malicious traffic detection	Threat and security systems

In addition to monitoring and automation use cases, the availability of a broad range of enrichment templates can enable a variety of customer experience measurements. With network usage, subscriber or billing data availability it becomes possible to develop detailed experience and network grading components. Designing comprehensive experience monitoring and grading requires a deep understanding of not just the network system but relevant dependencies determining experience. This can include in-home devices, node, CMTS or optical layers, interoperability dependencies and even Over the Top (OTT) service performance. Establishing a grading process first requires assembling a list of available template fields that can be used either in real-time or as part of a point-in-time analysis. In its most simplistic form, scoring can be defined as a range of values equating to either a positive or negative network experience. Deciding on the fields to be leveraged may require an understanding of geographic, market, network or capacity constraints.

While the availability of enrichment sources and overall system capability may vary, the table below provides several example fields from previously discussed enrichment sources to attempt to aggregate a network experience score at a client level. Providing an overall score at the client level enables additional roll-up or aggregate opportunities and can provide additional granularity should it be required. In this example, a simple score of either a 0 or 1 is used per grading category or column based on pre-defined rules. This grading could be expanded to more sophisticated scoring and inclusive of many other factors and columns. These pre-defined rules can include evaluation of peak utilization of network elements and resources impacting a client over any number of days (30 days in the table below).

Table 7 – Deriving network resource scores from traffic intelligence

Client	Anomaly Impact	Anomaly Score	Peak Network Utilization	Network Score	Service Interactions	Service Score	Total
10.0.0.1	2.06 hours	0	93%	0	0	1	1
10.0.0.2	0 hours	1	71%	1	0	1	3
10.0.0.3	0 hours	1	68%	1	1	0	2

6. Conclusion

In summary, this practice has focused on enabling a structured process utilizing optimized enrichment templates and flow data analysis at the software layer. Network fingerprinting is an invaluable process for managing and enriching standard traffic flow protocol data. It is an inexpensive solution to stand up and does not require expensive deep packet inspection (DPI) appliances or additional hardware within the network. Most of the data provided by network routers are available from standard flow exporters and while the output can vary slightly by vendor, it is possible to rationalize those fields to get a full view of network traffic. While enrichment processes may need to run at varying frequency depending on source and desired outcomes, the combination of traffic flow data with additional network elements can help provide end-to-end network transparency. The inclusion of fiber and data over cable service interface specification (DOCSIS) termination systems can provide additional subscriber details that further augment network management potential. These classification and enrichment techniques help with fundamental understanding of traffic patterns, subscribers and can assist in improving quality of experience (QoE), by right-sizing internal vs external network utilization. The availability of collected data enables network, capacity and analyst personnel to better leverage traffic flow data through common AI and ML models. These models enable the visibility of anomalies and potential forecasting of customer churn. Proactive network management can be the culmination of data collection, enrichment, AI modeling and associated alerting. It enables continuous anticipation of networking issues and provides an additional mechanism for improving overall customer experience. Network fingerprinting as an emerging technique allows for multiple system operators (MSO) to anticipate issues, evolve network activities and ensure customers can continue to expand their broadband consumption.

Abbreviations

AI	artificial intelligence
ASN	autonomous system number
CDN	content delivery network
CMTS	cable modem termination system
DHCP	dynamic host configuration protocol
DOCSIS	data over cable service interface specification
DPI	deep packet inspection
fps	flows per second
IP	Internet protocol
IPDR	Internet protocol detail record
IPFIX	Internet protocol flow information export
ML	machine learning
MSO	multiple system operator
OLT	optical line termination
OTT	over the top
QoE	quality of experience
RDK	reference design kit
sFlow	sampled flow
SNMP	simple network management protocol

1. Introduction

Frequency is the number of cycles per unit time. Communications often use signals occupying MHz and GHz spectrum. But when it comes to the network's operational health, it is the 1 to 10 nano-Hertz frequencies that matter the most!

How so? Those frequencies correspond to 30- and 3-year cycles, respectively. And most activities affecting the network's health (construction, upgrade, and maintenance cycles) fall within this range. This paper investigates the 5 W's of network upgrades around the pending Extended Spectrum DOCSIS 4.0 (ESD) rollout and its alternatives. It looks holistically at what makes economic sense over the full 30-year cycle, not just the next incremental step.

What network components are impacted? Over 30 years, a Hybrid Fiber-Coax (HFC) plant sees taps, amps and nodes going through 1 or more upgrade cycles, while Cable Modem Termination Systems (CMTS) and consumer premises equipment (CPE) upgrade even more often. Until now, these cycles were all independent. However, Distributed Access Architecture (DAA) and ESD now lock these together. Accounting for this, applying average per cycle costs and integrating over the "spectrum" is akin to performing a financial "spectral analysis." Both capital and operating expenditures may be captured this way, giving operators a long-term total cost of ownership (TCO) of the network.

When is the right time for various upgrades? Doing Fiber to the Premises (FTTP) now spends the bulk of the upgrade budget up front when 99% of its capacity goes unused. Can operators be wiser on when to invest in the network? When will the capacity be needed? Recent broadband bandwidth trends are reviewed and show a sharp decrease in subscriber consumption compounded annual growth rates (CAGR) over recent years. As an example, this might cause the network upgrade cycle to go from every 10 years to every 30 years with resultant economic impact. Upgrading too aggressively may be throwing away dollars in the near term.

Where do multi-system operators (MSOs) touch the network? Is it a complete overlay or just a surgical strike? Swap tap faceplates or go for 3 GHz tap housings? Keep existing amp cascade or push fiber deeper? Walking through the process forces operators to quantify materials, inventories, and project execution times.

Why choose a particular technology direction? Many upgrade decisions must be made soon and made well with the long term, full cycle consideration. Should operators upgrade amps to mid or high split or ESD?

Who will benefit from this? Network operators, small and large. From the long-term, big picture view this analysis gives, they'll be able to focus on just the near-term network operation and upgrade aspects, and plan for the budgets over the next 3-5 years with ease while keeping aligned with their 10- to 30-year cycle objectives. These are the 1-10 nano-Hertz frequencies that are our major concerns.

2. Broadband Traffic Engineering and BW Growth Trends Overview

2.1.1. Broadband Traffic Engineering

The CommScope (formerly ARRIS) team has led industry traffic engineering research for over a decade. [CLO_2014] introduced broadband Quality of Experience (QoE) using a simple formula with basic network capacity components. This evolved and [ULM_2019] gave an updated insight into calculating the service group (SG) capacity requirements:

Modified “COMMScope/CLOONAN’S CAPACITY EQUATION” Traffic Eng Formula:

$$C \geq (N_{sub} * T_{avg}) + (K-1) * T_{max_max} + T_{max_max} \quad (1)$$

The subtle change is that there are now three main components to the traffic engineering formula:

1. Peak Busy Period Average Consumption (i.e., $N_{sub} * T_{avg}$)
2. Peak Busy Period Ripple for managing QoE (i.e., $(K-1) * T_{max_max}$)
3. Headroom for maximum Service Tier Burst (i.e., $1 * T_{max_max}$)

While burst and ripple components manage a subscriber’s QoE, the consumption component is key to SG sizing. The T_{avg} growth rate has seen much research. ARRIS/CommScope has the most extensive broadband capacity monitoring history in the industry, collecting continuously since 2010 from the same MSOs. The 2022 data is in and downstream (DS) T_{avg} growth continues to slow.

The real multi-billion-dollar question is what’s the consumption growth for coming decades? For this paper, it is a three-decade window being considered. This growth drives our network investment strategies. Has T_{avg} growth slowed to a lower rate or is it no longer exponential? A companion paper by these authors [ULM_2022] investigated several possible growth trendlines including exponential, linear, Adoption S-curve and others. Our research measures how accurately each trendline matches last decade’s data. These bandwidth (BW) growth trajectories in [ULM_2022] were mapped out for 5/10/15 years. The resultant spaghetti plots in Figure 1 show a cone of uncertainty that grows over time, roughly doubling every 5 yrs.

2.1.2. Growth Rates for Broadband Peak Period Consumption

To understand the impact of these slowing growth rates, consider the following comparison to projections from just four years ago:

- 2018 DS Growth (43% CAGR) projection => DS T_{avg} = 100 Mbps/sub **by 2030**
- 2022 DS High Growth (21% CAGR) projection => DS T_{avg} = 100 Mbps/sub **by 2040**
- 2022 DS Low Growth (Linear) projection => DS T_{avg} = 100 Mbps/sub **in 200+ years**

[ULM_2022] implied that *the need for FTTP to all subscribers may be pushed back multiple decades*. This paper takes an economic view of different upgrade options for each of the low, medium, and high growth rate scenarios. From a network capacity planning perspective, [ULM_2022] conclusions on multiple growth trendline options were:

- the 5-year window provides a reasonably high confidence for near-term planning
- 10-yr window provides high, moderate, and slow growth ranges for longer term planning
- the 15-yr window shows too much variance and is more of an academic exercise.

This paper considers a 30-year window, so it is clearly noted that this falls under the academic exercise scenarios. However, it is still informative to see how this wide “cone of uncertainty” might impact our network migration economics.

Figure 1 – DS Tavg Growth Projections for 2022 to 2037

Figure 2 – Max Subs per SG for Low, Moderate & High DS Tavg growth, 1794/396 MHz

[ULM_2022] used the CommScope network capacity model to investigate several upgrade case studies. The 1794/396 MHz case study seen in Figure 2 showed that a node with 150+ subs can offer multi-gigabit service tiers; but the timing of additional node splits on the ESD plant is sensitive to which DS Tavg growth trendline it tracks. It shows there is no pressing need to push the HFC to very small (but inefficient!) Node + 0 (N+0) SG sizes in a 10-year window. This paper extends that analysis to 30-years to see how various upgrade options are impacted by the different growth trendlines.

2.1.3. Extending Tavg Growth Trendlines to 2052

The goal is to minimize up front investments while maintaining flexibility to increase network capacity and manage uncertainty risks. In this paper, there are several primary cases being considered in detail:

- Low growth scenario enabling 1.2 GHz DOCSIS 3.1 (D3.1) high-split to last 30 years
- Moderate growth scenario with a 1.8 GHz DOCSIS 4.0 ESD upgrade over 30 years
- High growth scenario with a 1.8 GHz DOCSIS 4.0 ESD upgrade in '23 and FTTP overlay in '44
- High growth scenario with a FTTP upgrade in '23

The impact of the other growth trendlines will also be investigated for each upgrade path to ascertain the operator's risk with each path.

The first step in projecting SG sizes out to 2052 is to extend the Tavg growth trendlines from [ULM_2022]. The DS Tavg growth trendlines are shown in Figure 3 and the upstream (US) Tavg growth trendlines in Figure 4. Because of the divergence of the various trendlines over the 30-year window, note that the Y-axis is now a log scale. Our studies will consider low, medium, and high growth scenarios.

The DS high growth scenario follows the 21% CAGR exponential trendline for the first 15 years. By the end of 30-years, the spread between the linear trendline and the 21% CAGR eventually becomes an almost absurd amount – 17 Mbps compared to 1,100 Mbps. For this study, the authors decided to drop the two extreme trendlines (upper and lower) for the 30-year point, maintaining that the probability of staying at the extreme for 30 consecutive years would be very low. The red ovals in Figures 3 and 4 indicate the trendlines used at 15-years and 30-years with a transition period between them.

For the 30-year period, the DS high growth then transitions to a more moderate 16% CAGR exponential trendline. The DS Tavg window being considered in 2052 still ranges from 22 Mbps to 356 Mbps. Note, even if DS Tavg stayed on the 21% CAGR for 30 straight years, the only impact on our analysis is that the 2052 numbers get pulled in 5-7 years earlier which is a minor impact to the overall financial analysis.

The US high growth scenario follows a similar methodology. It follows the 23% CAGR exponential trendline for the first 15 years, then transitions to a more moderate 18.5% CAGR exponential trendline. The US Tavg window being considered in 2052 ranges from 6 Mbps to 48 Mbps.

Figure 3 – Downstream Tavg Trendline Predictions, 2022 – 52

Figure 4 – Upstream Tavg Trendline Predictions, 2022 – 52

2.1.4. Projecting Service Group (SG) Sizes for a 30-year window

The ARRIS/CommScope Traffic Engineering formula shown earlier provides guidance on calculating SG sizes. For a given network (e.g., 1218/204 MHz HFC plant), the available capacity is known. Once T_{avg} and T_{max_max} are defined, then the maximum number of subscribers, N_{sub} , can be calculated. The DS and US T_{avg} for a given year are derived from the growth trendlines in the previous section. Low, medium, and high growth scenarios are considered.

The final piece to the puzzle is determining what to use for T_{max_max} . The authors decided to set the DS T_{max_max} to 5 Gbps. The rationale being that this can handle any known application today. If an application like virtual reality (VR) or augmented reality (AR) really takes off, then that will drive a higher T_{avg} growth trendline. Having a 5 Gbps service tier burst on top of that high T_{avg} should be more than sufficient. History has shown that it often takes a decade or more before new technologies become mainstream. This can be seen in how long it took High Definition (HD) video streams to become dominant. Ultra-HD 4K video stream has been around almost a decade and still is not dominant yet.

The max US service tier is defined by the particular type of network upgrade. The 204 MHz high split plant supports a 1 Gbps US tier. The 396 MHz ultra-high ESD split supports a 2.5 Gbps US tier. The 10G Passive Optical Network (PON) supports a symmetric 5 Gbps US tier. Again, there is no mainstream application in sight that would need more than a gigabit of burst speed.

Our analysis starts with a typical HFC SG with 200 subscribers (e.g., 400 homes passed (HP) @ 50% penetration). The CommScope network capacity model is then run for low, medium, and high scenarios to determine the maximum number of typical subs that can be support in each year through 2052. When that growth line passes through the 200 sub/SG limit, then the SG needs to be segmented (e.g., 1x1 Remote MACPHY Device (RMD) upgraded to 2x2 RMD). Similarly, once a growth line passes through the 100 sub/SG limit, then the SG needs to be segmented a second time (e.g., 2x2 RMD upgraded to 4x4 RMD). In reality, the number of homes passed per radio frequency (RF) leg is often unbalanced, so a 4x4 RMD may be of limited use and a node split is required instead. As will be seen in the upcoming results, the need for 4x4 segmentation is still 15+ years away for today's 200 sub service groups.

2.1.5. Network Capacity Modeling results for 1.2 GHz HFC Plant

The network capacity modeling results for a 258-1218 MHz HFC DS is shown in Figure 5. The low growth scenario can support 200 typical subs all the way until 2049 when the SG needs a 2x2 segmentation. The moderate growth scenario supports 200 subs per SG through 2033 when it needs a 2x2 segmentation. The network then supports 100 subs per SG until 2040 when a 4x4 segmentation is required. So, an MSO has a clear path to 2052 with a 1.2 GHz HFC DS for both the low and medium growth scenarios.

The high growth scenario is much more challenging for the 1.2 GHz HFC DS. The first 2x2 segmentation comes around 2030 while the next 4x4 segmentation is needed by 2035. The 4x4 segmentation then runs out of capacity around 2040. In reality, the operator will probably switch to either 1.8 GHz or 10G PON sometime in the 2035-40 timeframe.

The network capacity modeling results for a 204 MHz HFC US is shown in Figure 6. In the low growth scenario, US capacity is depleted sooner than the previous DS example. By 2037, the US needs to be segmented. This can be done with a 1x2 RMD replacing the 1x1 RMD. For medium growth, the US timeline is like the DS, although the 2x4/4x4 US does run out of capacity around 2045. This would then require further node splits or a switch to one of the other technologies. The US high growth scenario is very close timeline to the DS timeline.

Figure 5 – Max # of Typical Subs per SG – 258-1218 MHz HFC DS

Figure 6 – Max # of Typical Subs per SG – 204 MHz HFC US

2.1.6. Network Capacity Modeling results for 1.8 GHz ESD Plant

The network capacity modeling results for a 492-1794 MHz ESD DS is shown in Figure 7. The low growth scenario can support 200 typical subs through 2052 with no segmentation required. The moderate growth scenario supports 200 subs per SG through 2039 when it needs a 2x2 segmentation. The network then supports 100 subs per SG until 2047 when a 4x4 segmentation might be needed. Again, an MSO has a clear path to 2052 with a 1.8 GHz ESD DS for both the low and medium growth scenarios.

The high growth scenario is more interesting with the 1.8 GHz ESD DS. The first 2x2 segmentation is not until 2034. The next 4x4 segmentation is needed by 2038. The 4x4 segmentation capacity then holds out until 2044. At this point, the operator has at least three potential paths:

1. Continue to pull fiber deeper and split ESD nodes into smaller SG
2. Switch to FTTP for all customers
3. Do an FTTP overlay and selectively migrate heavy users to PON

The economics of the third option above is looked at in more detail in the upcoming sections.

The network capacity modeling results for a 396 MHz ESD US is shown in Figure 8. In general, all three US growth scenarios have very similar breakpoints as the DS scenarios. The only point that is different is with the medium growth scenario. The 2x2 US runs out of capacity around 2045 where a switch to 2x4 RMD might be needed.

Figure 7 – Max # of Typical Subs per SG – 492-1794 MHz ESD DS

Figure 8 – Max # of Typical Subs per SG – 396 MHz ESD US

2.1.7. Network Capacity Modeling results for 10G PON Plant

The 10G PON modeling assumes 128 HP per Remote Optical Line Terminal (R-OLT) port with 64 subs. The network capacity modeling results for a 10G PON DS is shown in Figure 9. The low growth scenario can support 64 typical subs through 2052 with no segmentation required. The moderate growth scenario supports 64 subs per SG through 2043 when it needs to drop to 64 HP and up to 49 subs through 2052.

The high growth DS scenario pushes the 10G PON capacity, just like it did ESD. Around 2036, it needs to drop to 64 HP and 32 subs. By 2042, the 10G PON needs to segment again to get to 32 HP and smaller SG sizes. This will probably be the time where an operator needs to start transferring heavy users to one of the next generations of PON technology (e.g., 25+ Gbps).

The 10G PON has plenty of US capacity and can handle low, medium, and high growth scenarios for 128 HP and 64 subs per SG through 2052, as is shown in Figure 10.

Figure 9 – Max # of Typical Subs per SG – 10G PON DS

Figure 10 – Max # of Typical Subs per SG – 10G PON US

3. Total Cost of Ownership for Various Network Upgrade Options

3.1. Network Upgrade Considerations

3.1.1. Network Evolution Example

Over the past ~30 years, HFC networks progressed from ragtag one-way community antenna video distribution networks to modern high-capacity video, voice, and data bi-directional networks of today. Figure 11 shows a high-level view of such a network. This example falls under the centralized architecture model, where all the sophisticated communication layer processing takes place in the Head-End. Here, signals are ‘packaged,’ and then ‘shipped’ over a more or less transparent physical network. The other side of processing takes place at the CPE / cable modem (CM).

The way the network was built is best described as an evolution: first the cables were installed; with the RF amplifiers and taps placed where required, and the same with the headend and customer premise gear. Once every ~30 years, the taps get a refresh – typically via faceplate upgrade – for example, 750 MHz taps would get upgraded to 1 GHz or 1.2 GHz taps. Amplifiers get renewed every ~15 years, either due to technological obsolescence or to reaching the end of reliable operation lifetime. Fiber nodes may get a refresh even more often than every 15 years. Node splitting, for example, is still an effective way to boost total capacity and service levels, in otherwise over-subscribed service groups. Finally, the headend and customer premise equipment refresh-cycles fall under just in time schedule – perhaps every 3-5 years, allowing for capacity boosts as needed, in the most cost-efficient way.

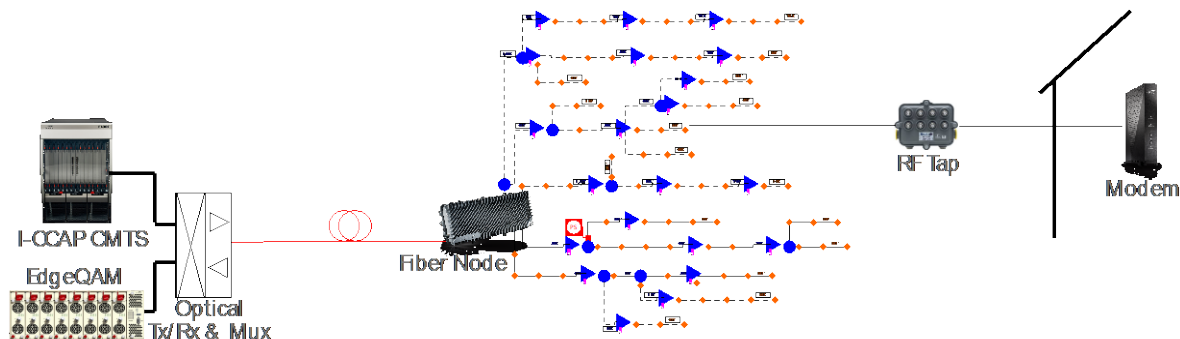

Figure 11: I-CCAP HFC network with head-end, field, & CPE network elements

The example network of Figure 11 may have 1 GHz taps installed 25 years ago, 750/870 or 1000 MHz RF amplifiers with 42/54 MHz RF split, updated 15 years ago, and perhaps 1 GHz nodes, with the same 42/54 MHz sub-split, updated 10 years ago. Headend and CPE may have been upgraded as recently as 5 years ago, with the latest wave of DOCSIS 3.1 (D3.1) deployments, correlated with introduction of 1 Gbps downstream data rates.

As learned in these COVID times, the networks delivered, and delivered marvelously, especially in the downstream. The 42 MHz upstream capacity was severely tested all day long with working and school from home. Some nodes struggled but were quickly upgraded with additional capacity. With FTTP/PON competition offering gigabit rates in the upstream - it is now imperative for MSOs to resolve the network's 42 MHz upstream capacity limitations. So, many operators are now considering their next network migration steps.

3.1.2. Network Upgrade Options to consider

CableLabs DOCSIS spec creators have envisioned these types of scenarios. Many paths exist to upgrade networks and boost its capacity in both downstream and upstream to extend the useful life of the network. Out of many options discussed in [Broadband Pie], the following upgrade scenarios of most interest are considered in this paper:

1. DOCSIS 3.1 Integrated Converged Cable Access Platform (I-CCAP) “high-split” (HS) upgrade
 - With 5-204 MHz upstream, 258 - 1,218 MHz downstream
2. DOCSIS 4.0 RMD ESD “ultra-high-split” (UHS) upgrade
 - With 5-396 MHz upstream, 492 - 1,794 MHz downstream, one of several ESD options
3. FTTP 10G R-PON (Remote OLT PON) upgrade
 - Effectively overbuilding the coaxial portion of the plant with fiber, and providing fiber drops to those homes that have signed up for the service

The FTTP upgrade provides lower operating costs (OPEX), in comparison to HFC networks [bbcmag FTTH OPEX] and [FTTH OPEX]. The more important question is: will those operating cost savings offset a much larger capital expenditure (CAPEX) required upfront to build an all-fiber network? Last year’s SCTE Cable-Tec Expo paper [Broadband Pie] considered this question, by looking into “total cost of ownership” (TCO) of nine various upgrade paths, including the three mentioned above. It used a fifteen-year period for which the total cost was calculated. This paper expands that analysis to consider a 30-year period, and in part to answer if the 15-year timeframe was too limiting.

3.1.3. Time Value of Money

To address any of these various duration questions, the “time value of money” (TVM) concept is one critical element to factor into the analysis. It is incorporated via a “discount rate” for the future years’ cash flows. For example, a discount rate at say 5% applied to \$100 received a year from now has a value today that would be ~\$95, or $1 / (1+5\%) = \$95.24$ exactly. The same applies to the expenses: one postponed by a year is ~5% less of an expense in today’s dollars. Similarly, today’s \$100 is worth \$105 a year from now.

Economists employ a dividend discount model (DDM) [Gordon] to estimate the present value of an infinite-series of future cash flows. A perpetual stream of annual \$100 expenses would be valued at \$2000, \$1333, and \$1000 in today’s dollars, with 5%, 7.5% and 10% discount rates, respectively. A difficult question is what exact discount rate to use – short and long-term interest rates, overall economy growth rate, and inflation rate are contributing factors, and the discount rate chosen affects the present value of future cash flows a lot!

Highlighted points in Figure 12 illustrate what percentages of that present value (PV) is still achieved if the perpetual flow were to cease flowing 15 or 30 years from now – also shown as a function of the discount rate. This concept, applied to TCO analysis, explains that working with a 15-year period considers only between 52% and 76% of the OPEX contributions, provided the discount rates are between 5% and 10%. Moving to 30 years, however, improves those numbers to between 77% and 94%. Given all the uncertainties involved, and that the authors will be thrilled if the overall model accuracy reaches +/-20 %, one may conclude, especially at 7.5% discount rate, to get to the 89% of the total value of OPEX is more than “good enough.” The 7.5% discount rate is chosen as a reasonable middle point between 5% (considered low) and 10% (considered high) discount rates.

Figure 12: Percentage of PV for an infinite cash flow stream

The 30-year window is also an important consideration for CAPEX too. Components such as amplifiers might need replacing every 15 years. With a 7.5% discount rate, the replacement costs for an amplifier 15-years from now adds an additional ~34% in today's dollars to the amplifier's CAPEX costs. Another replacement after 30-years adds another ~12% to the CAPEX. Looking at the finances from a spectral perspective provides a better insight into these recurring costs for some of the options.

3.2. 30-year Total Cost of Ownership (TCO) Assumptions

To get the total cost of ownership, both CAPEX and OPEX are included over a 30-year period.

3.2.1. Capital Expenditures (CAPEX)

CAPEX is determined by adding cost of materials, plus the cost of labor necessary to install the materials. Headend, field, and customer premise equipment are all accounted for. Breakout of what the initial upgrade CAPEX for the three outlined options is shown in Figure 13.

The network shown in Figure 11 is the starting point for each upgrade option. Its characteristics:

- I-CCAP topology, with 5-42 / 54-860 MHz upstream and downstream
- 21,120 feet of hardline coax plant
- 400 HP with a 50% take rate (i.e., 200 subscribers)
- One fiber node, 7 bridger & 14 line-extender RF amplifiers and 100 RF taps

Statistics for this node area work out to:

- 100 homes-passed per mile
- 5.25 RF amplifiers per mile
- 19 homes-passed per amplifier
- ~5 taps per RF amplifier and ~4 homes-passed per tap

This is very representative of a typical suburban North American HFC plant.

Figure 13: Initial CAPEX (\$ per HP) for D3.1 High-split; D4.0 ESD; & 10G R-PON upgrades

Figure 14: Initial CAPEX (\$ per HP) for D3.1 High-split & D4.0 ESD upgrades - detailed

Table 1: Initial upgrade CAPEX, per node area

	I-CCAP 1218/204 MHz High Split	DAA 1794/396 MHz UHS ESD	FTTP 10G R-PON 20% Underground	FTTP 10G R-PON 80% Underground
CMTS / Video license	\$3,250	\$800	\$800	\$800
CIN / Ethernet Switches		\$871	\$3,485	\$3,485
Head-End Optics	\$3,210	\$1,000	\$4,000	\$4,000
Node Hardware	\$4,100	\$7,000	\$11,875	\$11,875
Field Hardware	\$10,500	\$17,640	\$500	\$500
Field labor, incl node	\$6,050	\$6,800	\$13,563	\$13,563
Fiber, material + labor		\$2,112	\$84,480	\$211,200
Taps/splitters, mtrl + lbr	\$4,000	\$8,000	\$7,500	\$7,500
Drops, material + labor			\$40,000	\$40,000
CPE		\$240	\$24,000	\$24,000
Total, per SG or node	\$31,110	\$44,463	\$190,203	\$316,923
Total, per HP	\$78	\$111	\$476	\$792

**** Disclaimer: Price points discussed and shown in this document are meant to provide indicative general trends for these architectures, and as such should not be construed as an offer for selling any products at any of the price points shown. ****

Material and labor per node area are best-effort estimates, shown in Figure 14 and detailed in Table 1.

For I-CCAP high-split option, CMTS license covers additional DS and US enabled D3.1 spectrum. Furthermore, complete replacement of head-end optics, node and RF amplifiers is assumed, with digital return for the 5-204 MHz upstream spectrum. Field labor includes \$500 for the node replacement, \$250 per bridger and \$200 per line extender, plus \$1,000 for documentation update for the area. Only the tap faceplate is upgraded, at \$40 per tap.

For ESD 396/492 MHz ultra-high-split option, the head-end side of Figure 11 gets upgraded to the one shown in Figure 15 – the Cable Modem Termination System (CMTS), digital video Quadrature Amplitude Modulation (QAM) generators and analog headend optics are replaced by converged interconnect network (CIN), interfacing the Ethernet and video core with the node-located Remote PHY device (RPD) and/or RMD devices. Pluggable Dense Wavelength Division Multiplexing (DWDM) enhanced Small Form-factor Pluggable (SFP+) modules are shown at \$1,000 each, with one on each end of the digital optical link interfacing CIN and the node. 1.8 GHz Node and RF amplifier hardware are new products and assumed to be at 40% premium over those for 1.2 GHz. The 1.8 GHz ESD upgrade has some additions in comparison to the 1.2 GHz case, including a provision for 5% of aerial plant cable replacement, and an increase in the number of actives, from 7 & 14 to 10 & 14 bridgers & line extenders, respectively. Furthermore, a complete tap housing upgrade to 1.8 GHz is included at \$80 per tap, including material & labor.

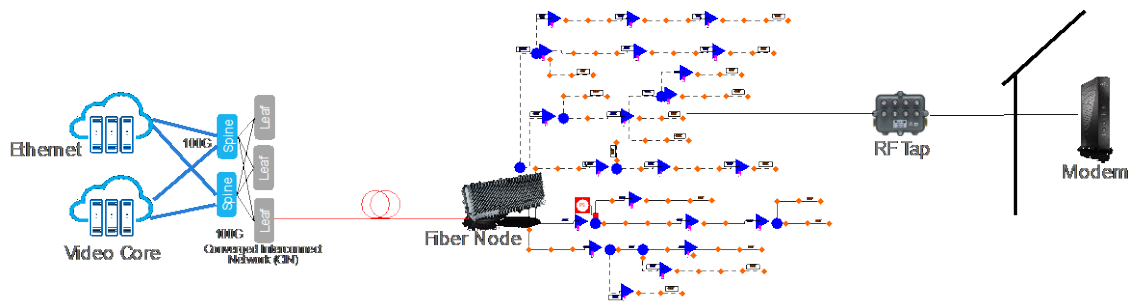

Figure 15: Head-end changes for DAA D4.0 ESD upgrade

For the 10G R-PON upgrade, Figure 15 topology serves as a blueprint, except that the complete hardline coax plant is overbuilt with fiber. The first PON option assumes an 80/20 percent mix of aerial to underground plant, with \$2/foot for aerial, and \$12/foot for underground - which comes to a blended cost of \$4/foot – for both material & labor to install. The second PON option assumes a 20/80 percent mix of aerial/underground plant with a blended cost of \$10/foot. The same CIN headend network of Figure 15 feeds node located R-PON remote optical line terminals (R-OLTs), using SFP+ modules at both ends, just like the ESD case. A quantity 4 of optical wavelengths are required, given the 1x 128 splitting ratio presumed for the 10G R-PON case. Field optical splitters costs are shown in taps row; drops, at \$200 each, and CPE, at \$120 each, are allotted for subscribed premises (50% of homes passed) only.

As can be seen by the results at the bottom of Table 1, the initial PON upgrade costs dwarf the initial HFC upgrade costs, by up to 10x more. The billion-dollar question is whether the PON networks save the operator enough over 30-years in OPEX and additional CAPEX savings to make this investment worthwhile.

3.2.1. Operational Expenditures (OPEX)

The OPEX includes headend and field power consumption, plant cable and drop cable repair and maintenance costs, and field active maintenance (material and labor to address equipment failures).

Field active maintenance cost in time is based on the heuristics curve from [Broadband Pie] and is repeated in Figure 16. As can be seen, there is a significant rise in failures after year 10.

Figure 16: Field actives percentage fail heuristics curve

I-CCAP 1.2 GHz headend powering needs are estimated as 124 Watts (W) per node area, including 50% cooling provision overhead for the buildings Heating, Ventilation and Air Conditioning (HVAC). Field line power supplies are presumed to operate with 85% efficiency, feeding 90W, 45W, and 25W to nodes, bridgers, and line extenders, respectively, assuming 3% in-coax ohmic loss.

For the 1.8 GHz DAA, the headend side consumption drops to 18W, while the field component assumptions change to 150W, 60W, and 35W, for nodes, bridgers, and line extenders, respectively.

The R-PON R-OLTs are modeled at 18W and 22W per 10G OLT port, on the headend and node side, respectively.

With \$0.12 per kilowatt-hour (kWh) assumption, the powering cost conveniently comes out to “kilo-dollar per kWh” for the whole year:

- 24 hours x 365.25 days = 8,766 hours in a year, times \$0.12 / kWh = \$1,052 per kWh per year

For the HFC upgrades, an annual upkeep is expected to be required for 1% of the hardline plant, as well as 1% of the drop-coax. This has also been built into OPEX. For the PON case, however, only 0.35% upkeep assumption of the cables, and 0.5% for the drop fibers has been considered.

3.3. 30-year TCO Cash Flows – in Nominal \$

Our economic models take in all the above CAPEX and OPEX assumptions and spit out TCO cash flows, over the 30-year period considered. Figures 17-21 display these cashflows, with plant OPEX, plant CAPEX, and CPE CAPEX color coded. Note the difference in scales. These are in nominal dollars and do not reflect the time value of money mentioned earlier. For each case, the initial upgrade CAPEX shows in year 2023. HFC plant OPEX grows slightly in time, driven by the increase of field actives failures, per Figure 16. Year 2038 shows the next big CAPEX investment, to address the aging of the HFC plant actives. HFC CPE CAPEX assumes 20% of all CPEs getting replaced every 3 years, in the D3.1 and D4.0 cases; and 25% of all CPEs replaced every 5 years in the case of the 10G PON.

Different Tav_g growth rates were used with different scenarios to show the potential range of costs. The 1.2 GHz high-split upgrade scenario assumes a low growth rate. This shows a best-case scenario from a cost perspective. The 1.8 GHz ESD upgrade uses the medium growth rate to represent a middle of the road scenario. Both R-PON scenarios and the ESD to R-PON migration assume a high growth rate.

The 2049 CAPEX upgrade in Figure 17 reflects the need to split the 1.2 GHz I-CCAP service group in order to keep up with the low-CAGR growth assumption. Similarly, the 2046 and 2042 CAPEX upgrades in Figures 18-20 reflect the need to split 1.8 GHz ESD and 10G PON service groups, in order to keep up with the moderate and high-CAGR scenarios, respectively.

Figure 17: TCO of 1.2 GHz HS upgrade, with plant CAPEX + OPEX, and CPE CAPEX

Figure 18: TCO of 1.8 GHz ESD upgrade, with plant CAPEX + OPEX, and CPE CAPEX

Figure 19: TCO for 10G R-PON, 20% U/G, with plant CAPEX + OPEX, & CPE CAPEX

Figure 20: TCO for 10G R-PON, 80% U/G, with plant CAPEX + OPEX, & CPE CAPEX

Figure 21: TCO for ESD to R-PON upgrade with plant CAPEX + OPEX, & CPE CAPEX

Figure 21 represents an interesting scenario where the operator invests in an ESD upgrade in 2023. However, if a high growth scenario is followed for 20+ years, then the ESD plant SG sizes start to become challenged in the '40s decade. This case study assumes a FTTP overlay that starts in 2044 and assumes 20% underground plant. The “heavy” DOCSIS users are migrated to FTTP. For our analysis, the 20/80 rule was followed where the top 20% move to FTTP while the lower 80% remain on ESD. With the 20/80 rule, the top 20% represent 80% of the BW usage (i.e., FTTP) while the lower 80% represents only 20% of total BW consumption. A blended approach like this can keep the majority of subscribers on HFC for many, many decades.

3.4. 30-year TCO Cash Flows – in 2023 \$

CAPEX and OPEX cash flows over time, as shown in Figures 17-21 above, provide lots of information, however, are hard to compare to each other given the different timing of different expenses. One way to deal with this issue is to bring valuation of all the future flows back to the present time – or, as shown in Figures 22-26 - to bring the valuations to 2023 dollars. As stated previously, a 7.5% annual discount rate has been used to perform this “cash travel in time.” In particular, note the decrease in the cost components that are 15-30 years in the future. This is perhaps most dramatic in figure 24 for the ESD to R-PON migration scenario. Compare Figure 24 to Figure 21 to see the effect of TVM.

Figure 22: TCO of 1.2 GHz high-split upgrade over time, in '23 dollars

Figure 23: TCO of 1.8 GHz ESD upgrade over time, in '23 dollars

Figure 24: TCO of ESD to R-PON upgrade in '23 dollars

Figure 25: TCO of 10G R- PON upgrade, 20% U/G, in '23 dollars

Figure 26: TCO of 10G R- PON upgrade, 80% U/G, in '23 dollars

3.5. A Nano-Hertz Spectral Analysis

Looking at these ‘cash flows over time’ graphs, a clear pattern emerges: some CAPEX takes place only once in 30 years (fiber plant build, HFC tap upgrade, demand-driven service group splits), every 15 years (aged actives upgrade), every 5 years (PON ONUs), 3 years (HFC CPEs), and some annually (OPEX). “Your mileage may vary” adage applies here, however; the above frequencies accurately reflect the assumptions made.

This is where the signal analysis time domain / frequency domain analogy came from: what would these expenses look like if viewed in the ‘frequency domain’? Figures 27-31 provide the answer.

Figure 27: 1.2 GHz high-split upgrade TCO in frequency domain, in ‘23 dollars

Figure 28: 1.8 GHz ESD upgrade TCO in frequency domain, in ‘23 dollars

Figure 29: ESD to R-PON upgrade TCO in frequency domain, in '23 dollars

Figure 30: 10G R-PON 20% U/G upgrade TCO in frequency domain, in '23 dollars

Figure 31: 10G R-PON 80% U/G upgrade TCO in frequency domain, in '23 dollars

Frequency of 'once every year' can be calculated in Hz, which is 1/s, by counting how many seconds there are in an average year (31,557,600), and then taking the inverse; to get 31.7×10^{-9} or 31.7 nano Hertz (nHz). That's why the annual OPEX in Figures 27-31 is positioned where it is. Similarly, 30-year periodicity is at ~1 nHz, 15-year at ~2 nHz, 5-year at ~6 nHz, 3-year at ~10 nHz, and so on.

The ~2 nHz dominant CAPEX peaks in Figures 27 and 28 reflect the 15-year cycle of active network elements upgrades (nodes, RF amps, headend optics), while ~1 nHz peaks comprise the 30-year cycle of RF tap replacements and occasional once in 30-year node splits.

The ~2nHz CAPEX peak in Figure 29, ESD to PON upgrade, is an almost exact replica of the same peak of Figure 28, ESD only upgrade, while the ~1 nHz peak captures the once in 30 years fiber overbuild. For the two PON upgrades in Figures 30 and 31, the ~2 nHz peak reflects 15-year cycle of R-OLT refreshes, while the left-most peak of ~1 nHz captures the rest: fiber overbuild, splitting network, drops buildout – investments that are made just once over the observed period. For all the five cases in Figures 27 -31, CPE capex reflects 3-year cycle for HFC, and the 5-year cycle for PON, while the OPEX shows at the annual-cycle frequency of ~31 nHz and is ~50% lower for the PON upgrades, in comparison to the HFC ones.

3.5.1. Network Upgrade Comparisons – D3.1 vs. ESD vs. FTTP

Comparison among various upgrade approaches seems easier in the frequency domain – in good part because this domain represents ‘integral over time,’ and in our case expressed in 2023 dollars. Table 2 compares the considered scenarios, by adding up NPV of plant CAPEX, plant OPEX and CPE CAPEX, already shown in the frequency domain plots, to get the comparison in NPV TCO.

Table 2: Network upgrade scenarios compared, in '23 dollars

Upgrade Scenario	1.2 GHz D3.1 HS	1.8 GHz D4.0 ESD	1.8 GHz ESD (w PON overlay ⁴⁴)	10G R-PON 20% Underground	10G R-PON 80% Underground
Tavg Growth Scenario	Low	Medium	High	High	High
NPV (Plant CAPEX)	\$103	\$146	\$209	\$468	\$785
NPV (Plant OPEX)	\$100	\$126	\$131	\$44	\$58
NPV (CPE CAPEX)	\$31	\$36	\$38	\$89	\$89
NPV TCO (7.5% TVM)	\$235	\$308	\$380	\$601	\$932
Total cash outlays over time	\$496	\$643	\$971	\$826	\$1,176

While the initial 10G PON CAPEX towers at up to ~10x the cost for the HFC upgrades, the TCO ratios for the 30-year period with OPEX included have dropped to 2x to 3x, for PON upgrade compared to 1.8G ESD upgrade; 2.5x to 4x compared to 1.2G HS I-CCAP upgrade. Time value of money discounting improves the HFC upgrades, given many expenses that are delayed in time. The PON upgrades, however, are heavily front-weighted, even though PON benefits from 50-60% lower OPEX, as compared to the two HFC upgrades.

Perhaps the most interesting result is the middle column – the ESD to R-PON migration. Traditionally, operators may ask why should they invest in ESD now if they must jump to FTTP in the future? Looking at the total cash outlays, in nominal dollars, in the last row of table 2, notice that this option comes in at \$971/HP while the equivalent 10G R-PON is at \$826/HP. However, factoring in the time value of money results in the ESD to PON migration scenario TCO of only \$380/HP in '23 dollars, while the R-PON

option is \$601/HP. That is almost 60% more cost for R-PON only in '23 dollars. So, if an operator chooses the ESD path in '23, the downside risk, if consumption were to follow the high growth rate, is very manageable and would costs significantly less than R-PON.

In summary, the PON upgrades still cost the operator double, triple, or even quadruple the amount of '23 dollars invested in the plant. But is this difference significant or immaterial to operators' budgets today? To answer this question, the next section compares these cost outlays to operators' existing business-as-usual CAPEX rates.

4. MSO Perspective – Current CAPEX vs. Upgrade TCO

Stepping back for a second, let's look at some key MSO's current capital expenditures to see how these various upgrades fit into their business-as-usual spending. Four USA cable operators: Comcast [CMCSA – cable segment only], Charter [CHTR], Altice USA [ATUS], and Cable One [CABO] are publicly traded companies and provide a wealth of information in their annual report filings and quarterly earning updates. Figure 32 shows annual amount of capital expenditures of each operator for the years 2019 – 2022. (The amounts for 2019-2021 are actually spent, the 2022 number is based on operators' full-year guidance numbers declared at their 2022 Q1 earnings calls). Comcast Cable and Charter, each with ~60 and ~55 million homes and businesses passed, are shown separately from the two smaller ones: Altice USA and Cable One, with ~9.3 and ~2.7 million home passings, respectively.

So, what, some may say? Well, these numbers on their own maybe don't say much. That is why they're often expressed as a percentage of revenue – and typically > 10% of the revenue, because cable is one capital intense business. Nevertheless, those same annual CAPEX numbers normalized by operators' number of homes and business passed (i.e., passings), are much more informative: Figure 33 shows such a normalization, with a weighted average line also added. Even without the addition of the weighted average line, most of the annual data points fall in the \$110-\$140 per home or business passed range, with the weighted average coming closely to the \$130/year value.

Of the four operators, ATUS has been the most vocal about migrating its customers to FTTP. Note how much higher their CAPEX jumped in 2022 compared to the other three operators.

Figure 32: Annual CAPEX for four USA MSOs: Comcast, Charter, Altice USA, Cable One

Figure 33: Annual CAPEX for four USA MSOs, Normalized per HP

But what percentage of annual CAPEX is directly related to the network of Figure 11? Charter [CHTR] 1Q22 investors presentation offers a clue – during the year 2021, about 27% of the CAPEX went to ‘CPE/Install,’ with the other 33% to the network side – for ‘Line Extensions’ (~23%) and ‘Upgrade/Rebuild’ (~10%) categories, as shown in Figure 34.

One thus may extrapolate that about $27\% + 23\% + 10\% = 60\%$ of overall operators CAPEX goes into the network, which, multiplied with the values of ‘weighted average’ from Figure 33 gives ~\$77 per-year per-home-passed, of which a slightly larger part (~\$42) applies to the plant and the rest (~\$35) to the CPE CAPEX. Note that a large portion of the CPE CAPEX applies to set top boxes (STB) and digital video recorders (DVR) for video service inside subscriber’s homes. As operators migrate to (Internet Protocol (IP) Video, there will be some reduction in the CPE CAPEX that could be applied to the network CAPEX.

			LTM	
	1Q21	1Q22	1Q21	1Q22
Cable	\$ 1,709	\$1,783	\$ 7,242	\$7,227
Mobile	112	74	533	444
Total	\$ 1,821	\$ 1,857	\$ 7,775	\$ 7,671
<i>Of which: Commercial</i>	\$ 333	\$ 365	\$ 1,397	\$ 1,477
<i>Of which: Rural Construction Initiative</i>	n/a	\$ 232	n/a	\$ 232

Highlights

- 1Q22 capex of \$1.9B comprised of \$1.8B cable and \$74M mobile
- Cable capex includes \$232M of rural construction initiative spend, most of which is included in line extensions capital
- Y/Y increase in line extensions of \$143M due to the rural construction initiative
- Y/Y decrease in support of \$48M primarily due to lower mobile capex and timing of vehicle spend
- Y/Y decrease in scalable infrastructure of \$40M primarily due to timing of spend
- Mobile capital expenditures of \$74M primarily for back office systems, most of which is included in support capital

Figure 34: CAPEX by category, from Charter's 1Q22 financial results

As a first sanity check, let's look at \$~50 per HP per year for network CAPEX, expanded every 30 years, with a 7.5% discount rate. This results in \$590 NPV TCO values expressed in 2023 dollars. Thus, compared to the values in Table 2, if CAPEX were to continue at the rates shown above, any of the HFC upgrade paths could be afforded. A fiber upgrade may be possible if the plant is mostly above ground. Otherwise, a significant increase in CAPEX over 30-years is needed if there is significant underground plant.

Now consider that the operator has roughly \$25/HP to \$30/HP per year available for these major network upgrades. It turns out that the operator could upgrade all systems to 1.2 GHz over three years; or upgrade all systems to ESD over a 4- to 5-year window. This seems very reasonable. A hybrid of mainly HFC upgrades, plus a careful mix of the FTTP PON ones, where necessary, is another possibility. The necessity is primarily driven by competitors' actions.

If the operators stay at \$25/HP to \$30/HP per year for the FTTP upgrades, these will need to get spread over 20 to 30-year window, and this would likely not fix the BW problems in a timely manner. If the operator bumps the network CAPEX investments up to \$80/HP to \$100/HP range (e.g., similar to what ATUS may have done), then FTTP upgrade path would take 5- to 6-years for mostly aerial plant and 8- to 10- years for mostly underground plant. And this doesn't include any HFC upgrades in the interim to remain competitive and provide required capacity to maintain existing QoE.

Caveat Emptor (buyer beware) warning is in order here – above statement are valid, provided all of the assumptions made above are valid.

5. Variations / sensitivity analysis

“One should not make predictions, especially about the future” is a quip variously attributed to Samuel Goldwyn of Metro-Goldwyn-Mayer fame, [Goldwyn], Yogi Berra of baseball-playing philosopher fame [Yogi], and to Niels Bohr, Nobel-prize-winning quantum physicist [Bohr]. Taking these esteemed gentlemen’s advice to heart, this section is more about the range of possibilities rather than some precise foretelling of how the networks shall evolve – because only time will tell.

5.1.1. HFC Sensitivity analysis

Thus, rather than provide predictions, Monte-Carlo analysis of Figure 35 and Figure 36 show a range of possible outcomes for TCO of the two HFC upgrades. The graphs show a range and probability of outcomes, based on a certain set of assumptions specified. These ‘frequency views’ are formed after a run of 100,000 trials is completed.

Figure 35: TCO Sensitivity for 1.2 GHz High-Split upgrade – 100,000 trials Monte-Carlo run

Figure 36: TCO Sensitivity for 1.8 GHz ESD upgrade – 100,000 trials Monte-Carlo run

Rather than discuss a single value under certain assumptions, as done in the previous section, these charts offer a range of outcomes, given certain ranges of assumed variables. Thus, a 95% confidence interval for 1.2 GHz high-split I-CCAP upgrade is \$193-\$310, vs. \$254-\$405 for the 1.8 GHz ultra-high-split ESD upgrade. Note that the high end of both 95% confidence intervals is ~30% higher than the base case.

To better understand the model's sensitivity to various assumptions, Figure 37 and Figure 38 display "Tornado charts", for the two HFC upgrade cases: 1.2 GHz high-split I-CCAP and 1.8 GHz ultra-high-split ESD. The Tornado chart ranks each variable's impact from most on the top to least on the bottom. The HFC upgrades are the most sensitive to the number of passings per node, followed closely by the discount rate assumed. Other variables had noticeably less impact and ranked as: cost of kWh of power, number of amplifiers in the network, and so on.

Figure 37: Sensitivity Tornado chart – 1.2 GHz high-split

Figure 38: Sensitivity Tornado chart – 1.8 GHz ESD

5.1.2. R-PON Sensitivity Analysis

10G PON cases have charts of their own: Figure 39 displays the distribution and range for the TCO of 10G R-PON upgrade with 20% underground plant. Its 95% confidence interval spans \$512-\$817; under various assumption ranges, as shown in the sensitivity Tornado chart of Figure 41. To no surprise, the % of underground plant had the biggest impact on sensitivity. The high end of the 95% confidence interval is ~36% higher than the baseline. This shows that FTTP upgrades have more sensitivity in their cost analysis than their HFC counterparts.

Figure 40 displays the distribution and range for the TCO of 10G R-PON upgrade with 80% underground plant. Its 95% confidence interval spans \$782-\$1,370 under various assumption ranges, as shown in the sensitivity Tornado chart of figure 42Figure 41. Because the % of underground plant is already very high,

the cost of fiber material & labor had the biggest impact on its sensitivity. The high end of the 95% confidence interval is almost 50% higher than the baseline, showing even more variability. This shows that the higher the % of underground plant, then the higher FTTP sensitivity becomes.

Figure 39: TCO Sensitivity for R-PON 20% U/G upgrade – 100K trials Monte-Carlo runs

Figure 40: TCO Sensitivity for R-PON 80% U/G upgrade – 100K trials Monte-Carlo runs

Order of variables affecting the TCO of PON upgrade differ from those of the HFC upgrades – understandably so – the cost of running new fiber is highly sensitive to the % of the plant that's underground, as opposed to aerial. Plant length is closely behind, as is fiber installation cost. Interestingly, the discount rate does not affect the outcome as prominently here as it does for the HFC upgrades. This can be explained by HFC annual costs fairly evenly distributed in time, and thus

benefiting or not from a high/low discount rate, while the PON costs are mainly upfront and as such don't get much of a benefit if the discount rate is high.

Figure 41: Sensitivity Tornado chart for the 10G R-PON 20% U/G upgrade

Figure 42: Sensitivity Tornado chart for the 10G R-PON 80% U/G upgrade

5.1.1. ESD to R-PON Sensitivity Analysis

Perhaps the most interesting upgrade path under consideration for the high growth projection is starting with an ESD upgrade in '23 and then to add an R-PON overlay in '44. This had a baseline NPV TCO of \$380/HP. The Monte Carlo sensitivity analysis for this scenario is shown in Figure 43. The 95% confidence interval is \$307/HP to \$533/HP. The top end of this blended upgrade scenario is ~40% higher than the base line.

The Tornado chart is shown in Figure 44. For this case, the discount rate is the most impactful variable followed by HP per parent node. The % of underground plant is a distant third to these inputs, with variation of ~\$37 per 20% increase in underground runs. This means that even an 80% underground plant

would add just \$110 to the NPV TCO of the ESD-to-R-PON upgrade, as compared to adding \$331 if PON upgrade were to be done in 2023.

Figure 43: TCO Sensitivity for ESD to R-PON upgrade – 100K trials Monte-Carlo runs

Figure 44: Sensitivity Tornado chart for the ESD to R-PON upgrade

6. Conclusion

Damn the torpedoes – the humankind’s inability to predict the future ought not to stop us from trying to envision what a possible range of network upgrade outcomes may look like – that’s what this paper is about. Common to all scenarios was the starting point of 400HP, 200 subs per node, with the top tier of 5/1 Gbps DS/US as the common goal.

The 1.8 GHz ESD plant upgrade handled the low to moderate DS Tav_g growth projections just fine, through the 30-year window. The moderate case needed two node splits – one in 2038 and the other in 2046. Its TCO/HP came to \$308 in '23 dollars. If DS Tav_g follows the high growth projection for 20+ years, then a R-PON overlay might be needed to migrate ‘heavy’ customers to FTTP. This increased the NPV TCO/HP up to \$380. This effectively provides a ceiling for the potential NPV TCO based on low to high growth scenarios.

For the low growth DS Tav_g projections, the 1.2 GHz high split I-CCAP upgrade held up surprisingly well, with just one node split required in 2049. Its TCO/HP came to \$235. For non-competitive markets

and/or tight capital budgets, this remains a solid option. However, if DS Tavg follows the moderate to high growth projections, then a switch to ESD or FTTP will be needed during the next decade.

The FTTP PON upgrades are often associated with the high growth scenarios, but cost 2x higher than ESD NPV TCO/HP (i.e., \$308 vs. \$601) when overbuilding 80% aerial plant; and 3x higher (i.e., \$308 vs. \$932) for 20% aerial plant (and the rest underground). Along the way, the 10G R-PON original 1:128 splitting group had to be halved twice: once in 2035, and second time in 2042. And if the DS Tavg growth follows the low or moderate projections, then the operator may be spending a lot of excess money it might not need to.

Pushing big spending decisions into the future does provide significant value in today's dollars, as seen in "1.8 GHz ESD upgrade now, overbuild with fiber in 2044" scenario. This scenario benefits from the lower NPV TCO of the ESD route, as well as from the future high capacity of PON, but only implemented if needed. The blended ESD/PON path NPV TCO comes in 37% saving compared to doing PON now, and only at a 23% premium, in 2023 dollars, as compared to staying with ESD for 30 years.

Based on the track record of the publicly traded USA MSOs, the CAPEX dollars are likely to stay available for the lower cost upgrade approaches, provided operators' profitability stays on part. Another option is to use a hybrid approach: a lower-cost HFC upgrades where the market drivers call for it, and the higher cost/higher capacity PON in competitive markets. To conclude, if in doubt, let the market show you the way.

1. Introduction

“Software is eating the world” quipped Mark Andreessen in 2011 [4]. Today it is apt to say that **“Open Source is eating the software world.”** From toasters to a helicopter on Mars, systems are using a robust amount of open source software in their stack. According to the 2021 Open Source Security and Risk Analysis Report by Synopsys [1], 75% of all codebases were comprised of open source code alone.

However, it is still not always easy to work with open source projects 30 years after open source came into being. Organizations and individuals experience challenges in gauging the health of a project: is it stable, secure, sustainable, and will it be there if I depend on it, are common concerns. While the acquisition of open source is free, there is significant effort needed to comply with the hundreds of open source licenses used. To be successful, it is important for organizations that consume open source to contribute back, and to engage with the project. Projects come in all shapes and sizes, with different processes, tools, and funding models; knowing how to navigate open source is a learned skill. As open source companies mature, they also need to learn to release code that they have created, and learn to build communities of users and contributors around it.

2. Open Source Development

Adopting open source development models is flourishing as more businesses discover the advantage of open source projects. Those advantages over proprietary solutions, and the mindset around open source, continue to change as it becomes a more prevalent solution pool. Open source is a mindset which can be applied to solve different problems; it is effectively thriving in software development, but we are seeing an open source development model being used for new hardware development as well, such as Reduced Instruction Set Architecture (RISCV), which involves open source being adopted across the central processing unit (CPU) industry. The recent COVID-19 pandemic also saw open source approaches used for contact tracing and collaboration across the medical industry. While a traditional approach followed a series of steps including requirement, design, implementation, testing and quality assurance (QA), system integration, and deployment all performed serially, in open source the work is done in smaller increments and a “release early release often” approach is adopted. Many of the steps described above are performed in parallel and are iterated more often which allows end users to access the code early in development cycles. This approach is quite successful as it allows faster development and testing, transparency and openness, rapid innovation, enhanced collaboration, and high-quality peer reviewed code.

2.1. Community

All successful open source projects build upon a healthy, growing community of users, developers, maintainers, and promoters. They all share a common goal which is served by the project. The communities are global in nature, comprised of people from diverse backgrounds, which empowers the project with new ways of solving problems with novel ideas. This helps project members to develop new features and capabilities at a faster rate than isolated internal teams could. A collective approach of the community consisting of talented people across the

world can deliver solutions faster and more rapidly innovate. This approach establishes an environment of efficient contributions and community team collaboration. An open source community has a strong desire to engage in meaningful productive work, aspiring to develop a sense of belonging, and make it easy for new members to feel at home and connected with others. Open source communities differ in many aspects and each has a unique culture. It cannot be assumed that what is learned as part of one community will be directly applicable in another community. Openness in community fosters authenticity, and members tend to respect it. Therefore, most thriving development communities are those that conduct their activities in open.

2.2. Reliability and Security

Open source projects host the source code in open repository infrastructures such as GitHub or GitLab, making the code more accessible to a wider audience of developers and individuals. This approach results in more individuals looking into the source code regularly. Some users will test newly developed code and provide feedback to developers. Because the code is reviewed in an open environment, healthy reviews are the norm, making the code more robust prior to acceptance[7]. Since code is subjected to much more thorough review and testing, it also tends to be more secure [6], and any security issues that do arise afterwards are handled briskly. Updates are frequent which provides a smaller window for exploiting any weaknesses in code. A major motivation in decision-making is to select the best possible solution. In some cases, this means selecting best technical solution instead of being influenced by other factors which might provide a quick but technically inferior solution. This merit-based approach is key reason for open source projects being more reliable and secure[5]. It is good to use security response time for patching security related bugs of a given project as part of selection criteria for an open source project.

2.3. Transparency

In an open-source community, code is available openly, and all discussions happen on open channels such as internet relay chat (IRC), web forums, or through mailing lists. All decisions regarding new features and defects also follow open channels. This information is very valuable for users as they can see the technical merits or limitations of the solution and avoid any unwanted surprises later in deployments. Open channels also encourage users to discuss the code issues they encounter with the community and forge collaborative solutions. This also avoids vendor lock-in which might be a consequence of using closed solutions.

2.4. Support and Maintainance

Any software will need support, and open source projects are no exception. While proprietary solutions are extensively supported by vendors providing a single point of contact, this model may not translate directly to open source, as the software is created by a number of developers covering different parts of the project. Therefore, it is important to look into the support aspect of projects and find third-party dedicated support or use the online community-provided support if that is sufficient. There may be no upfront cost to using an open source project, though there could be additional cost due to integration or maintenance of the project needed in the business solution. After some time, an open source project may stop supporting a prior version that was deployed in products, which could mean additional cost to engage third-party software support. It is beneficial to understand these hidden costs beforehand for better estimation of support costs

for the products. It is worth stating that the costs for support and maintenance will be reduced compared to a traditional approach, but it will not be zero, as some might proclaim or assume since the code is available for free.

2.5. Working with Open Source Communities

Each open source community is unique and has subtle characteristics which need to be well understood for one to effectively participate in the community. It is important to understand that communities are united by a common interest; finding this interest and understanding the goals of a given project is of utmost importance. Communities have laid out certain rules of engagement, though not all of them may be documented. These can be learned by reading through community channels, forums, and mailing lists, or by interacting with experienced community members.

Usually, projects have a README file which is a good place to get acquainted with the project. There are other common files which may be provided by projects including:

- CONTRIBUTING file, which would list contributing procedures and tools required.
- MAINTAINERS file, which is a good resource to learn about key developers and maintainers who can be valuable points of contact as you start engaging with the community.
- LICENSE or COPYING file, which lists the open source license governing the content of the source provided by the project. This is crucial information which should be well understood. It may require review by your organization's legal team to provide guidance on the mode of engagement that can be pursued.

Some projects with a large codebase and community create governing bodies to take care of project administration and future technical directions. These governing bodies are instrumental in shepherding the project and it is important to understand the role and functions of such committees if they exist.

There are frequently multiple projects available for a given requirement in a product. Therefore, it becomes important to select the best fit. The maturity of a project is an important mark; looking at the number of commits and rate of commits can give a good hint of project maturity. Some infrastructures such as GitHub also provides stars for a project which are awarded by users of the project; more stars means that more users found the project useful for their needs. This could be another parameter to check. Regular release cycles can be used to deduce how actively code is maintained. If a project does not have a deterministic release cadence it becomes difficult to engage with such projects because it would be hard to align with your project roadmap. In other instances, the number of open defects and the rate at which the issues are handled can serve as a good mark of project development. A larger number of contributors is a good sign as well, since it would mean that it would be easier to find help when needed, while diversity in committers could also be indication of good quality within a project. There are other markers that can indicate the strength of a project including Continuous Integration (CI), good documentation, and examples and lists of other projects using or depending upon the project. Open source project space is dynamic, and projects can be started and soon become stale or dead. The risk that arises due to this unpredictability can be minimized by taking precautions as mentioned above.

Contributing to a project is important and is the lifeline of any open source project. If you depend on an open source project, you should consider contributing to the project. Doing so would benefit your use case as it also supports the overall project. When we speak of contributing, it is often equated with contribution made in the form of code. Even though it is a significant contribution category, this is not the only way to contribute to a project. There are other aspects of projects that can benefit from contributions as well. Documentation is one key aspect of any project and does not strictly involve code right away. Open source projects interact via online forums or mailing lists, where many questions are asked, so active members can contribute by answering these questions. Website designs, infrastructure setups, providing computers for CI, defect triaging, organizing events, connecting community members, promoting and marketing the project, and mentoring new community members are additional ways to contribute to a project in a significant manner.

As one becomes a regular contributor, they can begin providing inputs for project directions along with new features and design decisions. These are deeper engagements which could require a significant time investment. Doing this, however, would be impactful and help steer the project and promote you into an influencer or leadership role in a project or community.

2.6. Open Source Licensing

Most open source software projects have licenses. If there is no license mentioned explicitly, then you should assume the software is not being licensed and therefore may not be copied, distributed, modified or otherwise used.

Some of the common open source licenses are GPL family, Apache 2.0, MIT, Mozilla Public license, and BSD family. Broadly, these licenses are classified as either copyleft or permissive. Copyleft licenses typically demand reciprocity and require that any derivative work is also licensed under the same obligations. The GPL v3 license is an example of a copyleft license. Some licenses are permissive, which grants license to use and re-license. BSD, MIT, and Apache are common examples of permissive licenses. Proprietary licenses are more restrictive than open source licenses on granting rights; these are typically non-free licenses. It is very important to learn and understand the implications of the license of a specific open source project. It will help in understanding the contribution and distribution mechanisms of the source code and its derivatives.

There are obligations to fulfill as a consumer of the project; a different set of obligations may be required to be fulfilled when distributing the project to your end-users and consumers. Generally, Open Source Program Office (OSPO) departments which help organizations in formulating the open source policies are the best resources to provide a detailed understanding of the open source licenses to developers and technical teams.

When open source components are used as part of a product, there may be more than one license which is in play. Therefore, it is absolutely important to be aware of every open source license used in products and create a license manifest. There are commercial and open source tools which can come to aid in building the open source license manifests. It is important to note that

these tools are not the final authority on signing off these manifests; assigned auditors should review the licenses and ensure that they are listed as required. These manifests are living documents, which can change as soon as the component list or dependencies change. As such, it is beneficial to generate these manifests along with production builds and have these manifests correspond to each exact source that is being used in each release.

For scalability, it is good to define an intake process in which teams are provided with the correct information and guidelines to choose a component and assess its license. This approach helps in making appropriate decisions early and avoids license-related showstoppers at later stages of a project, which can result in lost time, and in many cases has caused projects to be cancelled. A vetted process to get approval for using a particular license is good to have, with checks and balances to ensure that these kinds of problems are avoided. It is good practice to require that developers regularly take license-related training to stay current on open source licensing trends.

When creating open source projects and seeding them, it is also important to license the code appropriately. There could be many factors influencing this choice, including dependencies of the project, perhaps the inclusion of another set of open source components, or the situation in which code is licensed under a license which may be incompatible with the license you are trying to use for the new project. It is also important to align the license with project goals and community involvement. Some licenses may require more effort to fulfill compliance within the conditions in which the project will be used. Therefore, software architecture including static or shared linking may also play a part in determining which licenses are more suitable than others. It is important to consult with knowledgeable teams, especially the legal team supporting your group, to come to a decision on choosing a license. Choosing the “wrong” license can have serious consequences, so it is important to choose the best license for each project.

2.7. Supporting Key Open Source Projects

Open source dependencies for products can run deep, and in many cases the product may have a critical dependency on a potentially dead open source project. A typical response is to keep using dead code, as switching to an alternative could be quite disruptive if it would come at a time which was not planned. It is important to find your open source dependencies and evaluate projects closely for their health and long-term viability. Doing so provides a good overview of the strength of a product’s foundation. An open source project may be in need of computers for hosting testing infrastructure, there may be a downward trend in contributors, or the project may be maintained by a single person in their free time, making it important to find out how you may be called on to help a project. You may be able to support a project by donating funds, contributing bug fixes, making improvements, or introducing features. Some projects require conference sponsorship or event hosting. Creating a comprehensive support plan can be useful in maintaining continuity and helps avoid surprises when something in the community breaks down.

2.8. Seeding New Open Source Communities

Open source engagement evolves from being a user to becoming a participant, then further to being a contributor, influencer, or maintainer. These are helpful experiences to gain before starting a new community or seeding a project. Starting a new open source project involves many

activities besides making code available. There are millions of open source projects, and it is likely that a similar implementation is already available; how you differentiate your project is a key aspect to consider. An open source project would not go far without a vibrant and healthy community around it. When starting a new project, it is a big challenge to build a community of users, developers, and promoters. As such, one needs to define clear goals and a meaningful value for the audience that will drive its consumption. Doing so will help with community growth; there must be clear directions for someone new to get started with the project, and contribution guidelines and steps should be crisply defined. As communities are comprised of humans, it is important that members see a clear, tangible value in being part of community. Communities develop culture. It is not something that will be pre-defined; and, as it is essential for a community to endure, the proper care and feeding of community is necessary. Engagement models will define how new members are on-boarded, how friction is removed for regular members, and how core contributors are incentivized. This documentation will provide a good process to facilitate learning for members.

2.9. Open Source Program Office (OSPO)

As open source adoption has become prevalent, scaling is a challenge, particularly in large organizations. Some teams may be open source savvy and forge an open source-based solution which could be quite optimized and best in class, though it is not easy to replicate that level of success across different products and teams without effort. OSPOs are established to tackle such problems. OSPOs act as an interface between open source communities and the organization. OSPOs also helps connect various internal teams wanting to benefit from open source. They can be instrumental in defining open source policies for the company. Open source communities are quite dynamic in nature, and it is often required to have someone to actively look into the ongoing developments and make meaning of them from an organization's point of view. As noted above, projects periodically change their licensing terms. If these projects are used in a company's products, the OSPO can help in interpreting these changes and monitor relevant changes. OSPOs help in optimizing open source consumption, collaboration, and contributions. They keep track of statistics and data and monitor the progress on a regular basis. This type of data is important in measuring productivity relative to open source goals that the organization might have set forth. There are various events and conferences related to different open source technologies, and as projects are organized across different geographies, OSPOs track event calendars and bring vital information to the company teams. The OSPO also connects internal team members who may be participating in the same events. They can also help with internal initiatives to drive the open source mindset inside the organization, to promote inter-team collaboration and code sharing, resulting in similar benefits for proprietary code development as well. To assist with career growth in engineering, developers might be interested in speaking opportunities at open source events. While the call for presentations for these events happens months ahead of the event itself, the OSPO keeps this information current and keeps the teams informed about the deadlines. OSPOs can also help in adopting various processes for open source compliance and recommending scalable tools across the organization. Given these important functions, OSPOs are becoming an integral part of modern organizations.

2.10. Attracting Best Talent

Due to their open nature, ease of access to source code, and other related tools and infrastructure, open source projects provide fertile ground for training new developers. Many developers are enthusiastic about working in an open source project or environment where an “open first” approach is used for software development. If an organization is involved in using, collaborating, and contributing to open source projects, it can be a big incentive for top class developers to seek positions there. If an organization employs well-known open source developers, it motivates other developers to join the company to work and learn from the best developers and collaborators. To attract talented developers to your organization, showcasing your community participation, involvement, and contribution can go a long way. Doing this creates a large pool of developers and engineers with experience in open source technology, which in turn ensures that there are enough people available to work on future critical open source projects.

3. RDK and Open Source

Reference Design Kit (RDK) provides a set of software components which are used to build software stacks for video clients, video gateways, broadband routers and gateways, smart camera solutions, wireless access points, and more devices used in the home. RDK is used to quickly build efficient stacks. RDK has transformed cable software stacks by providing a robust platform backed by open source solutions and technologies. The initial profiles were video client and gateway devices, which soon expanded into broadband profiles, building routers, access points, and providing Data Over Cable Service Interface Specification (DOCSIS[®]), digital subscriber line (DSL), and fiber wide area network (WAN) based devices. In the future we will see 5G modems and routers, as well as smart TVs being built using the RDK software platform.

RDK started as a foundation with RDK Management being the custodian of the code and infrastructure. RDK has adopted open source best practices and improved upon its own processes iteratively over time, establishing clear contribution guidelines and processes which are readily available for community. There are also webinars and How-To documents made available for new and seasoned contributors. The community growth is measured in terms of new members and contributors joining the project. It also measures lines of code growth and number of changesets submitted and accepted on a quarterly basis. These measurements offer key insights into community engagement and growth. RDK started with most of the code being under RDK license but has since migrated to an Apache 2.0 open source license for all new code and also relicensed most of the original code under Apache 2.0. All new components are released under an Apache 2.0 license and made open source from day one. In some cases, components are being incepted on GitHub and developed directly in the open with community collaboration.

Such best practices have been adopted and tuned over a period of time as the project grew its userbase and the needs of the community for open collaboration grew beyond the initial set of members.

RDK has also regularly hosted community events including the annual RDK Conference and RDK Tech Summit. Attendance and topics discussed in these events have grown multifold. Where in the first conference topics focused mainly on video projects, topics now include broadband technologies, wireless connectivity, augmented reality, smart speakers, smart

cameras, and new open source code and features that are being created by the RDK community. These events also serve as key collaboration and networking opportunities for the community of developers and users. There are additional events like coding challenges which are organized throughout the year.

RDK has also embraced popular open source platforms for ease of development and to broaden community outreach. Projects are mirrored on GitHub as well. Starting with just a few projects, RDK today contributes directly to many upstream projects including Yocto, Webkit, and Gstreamer. At the same time, there are RDK initiated projects which are also being used beyond RDK in other projects. This fact demonstrates how RDK started as an open source user/consumer and slowly graduated to a participant, contributing to key projects, before finally producing and seeding projects and growing the community. RDK's commitment to open source has led to leadership and influence in the cable industry in particular. RDK now has templates for open sourcing projects. These templates include key files that an open source project should have. Members can utilize these templates to quickly learn and become proficient in open source processes. It now also helps new members to become good at using RDK components by offering trainings, webinars, and dedicated community support. There is a clear path for members to become contributors and maintainers of components.

As contributions grow, conflicts will happen where a decision to adopt a given implementation or another must be made. RDK has established Technical Advisory Boards for different profiles. These committees of maintainers and contributors broker a decision based on the technical merits of contributions and the RDK roadmap.

The RDK open source community also keeps a keen eye on the latest trends and developments in other open source communities and adopts tools or best practices that were successful for other communities such as adopting Slack for instant messaging and collaboration.

From custom licensing requirements to an “open first” development mindset, RDK has transformed itself and keeps learning from open source development and processes, incorporating these learnings to address its own community challenges.

3.1. RDK Infrastructure

RDK is hosted on <https://rdkcentral.com>, which includes instructions on how to join the community, documentation, and the code itself. RDK uses self-hosted gerrit and GitHub cloud infrastructure to serve the community. Jira is used for workflow management, defect tracking, and technical support. There is extensive wiki documentation available for technical know-how, webinars, FAQs, and more. Additionally, regular meetings are held for roadmap sharing, and general community synchronization and updates. Special interest groups (SIGs) are formed as needed to forge new features or address large scale problems such as security vulnerabilities.

3.2. RDK development and workflow

All new components for RDK are developed in open source as community members and developers contribute code on a regular basis. Contributions go through an established intake process. This process involves scanning code for license compliance, build verification, runtime

sanity testing, and code review. In addition, some members also validate the patches in their internal setup and provide the testing results back as community contributions. This approach establishes a robust intake process which provides sufficient testing during code development and helps avoid regressions that may be introduced by newly added code.

3.3. RDK Collaboration

The RDK ecosystem consists of different types of members. Hardware manufacturers, typically consisting of original equipment manufacturers (OEMs), silicon on chip (SOC) providers, and specialized hardware add-ons, build hardware for specific products. Independent software vendors provide value on top of RDK platforms. Application developers build and port their applications to the platform. Service providers use these products as vehicles to deliver the services to customers. Students and universities work with the RDK platform on experimenting with technologies, learning, and research. As we can see, there is a wide array of users and contributors. Each could be working on enhancing a given segment of the RDK, such as a SOC vendor interested in unleashing the power of hardware capabilities of CPUs and other co-processing units. They would require working toolchains and infrastructure to build upon. Similarly, application developers would require a working stack on production hardware or reference systems. RDK enables these key elements by providing infrastructure, tools, and techniques upon which everyone can build. A common set of workflows for code development and acceptance criteria means that contributors are adding value for each other, and an established code quality is maintained. A common set of references are maintained as hardware platforms which are easily accessible to the community and are close enough to product hardware which users might be working on. This result provides a quick on-ramp for porting and increasing feature velocity.

3.4. Key Takeaways from Open Collaboration

The open platform that RDK has built provides many additional benefits. It has improved code reuse; since code is openly available, there is less duplication. A new stack uses common building blocks which are the same across all profiles, and scale horizontally. This stack also includes common build infrastructure and CI systems. It has resulted in better use of resources and enabled the community to avoid redundant work. Promoting re-use means that a modular software design has emerged. A departure from a monolithic mindset to a component-based mindset has been an on-going transformation. As components take shape, it has improved code ownership and maintenance, as expert teams are able to function independently while developing components maintained by them. It is an engineering community with collaboration mainly around source code. This construct has provided opportunities for any new developer, student, or other entity to submit pull requests and contribute. The feedback loop is essential for learning, and it has helped individual members and member organizations develop in-house expertise rapidly. Open source RDK has also helped training organizations to develop good programs and they can easily keep these modules up to date as the code changes, providing fresh courses and training events. These programs serve as a critical part in growing the developer base. Application developers can build their applications once and deploy many times on different RDK-based systems, streamlining the efforts to improve the application experience. There is a rapid expansion of device profiles which can be attributed to the key points discussed above.

4. Conclusion

The use of open source development methods and processes is on the rise, offering significant advantages over traditional closed software development methods. Major pieces of many complex software stacks today consist of open source software, and its share is on the rise as well. It is important to become a wise consumer and thoughtful producer of open source software. Doing this requires a deep understanding of open source communities, open source licenses, and various projects involved in building products. Strategically aiding and sustaining the communities supporting and building critical software is essential. Scaling to use open source software across larger organizations is a challenge which is being addressed by dedicated Open Source Program Offices which serve as liaisons between internal development teams and reach out to open source communities. The “open first” mindset is also on the rise, where open source solutions are sought first and developed and customized.

Abbreviations

CPU	central processing unit
DOCSIS	Data Over Cable Service Interface Specification
DSL	digital subscriber line
IRC	internet relay chat
OEM	original equipment manufacturer
OSPO	open source program office
QA	quality assurance

1. Introduction

In dense neighborhoods, there are often dozens of homes in close proximity. This can either be a tight city-block with many single-family homes (SFHs), or a multiple dwelling units (MDU) complex (like a big apartment building or condominium). Each home in such a neighborhood (either a SFH or a single unit in a MDU complex) has its own Wi-Fi access point (AP). Because there are few (typically 2 or 3) non-overlapping radio channels for Wi-Fi, neighboring homes may find themselves sharing a channel and competing over airtime, which may cause bad experience of slow internet (long latency, buffering while streaming movies, *etc.*). Existing APs sometimes have smart channel selection features, but because they work independently (the APs do not coordinate), this can cause a cascade of neighboring APs constantly switching channels, which is disruptive to the connectivity of the homes. Wi-Fi optimization over all the APs in a dense neighborhood is highly desired to provide the best user experience.

We present a method for Wi-Fi channel selection in a *centralized* way for all the APs in a dense neighborhood. We describe how to use recent observations to estimate the potential-pain matrix: for each pair of APs, how much Wi-Fi-pain would they cause each other if they were on the same channel. We formulate an optimization problem – finding a channel allocation (which channel each home should use) that minimizes the total Wi-Fi-pain in the neighborhood. We design an optimization algorithm that uses gradient descent over a neural network to solve the optimization problem. We describe initial results from offline experiments comparing our optimization solver to an off-the-shelf Mixed-Integer-Programming solver. In our experiments we show that the off-the-shelf solver manages to find a better (lower total pain) solution on the train data (from the recent days), but our neural-network solver *generalizes* better – it finds a solution that achieves lower total pain for the test data (“tomorrow”).

2. Wi-Fi Pain Metric

To measure the “pain” caused to the users in a dense Wi-Fi space, we define a new Wi-Fi Pain Metric. The main cause for Wi-Fi density pain is when a home’s neighbors are using the same radio channel and occupying much of its airtime: when my home’s AP senses high interference (“others” are using the channel), my home’s devices (including my AP) will have to wait longer times before they can send their packets over the radio channel, and this will cause the experience of slowness.

However, if my home barely has internet traffic during the night, while my neighbors use the same Wi-Fi channel heavily, the interference at night doesn’t cause me any pain. The pain comes when my neighbors use the channel heavily *while* my home tries to use the same channel. In addition, my home may have a lot of internet traffic at the same time as another home in my apartment building, but because there are five floors separating the two homes, our Wi-Fi signals never interfere with each other (the homes cannot “sense” each other – we will define this more formally later).

To simplify, we notice that in a dense neighborhood, homes cause each other Wi-Fi pain when three conditions are met: the homes can sense each other, they tend to have a lot of internet traffic at the same times, and they use the same radio channel. The first two are regarded as given conditions of the neighborhood (we can measure or estimate them, but we cannot control them)

and the third is the aspect that we can control – which channel does each home use. We treat these three components as independent. Let's now formalize the overall pain mathematically with these three components, for a neighborhood with n homes and n_c Wi-Fi channels:

- The **(binary) sensing** matrix, $S^b \in \{0,1\}^{n \times n}$. $S^b_{i,j}$ is 1 iff home i can sense (and be interfered by) home j .
- The **co-usage matrix** $U \in \mathbb{R}_+^{n \times n}$. This describes how much homes tend to have internet traffic at the same time. Notice, it doesn't matter which channel each home is using, and it doesn't matter if the homes can "sense" each other. This component only cares about the behavior patterns of the homes' residents and devices (specifically, the internet-activity patterns).
- The **channel allocation matrix**: $C \in \{0,1\}^{n \times n_c}$. For each home (row) which channel is assigned to it – exactly one channel (out of the n_c options) has a value of 1. Typically, n_c is 2 or 3.

The pain that home j causes to home i depends on the three conditions we mentioned – this is expressed with multiplication:

$$\sum_{c=1}^{n_c} S^b_{i,j} U_{i,j} C_{i,c} C_{j,c}.$$

Notice, that we use matrix C twice in the formula and inside a sum over the possible channels (c) – this is to capture if the two homes are using the same channel: if the two homes are not on the same channel, the whole sum will be 0, but if they are on the same channel, the sum will have a single non-zero element $S^b_{i,j} U_{i,j}$. Similarly, if the two homes don't even sense each other ($S^b_{i,j} = 0$), the whole sum will be 0 (even if they are using the same channel) – this can describe two homes that are physically far away from each other in the neighborhood, or have many walls between them, so the radio signal doesn't travel from one to the other. We assume additivity: the pain that home i senses from the neighborhood is the sum of the pain that it senses from all the neighborhood's homes:

$$pain_i = \sum_{c=1}^{n_c} \sum_{j=1}^n S^b_{i,j} U_{i,j} C_{i,c} C_{j,c}.$$

To simplify the formula, we combine the two components that we cannot control and define the **potential-pain matrix** $P = S^b \circ U$ (elementwise multiplication). $P_{i,j} = S^b_{i,j} U_{i,j}$ describes the pain that home j would add to home i if they were using the same channel. The total pain in the neighborhood is a sum over the homes:

$$pain^{total} = \sum_{c=1}^{n_c} \sum_{i,j=1}^n S^b_{i,j} U_{i,j} C_{i,c} C_{j,c} = \sum_{c=1}^{n_c} \sum_{i,j=1}^n P_{i,j} C_{i,c} C_{j,c}$$

And we can express it in matrix form:

$$pain^{total} = \sum_{c=1}^{n_c} [C^T P C]_{c,c} = Tr(C^T P C)$$

Figure 1 – Channel Allocation for a Dense Area

Figure 1 illustrates part of a made-up dense neighborhood (right image) – a floor plan with 8 apartments in an apartment building, and the potential-pain matrix for the 8 homes (left image), where darker shades of gray represent higher potential-pain value. The floor plan in the figure has two colors to the APs in the homes, representing a possible channel-allocation to two channels (blue and green).

Homes 101 and 104 are far away from each other (see the floor plan), so their APs never sense each other – this explains why they have a blank (0) value in the matrix – they have 0 potential to cause each other pain. This also explains why a smart channel allocation may allocate the same channel (green) to these two homes.

Home 106 represents a heavy internet user (most of the day has a lot of traffic), so it has the potential to cause much pain (darker shade in the matrix) to the homes that can sense it and typically have internet traffic at the same times (103, 104, 105). Homes 101 and 102 can sense home 106, but they may have internet traffic at different times of the day than home 106, so they have lower potential pain from 106 (medium gray shade). It makes sense to put home 106 on the blue channel and isolate it from homes 103, 104, and 105 (allocated the green channel).

3. Optimization Problem and Solvers

We can now define the main optimization problem as follows:

$$C^* = \arg \min_{C \in \{0,1\}^{n \times n_c}} Tr(C^T P C)$$

$$s. t.$$

$$\forall i \in \{1 \dots n\}: \sum_{c=1}^{n_c} C_{i,c} = 1$$

This problem assumes we know (or estimate from recent data) the potential-pain matrix P – it is the conditions of the neighborhood, the potential of homes to cause Wi-Fi pain to one another.

The task of the optimization is to select a good combination of per-home channels, to minimize the overall pain that the homes cause each other. One of the reasons for this *centralized* channel selection approach is to avoid too many channel changes – frequent changes can be disruptive to the users’ connectivity experience. So, a typical use would be to solve this optimization problem, set the selected channels to all the neighborhood’s APs, and keep the channels fixed for a while (e.g., a whole day, a whole week).

3.1. MIQP Problem Solver

We note that our optimization problem is a mixed-integer quadratic programming (MIQP) problem: the search parameter C appears in the objective function (the formula for total pain) in a quadratic form, and its values are constrained to be integers. This is a non-convex problem, and we don’t have an algorithm that can guarantee finding the global optimum (the very best combination of per-home channels) in reasonable time.

There are commercially available solvers, like Gurobi (Gurobi Optimization, 2022), that use a branch-and-bound approach to solve mixed integer programming problems (including the quadratic type). These methods iteratively try to rule out parts of the parameter-space and narrow down where we can find the global optimum, as well as narrow down the gap between lower and upper bounds for the optimal objective value. These tools often manage to reach the global optimum and they employ various heuristics to try to speed up the process.

3.2. Neural Network Gradient Descent

We propose an alternative method to solve the optimization problem. We construct a neural network model to calculate a soft-approximation of the neighborhood’s total pain, given any combination of channel allocation, and use gradient descent with back-propagation to change the underlying parameters until the pain reduces to a local minimum. The model is illustrated in Figure 2.

The model’s parameters are represented as a matrix $W \in \mathbb{R}^{n \times n_c}$. The input to the model is a dummy scalar variable $\beta \in \mathbb{R}_+$. Using W and β , the model calculates a “soft” version of channel allocation $C^{\beta, W} \in [0, 1]^{n \times n_c}$ by using the softmax operation on each row of βW :

$$C_{i,c}^{\beta, W} = \frac{e^{\beta W_{i,c}}}{\sum_{d=1}^{n_c} e^{\beta W_{i,d}}}.$$

The resulting matrix $C^{\beta, W}$ has each row (for home i) describing a probability distribution over the n_c optional channels. This is not a valid channel allocation (in practice each AP only uses a single channel at a time), but this is a soft approximation of a valid channel allocation.

The model then incorporates the potential pain matrix P as a fixed given input and uses $C^{\beta, W}$ to calculate a soft approximation of the total pain:

$$\text{pain}^{\beta, W} = \text{Tr}(C^{\beta, W^T} P C^{\beta, W}).$$

Notice, that the input variable β controls the order of the approximation: with a small value, like $\beta = 0.1$ the soft channel allocations in $C^{\beta,W}$ will be closer to a uniform distribution over the n_c channels. With a higher value, like $\beta = 100$, the soft channel allocations better approximate a valid channel allocation – where for each home only a single channel gets a value close to 1 and the other channels get a value close to 0.

To solve the optimization problem, we start by randomly initializing the parameters W (e.g., using an *i.i.d.* standard normal distribution), and then use gradient descent (with back-propagation) to reduce the approximated total pain $pain^{\beta,W}$. In addition, we start by using a small value of β as input, and slowly increase it. This helps the algorithm first find a good global area and only later fine tune the parameters to a local minimum. After this procedure converges to a local minimum, and the parameters are tuned to values W^{end} , we can get the solution (the chosen channel allocation) by looking at the approximated channel allocations (for large β) and thresholding their values:

$$C_{i,c}^{end} = 1 [C_{i,c}^{1000,W^{end}} > 0.5].$$

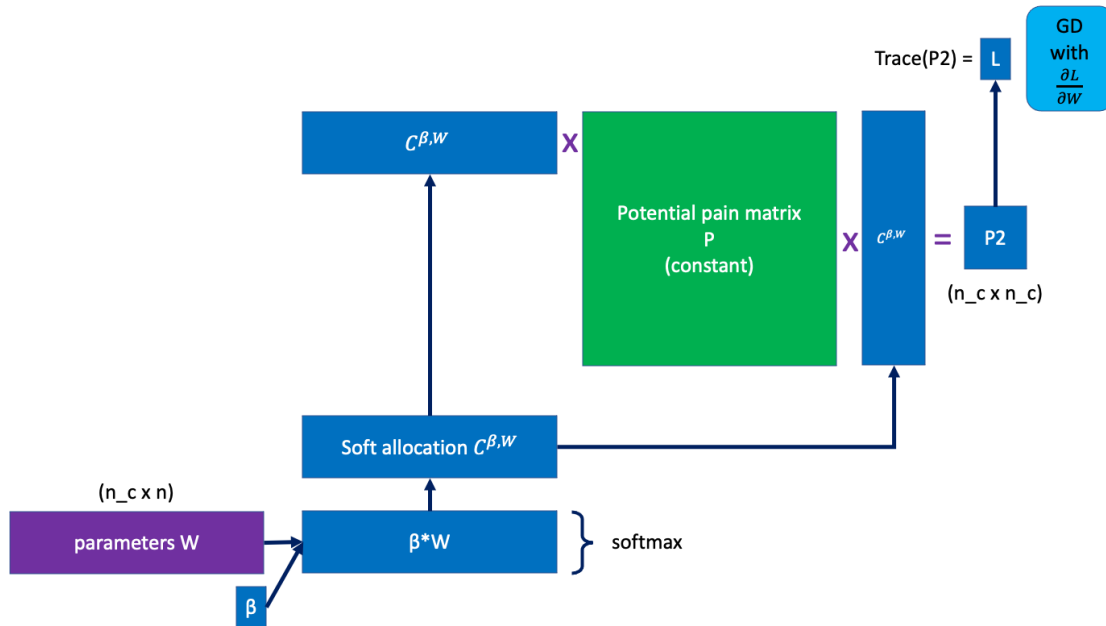

Figure 2 – Neural Network Approach with Gradient Decent (GD) and Back Propagation

While this gradient descent approach does not presume to find a better (lower) optimum than off-the-shelf solvers, we want to highlight a few advantages it has:

- This approach doesn't assume that the potential pain matrix P is symmetric, while other methods may rely on convex relaxations of the optimization problem, requiring them to have a symmetric matrix for the quadratic form.

- This approach can be modified to solve a different optimization problem that tries to minimize the *worst-home-pain* instead of the total, or *average-home-pain*. By making slight changes to the neural network, it can approximate the pain of the worst suffering home, and the optimization will try to minimize that value.
- This approach runs efficiently, quickly reaching a local minimum.
- This approach does not “try too much” to get to the global minimum. We want to generalize to near-future data, so we should avoid overfitting to the most recent days’ data.

4. Preliminary Experiments

During summer 2021, we conducted a few offline experiments with data from a big apartment building. We had data from 66 homes in the building, so we treated them as “the neighborhood’s homes” for the experiment. We tried various combinations of different aspects, and we share here some of our preliminary experiments and results. In these experiments, we simulated running the optimization on a reference date, to select the channel allocation for the following day. We collected data from the homes in the neighborhood from the recent days up to (and including) the reference day (the “train days”), calculated the potential pain matrix, and solved the channel allocation problem. We did a similar calculation to get the potential pain matrix for the day following the reference day (the “test day”). We evaluated the total pain on both the train days and the test day, given the chosen channel allocation, keeping in mind that the real goal is to improve (minimize) the pain on the *test day*.

4.1. Estimating Potential Pain

We estimated the two components of the potential pain separately: the (binary) sensing matrix S^b and the internet co-usage matrix U . Figure 3 illustrates this process: the colors in the matrices represent the cell values, ranging from 0 (dark blue) to high values (bright yellow). Each matrix has a different range (see the color-bar to the right of each image).

The co-usage can be defined as some version of multiplying two home’s internet-traffic time-series ($u_{t,i}$ represents home i ’s usage at time t). In this paper we use $U_{i,j} = \log(1 + \sum_t u_{t,i} u_{t,j})$, but we can have many variations: sum each home’s time-series first and then multiply, use a different non-linearity than logarithmic, apply non-linearity on $u_{t,i}$ alone to produce a non-symmetric version, *etc.* To estimate the co-usage matrix U , we used periodic measurements that each AP takes every 15 minutes. Specifically, we used a measurement of percentage of airtime that the AP occupied the channel to *transmit* data to the home’s devices (the “download” direction, assumed to occupy the majority of airtime in a typical home). We smoothed the quarter-hourly measurements to hourly quantities. We experimented with both measurements from whole-days (all hours of the day) and evening-time (only using measurements from 7pm-10pm local time), but here we focus our results on evening-time. For estimation with the recent n_d days, this results in a time-series (vector) of $3n_d$ hourly values for each home. We then calculated the cross-correlation between homes (the dot product of two homes’ time-series) and took the $\log(1 + x)$ of these values.

Figure 3 top row illustrates the process of estimating the co-usage matrix: starting with a Wi-Fi usage time-series for each home (top left). The image shows 10 homes and airtime-percentage values from 96 time points. This narrow matrix is multiplied by its transpose to produce the usage correlation matrix (for each pair of homes the value is the dot product of their two time-series). These correlation values can be extremely large (notice the color-bar reaching values of 200k), so we then apply logarithmic compression to form the co-usage matrix U .

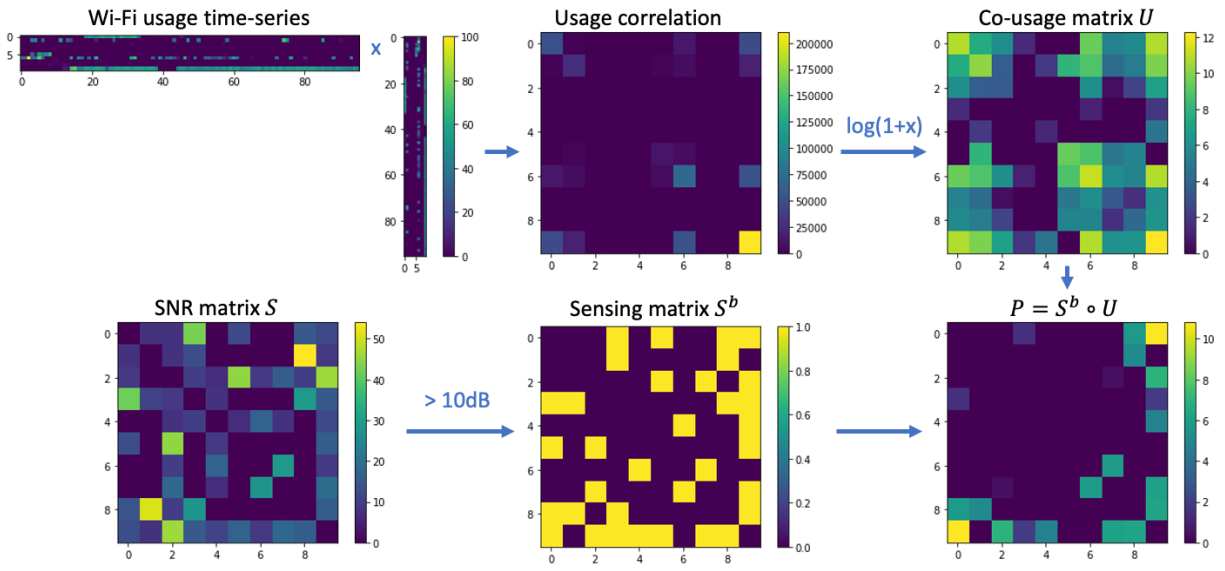

Figure 3 – Estimating the Co-Usage, Sensing, and Potential Pain Matrices

For estimating the sensing matrix S^b , we used radio-scan reports from the APs in the neighborhood: each AP performs a scan multiple times a day to look for Wi-Fi beacons in the air. The AP records the media access control (MAC) address of every other AP that it senses, and the signal to noise ratio (SNR) of the sensed beacon. We mapped sensed Wi-Fi MAC addresses to the familiar APs that are part of the neighborhood. The scans reported additional sensed entities that came from external APs (which we don't know and cannot control). For each pair of homes $\langle i, j \rangle$ in the neighborhood, we averaged the SNR values (over a period, like a week) of how strongly home i 's AP senses home j 's AP. We can call these variables the SNR matrix S (typically having non-negative real values), illustrated in Figure 3 bottom left image for 10 homes. In our experiments, we chose to symmetrize the sensing matrix: $S \leftarrow 0.5(S + S^T)$. We applied a threshold of 10dB to produce the binary sensing matrix S^b (Figure 3, bottom middle image). Notice that since an AP never "sensed itself" in the radio scans, we naturally get zeros in the diagonal. This fits our formulation, because we wish to only model the pain that homes cause other homes, not themselves.

We multiplied (elementwise) these two estimated matrices U and S^b to form the potential pain matrix P (bottom right image in Figure 3).

For the test day, we calculated the co-usage matrix U from the test day's usage measurements. However, we used the same SNR matrix S as we did for the train days. This is because we didn't

have sufficient scan measurements from every day, and because we assumed that “who can sense whom” stayed stationary over a longer time (~a month).

4.2. Optimization Details

We used the Gurobi package (Gurobi Optimization, 2022) as a MIQP solver. For our neural network algorithm, we implemented the network using TensorFlow (Martín Abadi, 2015) and Keras (Chollet, 2015). Every update step had just a “single example” input into the network. We increased the value of the input variable β in phases (running 6,400 update steps in each phase) with values: 1, 10, 100, 1000. We used ADAM optimizer with learning rate 0.001.

4.3. Results

Table 1 – Experimental Results

	Train days	Algorithm	Total pain – per train day	Total pain – test day
1.	1 (Aug 24)	Gurobi	58.2	194.0
2.	1 (Aug 24)	Neural Network	58.2	184.9
3.	4 (Aug 21-24)	Gurobi	64.5	166.3
4.	4 (Aug 21-24)	Neural Network	69.9	143.8

We show in Table 1 results from a few of our offline experiments with a single neighborhood. These were all done with train days up to (and including) August 24th and testing on usage data from August 25th. In these experiments, we used usage (and scan information) from the 2.4GHz frequency and we simulated solving the channel allocation for $n_c = 2$ channels. Rows 1-2 show experiments where there was only a single training day, compared to 4 training days in rows 3-4 (the table reports the average total pain per train day). The results show that when training with data from more days, we could achieve a worse (higher) total pain on the train data, but a better (lower) total pain on the test day, which is what we want to achieve. As expected, our neural network solver did not beat Gurobi’s solution on the train days. However, the neural network solver’s solution generalized better to the test day – it achieved a lower pain than Gurobi’s solution (in both the 1-train-day and 4-train-days scenarios).

5. Conclusion

We have discussed the problem of Wi-Fi airtime competition in a dense neighborhood and the need for a centralized channel selection solution. We defined a Wi-Fi pain objective, based on the co-occurrence of close neighbors having a lot of internet traffic at the same time on the same radio channel. We formulated the pain such that all the relevant information is captured in a single square matrix P , indicating for each pair of homes how much pain would one add to the other if they were using the same channel. We formulated an optimization problem and offered two alternative solvers for it: an off-the-shelf MIQP problem solver and a tailored neural network solver. We conducted preliminary offline experiments with data from a real neighborhood and demonstrated how we can achieve better generalization (lower pain for “tomorrow”) with more training days and by using our neural network solver.

5.1. Future Directions

There are still many more directions to research, including various flavors of Wi-Fi pain (non-symmetric definitions of potential-pain, weighting different days of the week, *etc.*), and adjustments to the optimization algorithm (e.g., regularization on the parameters W , schedule of changing β). An interesting direction is minimizing the worst-home pain and seeing how it influences the average-home pain. We will conduct more offline experiments with many more neighborhoods. Additionally, actual trials will reveal more reliably how helpful is centralized channel selection and A/B tests can help demonstrate which methods are better. In actual channel-selection experiments, we can more directly measure the sensed interference that every AP experiences from its environment. More importantly, we'll have to assess the effect on the residents' subjective experience of slow internet and Wi-Fi "pain".

6. Acknowledgements

We thank Zhehao (Kenny) Zhang for running the offline experiments, and Shelley Leung for processing telemetry data. We thank Obi Asinugo, Zekun (Katherine) Yang, Ali Mohammadi, Teddy ElRashidy, and Colleen Szymanik for great discussions and guidance about this interesting Wi-Fi problem.

1. Introduction

1.1. vCMTS and DAA

The distributed access architecture (DAA) specification, or modular head-end architecture version 2 (MHAv2), was introduced to address cable headend space and power limitations. The traditional integrated CMTS (iCMTS) or cable converged access platform (CCAP) functions were split into two: the physical (PHY) function, and the core function. The remote PHY device (RPD) provides the PHY function, while the core functions consist of CMTS and CCAP operating on the MAC or IP layers.

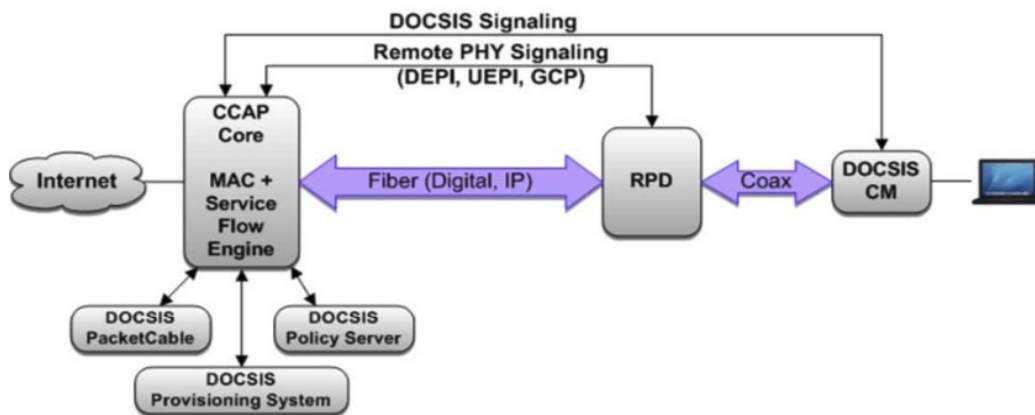

Figure 1 - MHAv2 [Source: CM-SP-R-PHY Specification]

The split allows the core functions to run on a cloud computing platform. The virtualized CMTS/CCAP (vCMTS/vCCAP) is a collection of software applications, built upon the microservice architecture pattern and targeted for cloud computing platforms. Comcast Cable has built its own private cloud in order to host these vCMTS software applications.

1.1. vBNG

CableLabs' DOCSIS Provisioning of EPON (DPoE) specification enables an operator to deploy EPON technology using the existing DOCSIS based backend systems. This specification allows an optical network unit (ONU) to be emulated as virtual cable modem (vCM).

The Comcast Private Cloud can host the virtual broadband gateway (vBNG) application which supports EPON technology. Like DPoE, vBNG emulates an ONU in order to utilize DOCSIS based network device provisioning backend systems.

1.2. PPODs

A typical private cloud is likely to consist of many server racks. Like peas in a pod (PPOD), these server racks are built identically providing operational efficiency and easy scalability. There are thousands of 'peas' (servers) spread across hundreds of PODs in an operator's network.

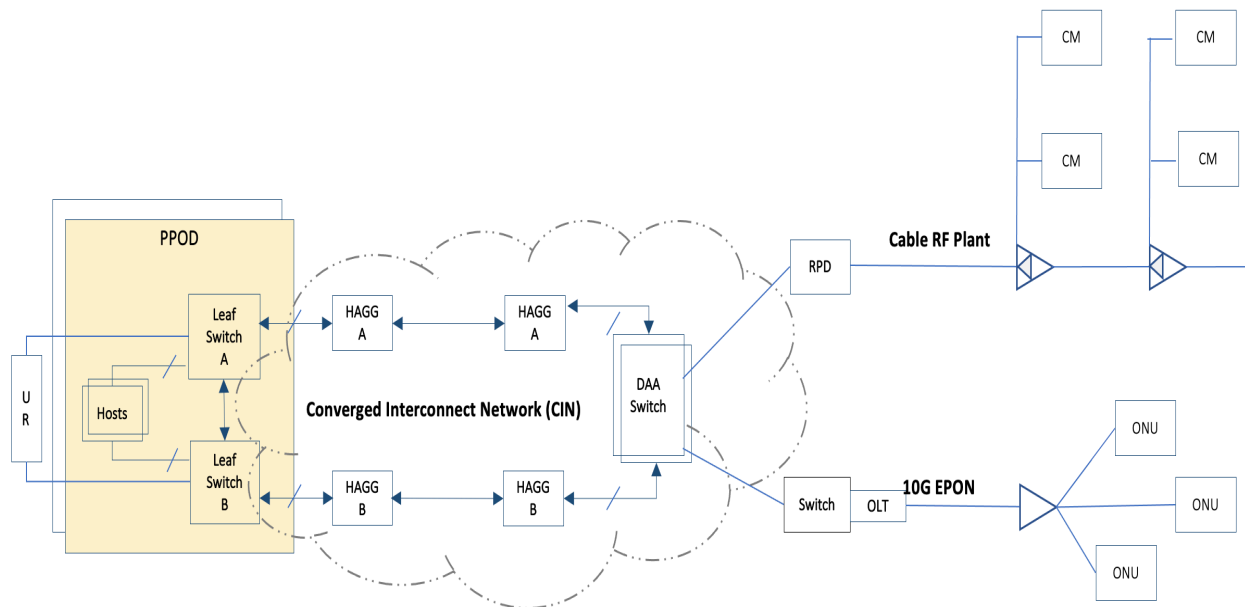

Figure 2 - Logical View of Access Network and Compute Nodes in a Leaf/Spine Architecture

The PPODs are deployed across hundreds of sites nationwide. Each PPOD contains several servers which form a compute cluster, each server has dual ethernet ports connecting to a pair of leaf switches. vCMTS and vBNG workloads are deployed and replicated on these PPODs OLT and RPD traffic is tunneled to or from the vBNG and vCMTS via the converged interconnect network (CIN) via a leaf-spine switch fabric. Upstream traffic to or from the internet is routed via upstream routers (URs)

1.3. Carbon Neutrality and Purpose

Looking ahead to Comcast's commitment to being carbon neutral by 2035, the question becomes, what can we do to “green-up” our PPODs, make them more energy efficient, and in the process reduce our operational expenditures?

In this paper, we will discuss what is involved to provide energy consumption observability for the Comcast Private Cloud. We will discuss the techniques that we employ to provide immediate energy saving as well as more advance techniques based on load and demand characteristics of our containerized network function (CNF) workloads. This paper will conclude with the lessons learned and future strategy for energy efficiency looking beyond the PPODs, in the wider Comcast ecosystem.

2. Observability

2.1. Framework

Since the start real time observability has been crucial for the Comcast Cable Private Cloud, as such we have built a stack based upon on Elasticsearch, Logstash, and Kibana (ELK) stack and Prometheus, a time series database (TSDB).

At a high level, the Prometheus server periodically scrapes metrics from targets in the PPOD. The long-term metrics are pushed to S3 ThanosStore, with Grafana dashboards providing a human friendly interface. ThanosQuery provides a distributed query engine for short-term locally cached metrics.

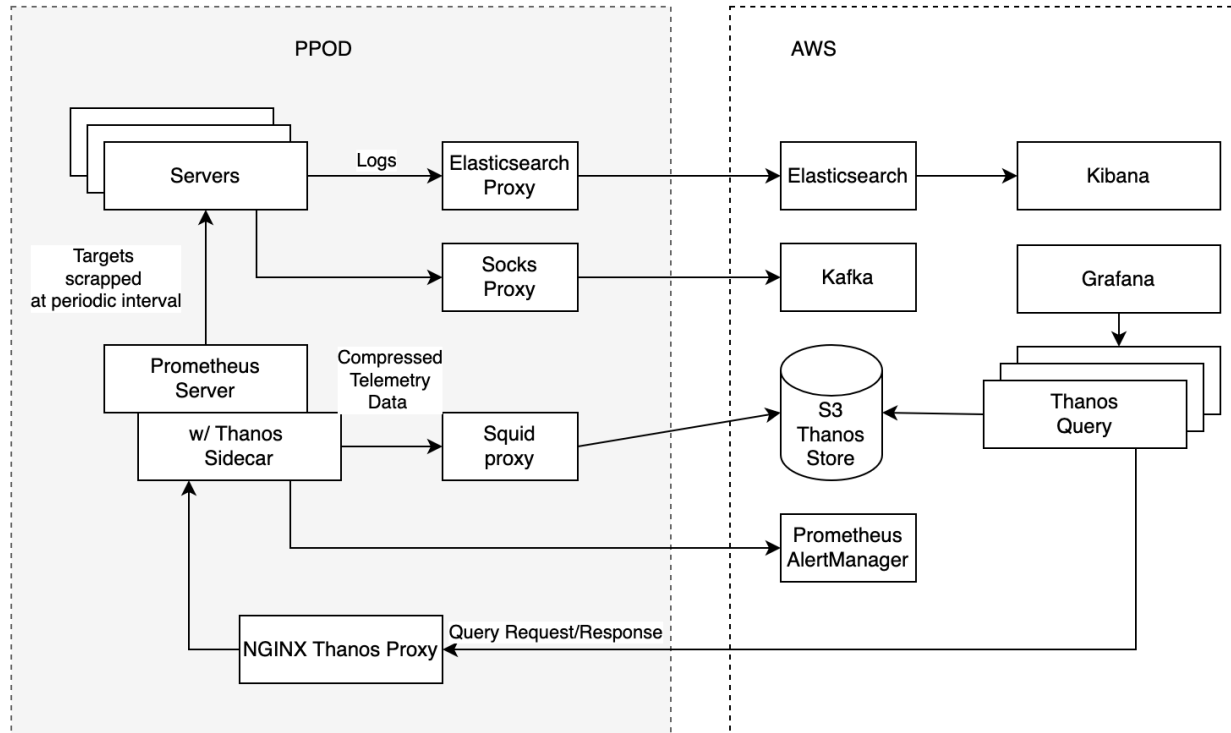

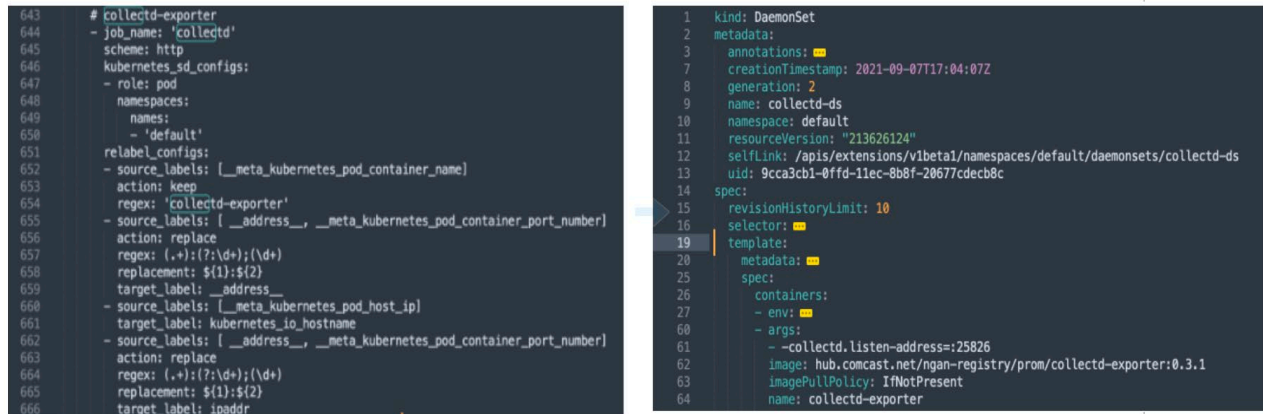

Figure 3 - PPOD Observability Framework

In the subsections which follow, we describe the components which provide power consumption metrics.

2.2. Collector and Monitor

2.2.1. Collectd

Collectd is a Linux daemon that collects, stores and transfers performance metrics on a per host level. Collectd is deployed as a DaemonSet for all hosts, in each PPOD. Prometheus in turn scrapes the metrics provided by Collectd.

2.2.2. IPMI Plugin

Collectd supports numerous loadable plugins. The Intelligent Platform Management Interface (IPMI) plugin uses the OpenIPMI library to read hardware sensors on the host in order to provide power consumption metrics as shown in the figure below.

2.2.4. Grafana Dashboard

Power consumption data visualization can be easily created and customized via a Grafana Dashboard. The figure below shows the power consumption by host and by PPOD. The charts on the left show the total power consumption by host and by PPOD. The charts on the right show the breakdown by the power supply unit by host and by PPOD.

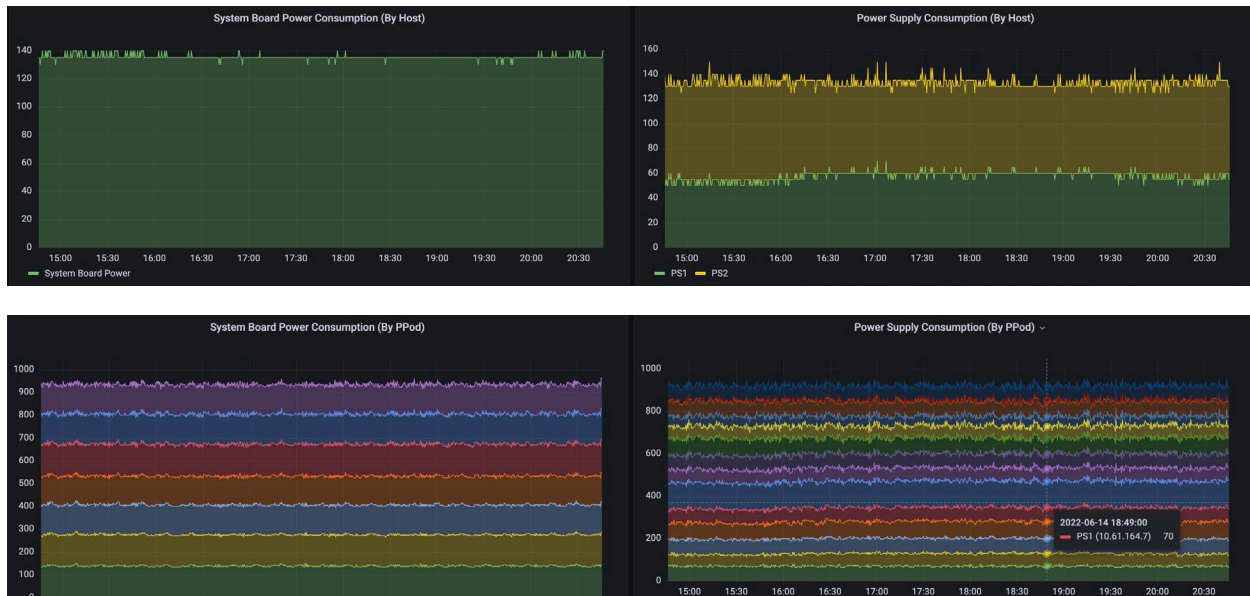

Figure 7 - Power Consumption Dashboard¹

3. Hot Standby & Power Saving Mode

3.1. Hot Standby

Power supply unit (PSU) hot standby, also referred to as hot sparing, is the ability for a single power supply to transform input to platform required voltage while keeping an idle power supply in reserve, as seen in Figure 8. The platform stages PSUs on or off dependent upon the platform's throughput and required power. The power supply in standby configuration does not transform input voltage to platform required voltages but does maintain telemetry, connection to the common buss, and is instantaneously available to support higher energy demand or in support of loss to the active-primary power supply.

It is through this idle state operators can realize a reduction in energy consumption. In dual redundant mode, the platform's required load will be split $\approx 50\%$ on each PSU. If the PSU has an 800-watt capacity and is only loaded with 100-watts (12.5%), it may not be optimally loaded. This creates transformation through two PSUs and impacts energy dissipated to transform voltage; total dissipation is dependent on the efficiency curve of the PSU and the output load. If we optimize the load, by enabling hot standby, we can improve the efficiency and reduce the number of locations voltage is transformed. By moving from dual-redundant operation at 100-watts (12.5%) of PSU0 and PSU1's capacity utilized, hot standby operation loads PSU0 at 200-watts (25% capacity).

Figure 8 - Dual-Redundant vs. Hot Standby Line Drawing

Several original equipment manufacturers (OEMs) offer this platform setting today. In initial trials, a $\sim 4.5\%$ reduction in energy consumption for the deployed solution was documented.

Load-side power distribution measurements were captured with dual-redundant power supplies active for a minimum of (7) days prior to enabling of hot standby for the platforms tested as seen in Table 1. The platforms were then set to hot standby mode and measurements captured over time (30 days) before returning to dual-redundant mode for additional measurement.

During the hot standby trial time two distinct events were observed in which platform power exceeded the threshold for a single supply, the hot standby was brought into operational state, and then returned to hot standby with no service impact observed.

Table 1 - Hot Standby Enabled Then Disabled Data Segment

For platforms which do not currently offer hot standby configuration, measurements were captured in dual-redundant state by aggregating channel loads as seen in Table 2. Channel 12, for example, was drawing a total of two amperes in dual-redundant mode. Power was removed from the B-side load distribution by way of opening breakers in order to test the specific platform load and its effect on PSU efficiency curve as seen in Table 3. Channel 12 was now only drawing 1.7 amperes. Energy avoidance was calculated with the nominal consumption of a PSU in hot standby factored for those devices by adding 13-watts of load, as seen in Figure 9. This process was performed on two separate PPODs of varying compute load and tested for 24-72 hours before restoring B-Side power.

Figure 9 – Server Rear Elevation Dual-Redundant vs. Hot Standby Watts Consumed

As DAA expands the proliferation of server-based rack architectures, hot standby presents itself as a low-impact, reliable, and sustainable practice to aid in the drive toward carbon neutrality. Given the change and impact to installation and operational practices, processes must be built to ensure load is equally distributed across AC & DC plant circuits.

3.2. Intel CPU Power Saving Mode

All servers in a PPOD are Intel CPU based. Intel processors can be controlled by the following:

- Per core C-State
- Per core P-State

The C-State is an idle power state in which the processor is not executing instruction. The P-State is for various voltage or frequency levels in which the processor is still executing instructions.

For configuring and controlling C-states, on most modern Linux platforms C-states are automatically enabled, this is done via a combination of basic input/output system (BIOS) settings and the intel_idle driver. In order to dynamically force the system to a lower C-state (more power intensive) one can open the file `/dev/cpu_dma_latency`, and write a low value, usually (5) or under to this file. The value found in `/dev/cpu_dma_latency` represents the amount of latency in microseconds allowed for C-state transitions, by forcing this to a low value this should limit the CPU to C0 during active workloads and C1 during idle. For as long as this file remains open the C-states will be forced to these lower states.

Our first step was to understand C-state, workloads, and how they influence the power consumption of a host. This is accomplished by scheduling the workloads on a host, then measuring the power consumption data with C-state enabled and disabled.

Figure 10 - Power Consumption for Host with C-State Disabled¹

Our test result shows that with C-state saving mode disabled, the power consumption level remains constant for any number of CNF workloads scheduled on to a given host.

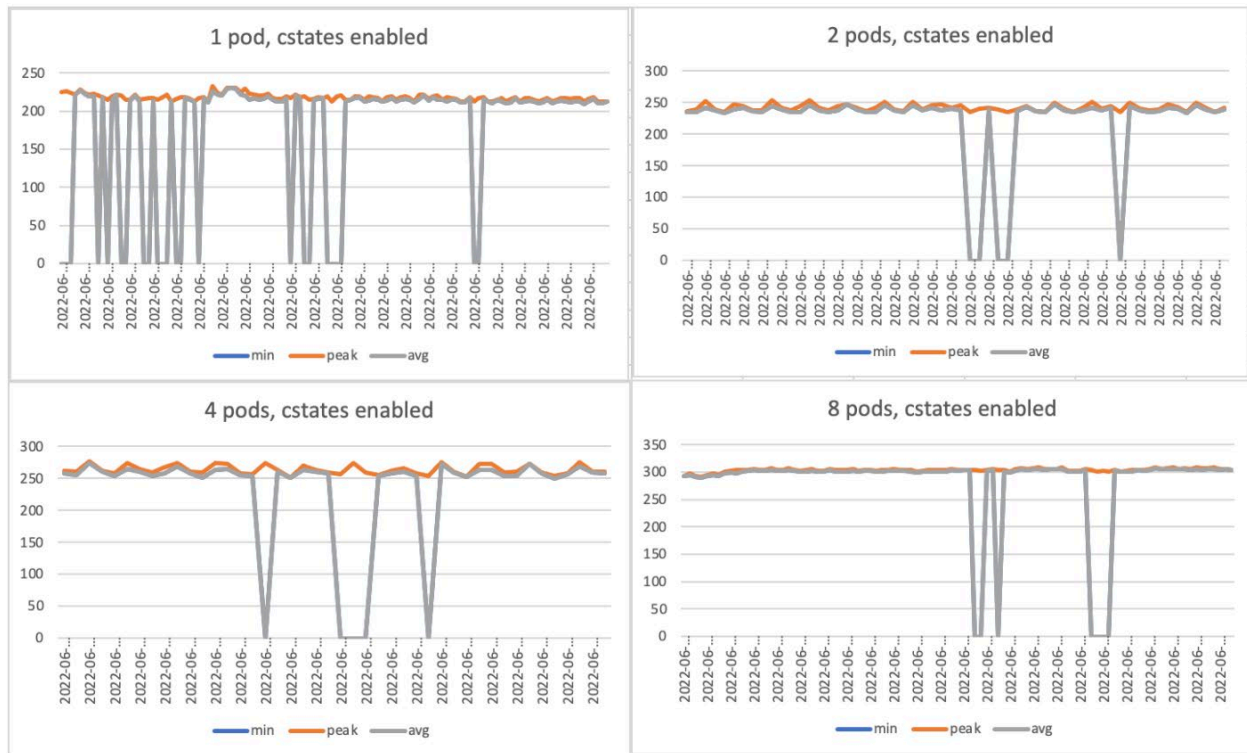

Figure 11 - Power Consumption of a Host with C-State Enabled¹

With C-state enabled, as the number of CNF workloads deployed on a given host increases, the power consumption level rises. This is shown in Figure 11.

3.3. Future Considerations

The aggregate usage can be generalized as similar demand curve each day. An example of subscriber usage aggregated across all workloads within a PPOD is shown in Figure 12 and Figure 13. The Y-axis represent the workload usage percentage normalized by the access technology capacity service by the CNF. The X-axis is day of the month.

Figure 12 plots several diverse, individual workloads usage in a PPOD. Figure 13 is a stacked version, which provides a better view of the aggregate usage curve. The pattern is similar for all PPODs across all sites.

Figure 12 - Workload Utilization Percentage for a PPOD for One Week¹

Figure 13 - Stacked Workload Utilization Percentage for a PPOD for One Week¹

A system is elastic and can adapt to workload changes by provisioning and deprovisioning resources, in order to meet demand. On the compute cluster, significant CPU core resources are isolated and dedicated to the DPDK CNF workloads. The required CPU core resources for the CNF workloads are very much traffic or network IO bandwidth driven.

In the future, we will be exploring the following approaches to match the CPU resources to the traffic demand:

- A. CPU P-State control by software application to match the short-term traffic demand
- B. Bin packing of workloads across hosts to match the longer-term traffic demand
- C. Combination of the above

Beyond the PPOD, we could also explore the overall capacity planning process in terms of spectrum activation. For example, an average 50-subscriber service group having low bandwidth demand requires far less spectrum and compute resources activated, as compared to that of an average 500-subscriber service group having much higher bandwidth demands. Can the capacity planning process be automatic, just-in-time, and elastic?

¹We collect, store, and use all data in accordance with our privacy disclosures to users and applicable laws.

4. Conclusion

We started with energy consumption observability for the Comcast Private Cloud. We quantified the power savings of ~4.5% by reconfiguring the PSUs to hot standby; this will be operationalized for PPODs being put into production in late-2022/early-2023. As hot standby is platform specific, integrated software-based, user-defined configuration, we will be working with OEMs to explore how many existing platforms can be integrated through software upgrades. All hosts in PPODs are already provisioned with C-State power saving mode enabled.

The measured power consumption metrics for host with CPU C-State setting and various CNF workloads provide us the insight into the potential savings. The future strategy for energy efficiency is very much aligned with our cloud native architecture evolution; meaning it is just-in-time and elastic to workload changes by automatically provisioning and deprovisioning resources, such that the available resources match the demand.

1. Introduction

There is currently a strong demand for high resolution video content, particularly for the high-definition (HD) and UltraHD video content to be displayed on a variety of devices, ranging from Smart TVs and laptops to mobile devices and smartwatches. There is a continuous need to decrease video transmission bit-rate, especially for delivery over wired and/or wireless/cellular networks without reducing visual presentation quality [1]-[4], [5].

In addition, the HDR UltraHD video content is recently attracting a lot of attention due the relatively high luminance levels and fine shadow details, which extend much beyond conventional Standard Dynamic Range (SDR) content. The HDR technology makes it possible to present highly bright signals along with very dark signals on the same video frame, thereby providing a high contrast ratio within the same image. In addition, the HDR video content is usually combined with a Wide Color Gamut (WCG), such as BT.2020, thereby enabling to present video with a significantly extended color spectrum. Particularly, HDR has gained its popularity after the development and approval of the High Efficiency Video Coding (HEVC) standard, i.e. H.265/MPEG-HEVC, in 2013 [6].

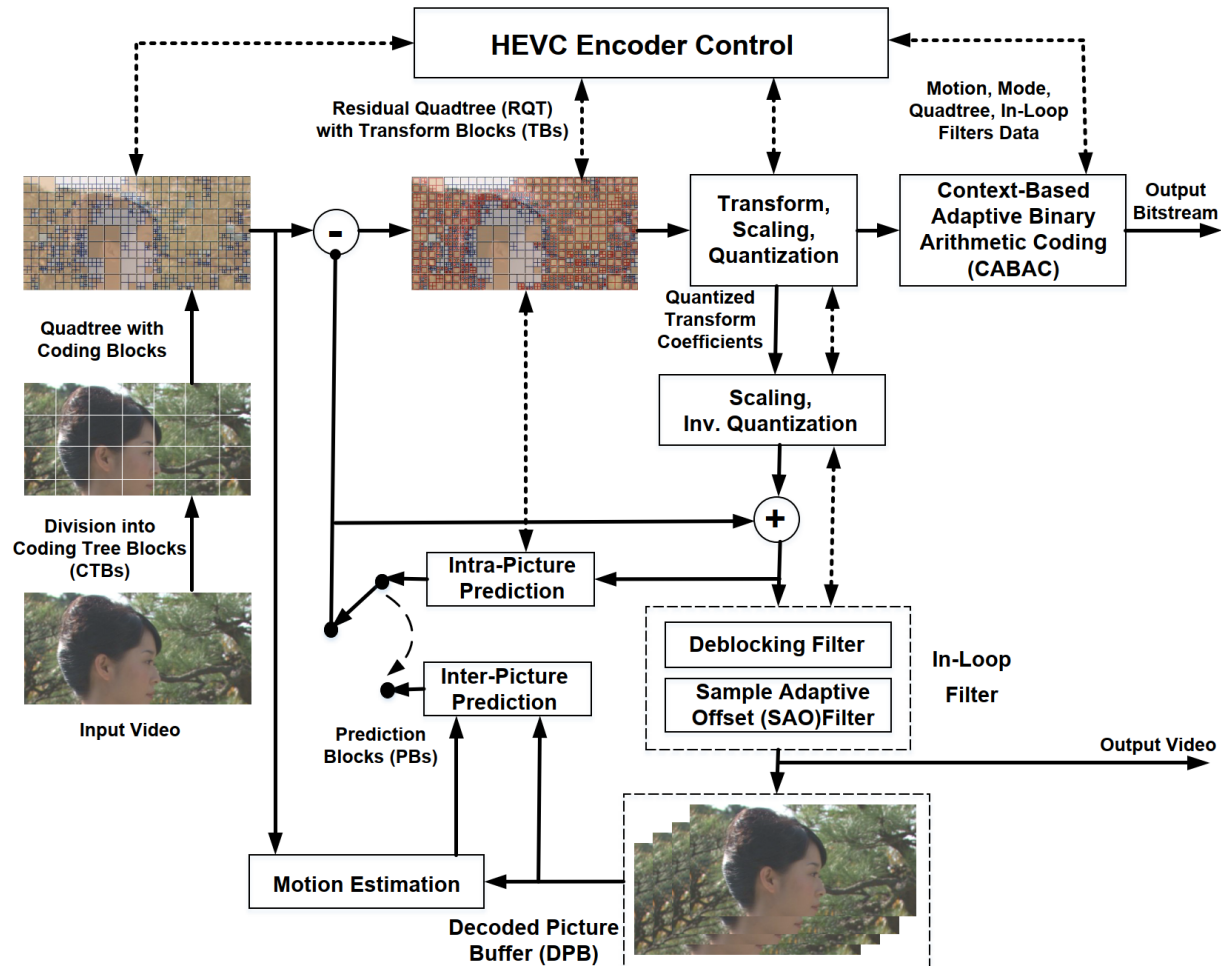

Figure 1 – The schematic block diagram of the H.265/MPEG-HEVC encoder.

The development of the first version of HEVC by the Joint Collaborative Team on Video Coding (JCT-VC) of ITU-T Video Coding Experts Group (VCEG) and ISO/IEC Moving Pictures Expert Group (MPEG) was officially finalized in January 2013 [6]. *Figure 1* illustrates a block diagram of the H.265/MPEG-HEVC encoder. After that, the final aligned HEVC specification was approved by ITU-T as Recommendation H.265 and by ISO/IEC as MPEG-H, Part 2. About one year later, the 2nd HEVC version was finalized, incorporating the Range Extensions (RExt) as well as the Scalable and Multi-view Extensions (SHVC and MV-HEVC, respectively) [7]. In turn, the 3rd and 4th HEVC edition were issued in 2015 and 2016, further containing the 3D Video Coding Extensions (3D-HEVC) and the Screen Content Coding Extension (HEVC-SCC), respectively [8], [9]. When developing the H.265/MPEG-HEVC standard, high-resolution video coding was considered as one of its main potential application scenarios, while keeping it applicable to almost all existing use cases that were already targeted by H.264/MPEG-AVC. The development process of H.265/MPEG-HEVC was driven by the most recent scientific and technological achievements in the video coding field. As a result, when compared to its predecessor - H.264/MPEG-AVC, H.265/MPEG-HEVC is able to achieve a bitrate reduction of roughly 50% for substantially the same visual quality [1]-[4].

Video applications continue to gain a lot of traction and to have an enormous demand. A very significant increase in the bandwidth requirements is expected by 2023, particularly due to the increase in the resolution supported by devices. It is expected that 66% of the connected flat-panel TV sets will have the support for the Ultra-High Definition (UltraHD) resolution compared to only 33% in 2018 (note that “UltraHD” in this paper refers to the 3840x2160 resolution, also known as 4K or 2160p). The typical bitrate for a 60fps 4K HDR10 video is between 15 to 24 Mbps, nearly four times the typical High-Definition (HD) video bitrate [5].

As a result, there is a continuous strong need to further decrease video transmission bitrate, especially for the UltraHD content, substantially without reducing the perceptual visual quality.

2. Background: Human Visual System

One of the most popular approaches for improving video quality is related to considering *spatial frequency sensitivity* of Human Visual System (HVS). As known, the HVS system is a part of the central nervous system, which enables processing of visual details and generating non-image photo response functions by obtaining and processing visible information. Thus, for example, during the coding process, the values of the Discrete Cosine Transform (DCT) frequency coefficients can be attenuated by applying quantization matrices: i.e. lower spatial frequencies are usually quantized with smaller quantization parameters (QPs), while higher spatial frequencies - with larger QPs [10], [11].

However, the improvements in visual quality of the related state-of-the-art approaches are relatively small, and more efficient solutions are desirable. In addition, most of the state-of-the-art pre-processing methods are designed for the relatively low-resolution SDR video content, and as a result, these methods found to be mostly inefficient for HDR UltraHD.

In turn, this is also true for the coding schemes that aim to remove fine details below a predefined visibility threshold, which is referred as Just Noticeable Difference (JND). As a result, the state-of-the-art JND-based schemes do not provide sufficient video quality improvement for the HDR UltraHD video content as well.

In this paper, two important perceptual video coding optimizations techniques are presented and discussed in details: *Section 3* describes a novel perceptual video optimization framework based on authors' work presented in [10], [11], and *Section 4* describes a joint backward and forward masking encoding scheme, based on authors work presented in [12]. Then, future directions for perceptual video coding optimizations are provided in *Section 5*, while this paper is concluded in *Section 6*.

3. Perceptual Video Quantization Framework

The human visual system (HVS) is considered to be a very complex system, while a level of contrast that is required to generate a response perceived by HVS is known as a contrast threshold of a sinusoidal luminance pattern. In turn, an inverse of this threshold is called “contrast sensitivity”, and it varies as a function of a spatial frequency.

3.1. Background: Contrast Sensitivity Function

The relationship between the spatial frequency and contrast sensitivity is known as a contrast sensitivity function (CSF) that differs for achromatic and chromatic scenes. The term Contrast Sensitivity (CS) often relates to visual acuity, thereby being able to differentiate between the object and the background [10].

In turn, CSF generally defines the sensitivity of the observer to various frequencies of visual stimuli, e.g., sensitivity to vertical black and white strips grating as a function of spatial frequencies [13],[14]. In case, the above frequencies are higher than a threshold predefined by the Human Visual System (HVS), the human observers are not able to differentiate between the strips. Also, generally, the HVS sensitivity to luminance significantly differs from the HVS sensitivity to chrominance.

The HVS is more sensitive to low spatial frequencies than to high spatial frequencies [15]-[18], and by assuming that HVS is isotropic, it can be modeled as a nonlinear point transformation that is followed by a Modulation Transfer Function (MTF) [19].

Later, this approach was practically used in developing a HVS-based quantization table for the JPEG still image compression standard [20], [21]. Authors of [21] derived this table by incorporating a HVS model developed by Daly [15]-[18] with an uniform quantizer, and further claiming that by replacing the JPEG quantization table with their HVS-based quantization table, obvious perceptual quality improvements are achieved. More specifically, the authors of [21] applied a 1st order low-contrast MTF of the HVS model proposed by Daly for generating a HVS-based quantization table for the baseline JPEG image compression standard, as follows below.

16 16 16 16 17 18 20 24		16 16 16 16 17 18 21 24
16 16 16 17 18 20 24 25		16 16 16 16 17 19 22 25
16 16 17 18 20 24 25 28		16 16 17 18 20 22 25 29
16 17 18 20 24 25 28 33		16 16 18 21 24 27 31 36
17 18 20 24 25 28 33 41	16 16 16 16	17 17 20 24 30 35 41 47
18 20 24 25 28 33 41 54	16 16 16 16	18 19 22 27 35 44 54 65

24 25 28 33 41 54 71 91	16 16 16 16	24 25 29 36 47 65 88 115
<i>Default Quantization Matrix of 8x8 size for Inter-prediction unit (including the Luma, Cb and Cr components)</i>	<i>Default Quantization Matrix of 4x4 size for Inter-/Intra-prediction unit (including the Luma, Cb and Cr components)</i>	<i>Default Quantization Matrix of 8x8 size for Intra-prediction unit (including the Luma, Cb and Cr components)</i>

Figure 2 – The default perceptual quantization matrices defined in the HEVC standard.

The HEVC video coding standard allows usage of perceptually-tuned frequency-dependent quantization matrices, instead of applying a constant quantization parameter (QP) on each coding block. These matrices better suit the HVS characteristics by allowing to quantize higher frequencies in a stronger manner, while their sizes vary from 4x4 to 32x32. However, the specification of the HEVC standard [6]-[9] only defines default quantization matrices for 4x4 and 8x8 transform blocks (see *Figure 2*).

The rest of matrices, i.e. for transform block sizes of 16×16 and 32×32 , are obtained by upsampling the original 8×8 perceptual quantization matrix respectively. More specifically, the original 8×8 matrix is replicated: each block in the 8×8 matrix is replicated to the 2×2 area of the 16×16 transform block and to the 4×4 area of the 32×32 transform block, as shown in *Figure 3*.

Figure 3 – Upsampling the default 8×8 HEVC matrix for obtaining default matrices for 16×16 and 32×32 transform block sizes.

Depending on the transform block type (i.e. used for *Intra* or *Inter*-picture prediction) and transform block size (i.e. 4×4 , 8×8 , 16×16 or 32×32), the HEVC standard employs twenty quantization matrices: 8 matrices for *Y (Luma)* component and 6 matrices for each of *Cb* and *Cr (Chroma)* components, as specified in *Table 1* below.

Table 1 - HEVC Transform Block Type/Size-Dependent Quantization Matrices.

Block Component	Type/size-Dependent Quantization Matrices
Y (<i>Luma</i>)	Intra 4×4 , Intra 8×8 , Intra 16×16 , Intra 32×32 ; Inter 4×4 , Inter 8×8 , Inter 16×16 , Inter 32×32 .
Cb (<i>Chroma</i>)	Intra 4×4 , Intra 8×8 , Intra 16×16 ; Inter 4×4 , Inter 8×8 , Inter 16×16 .
Cr (<i>Chroma</i>)	Intra 4×4 , Intra 8×8 , Intra 16×16 ; Inter 4×4 , Inter 8×8 , Inter 16×16 .

In addition, HEVC allows to use other quantization matrix values (i.e. *customized* quantization matrix values) besides the default values. For that, the above-mentioned customized quantization matrix values can be transmitted within the HEVC bitstream Sequence Parameter Set (SPS) or Picture Parameter Set (PPS), while coding these customized values by using so called Differential Pulse Code Modulation or in short DPCM. Similarly, the 16×16 and 32×32 quantization matrices are obtained by upsampling corresponding 4×4 and 8×8 quantization matrices (see *Figure 3*).

In spite of the fact that the HEVC default perceptual quantization matrices of *Figure 3* are based on HVS, they were initially developed and tested on low-resolution JPEG images, such as 512×512 pixels. Therefore, they almost didn't provide any benefits for UltraHD video content, that has the 3840x2160 resolution in terms of luma samples, which is the most popular resolution nowadays. As a result, this is currently also a reason for the relatively low popularity of these default perceptual quantization matrices, which most often are not used at all.

In the following section, the design and development of novel perceptual quantitation matrices for encoding UltraHD HDR video content is presented, further being inspired by investigating CSF of a human visual system. The novel perceptual quantitation matrices significantly improve perceived video quality without a need for pre-processing and without an increase in coding computational complexity.

3.2. Perceptual Quantization Matrices for UltraHD Resolution Displays

The contrast sensitivity of the human eyes, and more generally – of the human visual system as the whole, is one of the main factors how humans perceive achromatic or chromatic images. Therefore, when developing HVS-based models, it is especially important to determine the Contrast Sensitivity Function (CSF) as accurate as possible. For that, it is important to consider substantially all known HVS characteristics that have any impact of the CSF [22].

With this regard, in addition to the HVS-based models developed by Mannos&Sakrison and Daly at the end of the 20th century, Barten in his paper from 2004 proposes a more accurate HVS-based physical model/formula for the contrast sensitivity of the human eye. Particularly, in his work, Barten considers a plurality of HVS parameters, such as photon noise, neural noise, external noise, lateral inhibition, eye pupil diameter, eye pupil size, angular size of the object, luminance conditions, etc.

As a result, Barten's HVS-based CSF model is considered to be the most accurate for representing the HVS contrast sensitivity, and considered to be the best CSF model to date [23]-[25]. However, Barten's model is very complex, and its usage for an accurate determining of efficient perceptual quantization matrices, either in HEVC or in other emerging video coding standards, is found to be very challenging.

Therefore, at the 1st step of authors work [10], perceptual quantization matrices to be employed during the video coding loop have been designed by fitting the Daly's HVS-based model into the Barten's HVS-based CSF model.

In turn, at the 2nd step, the CSF-tuned human visual coefficients are empirically optimized by gradually attenuating high frequencies in a much stronger manner than low frequencies, and further giving priority to luminance (Luma) over chrominance (Chroma) due to the fact that human eye is more sensitive to Luma changes than that of Chroma [10].

For obtaining experimental results presented in this section, a special emphasis was made on video sequences having a 10-bit sample representation and UltraHD spatial resolution (particularly, the 4K resolution – i.e. 2160p, or more specifically, the 3840x2160 resolution in terms of luma samples), as presented in *Table 2* below.

Table 2 - HDR UltraHD test video sequences.

Tested Video Sequences	No. of Frames	Frame Rate per Second	Resolution	Dynamic Range
Lucy (provided by NBCUniversal [®])	8425	24	3840x2160	HDR
Everest (provided by NBCUniversal [®])	7202	23.98	3840x2160	HDR
Warcraft (provided by NBCUniversal [®])	8177	23.98	3840x2160	HDR
Regatta (provided by UltraHD forum [®])	5841	59.94	3840x2160	HDR

In *Figure 4* below, sample frames of the above-mentioned tested sequences are presented.

Figure 4 – A sample frames from the tested sequences: (a) “Lucy”; (b) “Everest”; (c) “Warcraft”; (d) “Regatta”.

These tested video sequences can be generally characterized as follows:

- “Lucy” – includes many action scenes, many fast motion scenes, mixed content [26];
- “Everest” – includes mountains views, many snow scenes, mostly slow motion scenes [26];
- “Warcraft” – includes various computer-generated content, mostly fast motion scenes [26];
- “Regatta” – includes many water scenes, many fast motion scenes [27].

The x265 open source HEVC-based encoder [28] was selected for implementing the proposed perceptual quantization framework due its ubiquity in the industry and flexibility in configuration, as well as due to its

good coding performance. When encoding the video sequences of *Table 2* with the target bit-rates of 8Mb, 10Mb, 12Mb and 14Mb, the BD-BR coding gains are significantly large in terms of both PSNR [29] and SSIMPlus [30], [31]. Specifically, the BD-BR PSNR and BD-BR SSIMPlus bit-rate savings for the HEVC encoding with the proposed QMs versus HEVC encoding with the constant QP reach coding gain of 15.5%, for encoding the “Lucy” video sequence, as is shown in *Table 3* below.

Table 3 - BD-BR PSNR and SSIMPlus bit-rate savings for the HEVC encoding.

Tested Video Sequences	BD-BR SSIMPlus Proposed QMs vs. Default HEVC QMs	BD-BR SSIMPlus Proposed QMs vs. no QMs
Lucy	-13.5%	-15.5%
Everest	-3.8%	-5.9%
Warcraft	-6.1%	-6.0%
Regatta	-10.6%	-11.9%

As can be clearly seen from *Table 3*, by employing the proposed perceptual QMs, significant coding gains of up to about 16% are achieved.

Especially, these coding gains are significant in terms of the SSIMPlus metrics, while for the “Regatta” video sequence the coding gain is the most significant - the “Regatta” video content is considered to be hard to encode, since it contains many water scenes, and the proposed perceptual QMs perform much better for such content.

In turn, *Table 4* below presents BD-BR PSNR and BD-BR SSIMPlus bit-rate savings for the HEVC encoding with the proposed perceptual QMs versus HEVC encoding with the constant QP per Common Test Conditions (CTC) defined in [32] – i.e. without employing the default HEVC QMs.

Table 4 - BD-BR PSNR and SSIMPlus bit-rate savings for the HEVC encoding.

Tested Video Sequences	BD-BR PSNR Proposed QMs vs. no QMs	BD-BR SSIMPlus Proposed QMs vs. no QMs
Lucy	-2.5%	-6.3%
Everest	-0.9%	-5.8%
Warcraft	-1.0%	-7.9%
Regatta	-2.4%	-11.3%

In this case, as seen from *Table 4*, the coding gain as a result of employing the proposed QMs is even larger and is up to 11.3%.

Below, as an example, the breakdown of the “Regatta” video sequence is presented, thereby showing the SSIMPlus score in a range between 0 and 100, while the larger the number - the better the video quality is (100 is the best possible quality). As is clearly seen from *Table 5*, when the proposed perceptual QMs are employed, the SSIMPlus score [30], [31] is significantly higher – i.e. it is more than 1 point - compared to encoding with a constant QP per CTC [32] (i.e. marked as “no QMs” in the above table). Similarly, the encoding with the default HEVC QMs provides a little improved visual quality compared to the above-mentioned constant QP encoding, but still much worse quality compared to the encoding with the proposed perceptual QMs. In turn, the minimal SSIMPlus score is increased by 1 point for the bit-rates of 8Mb, 10Mb, 14Mb, and by even 2 points for the bit-rates of 6Mb, 12Mb, which is visually noticeable.

Table 5 - SSIMPlus scores for encoding the Regatta video sequence.

Target Bit Rate (Kb)	SSIMPlus (no QMs)	SSIMPlus (Default HEVC QMs)	SSIMPlus (Proposed QMs)	Minimal SSIMPlus (no QMs)	Minimal SSIMPlus (Default HEVC QMs)	Minimal SSIMPlus (Proposed QMs)
6,000	83.09	83.14	84.16	68	68	70
8,000	86.31	86.42	87.49	74	74	75
10,000	88.61	88.74	89.80	78	78	79
12,000	90.28	90.42	91.40	81	81	83
14,000	91.49	91.65	92.56	84	84	85

Perceptual quantization matrices for mobile devices, such as tablets and smartphones, which have much smaller display sizes, thereby allowing a significant reduction in the overall video transmission bit-rate by removing non-perceivable details from each video frame, are discussed at the next section below.

3.3. Perceptual Quantization Matrices for Mobile Device Displays

For mobile devices, which have smaller display sizes, there is a need to develop dedicated perceptual quantization matrices for coding High Dynamic Range (HDR) mobile device-based video content. The perceptual quantization matrices proposed at [11] are based on Human Visual System (HVS) and utilized for reducing video transmission bit-rate and for optimizing perceived visual quality of video content to be displayed on mobile devices, such as tablets and smartphones.

According to video coding scheme proposed at [11], visual quality of the HDR UltraHD video content is significantly improved, for substantially the same bit-rate, in terms of the popular objective quality metric SSIMPlus. On the other hand, the video transmission bit-rate is significantly reduced by up to about 25%, while keeping visual quality of the video content, to be displayed on a mobile device screen, substantially at the same level.

Similarly to what is explained at the previous section, the x265 open source HEVC-based encoder [28] was selected for implementing the proposed perceptual quantization framework due its ubiquity in the industry and flexibility in configuration, as well as due to its good coding performance.

Table 6 below presents, in its right column, the BD-BR SSIMPlus bit-rate savings for the HEVC encoding with the proposed perceptual quantization matrices (QMs) that are optimized for *mobile devices* versus HEVC encoding with the default QMs, as defined in the HEVC specification. In addition, in the middle column, are presented the BD-BR SSIMPlus bit-rate savings for the HEVC encoding with the proposed perceptual QMs that are optimized for *mobile devices* versus HEVC encoding with the constant QP as defined in CTC [32]– i.e. without employing the default HEVC QMs. As can be clearly seen from Table 6, by employing the proposed perceptual QMs, significant coding gains of up to about 25% are achieved. It should be noted that for the “Regatta” video sequence the coding gain is the most significant - the “Regatta” video content is considered to be hard to encode, since it contains many water scenes, and the proposed perceptual QMs perform much better for such content. Below, as an example, the quality scores for encoding the “Regatta” video sequence with target bit rates varying between 2Mb and 5Mb are presented, thereby showing the SSIMPlus score in a range between 0 and 100, while the larger the number - the better the video quality is (100 is the best possible quality).

Table 6 - BD-BR SSIMPlus bit-rate savings for the HEVC encoding.

	BD-BR SSIMPlus	BD-BR SSIMPlus
--	----------------	----------------

Tested Video Sequences	Proposed QMs vs. Default HEVC QMs	Proposed QMs vs. no QMs
Lucy	-15.5%	-16.8%
Everest	-21.4%	-22.2%
Warcraft	-5.9%	-7.8%
Regatta	-22.2%	-23.9%

Also, as it is clearly seen from *Table 7*, when the proposed perceptual QMs that are optimized for *mobile devices* are employed, the SSIMPlus score is significantly higher – i.e. it is up to about *2 points* compared to encoding with a constant QP according to CTC [32], i.e. marked as “no QMs”. Similarly, the encoding with the default HEVC QMs provides a little improved visual quality compared to the above-mentioned constant QP encoding, but still much worse quality compared to the encoding with the proposed perceptual QMs. In addition, the minimal SSIMPlus score is increased by a very significant number of up to *7 points* for the bit-rate of 3Mb, which is visually clearly noticeable.

Table 7 - SSIMPlus scores for encoding the Regatta video sequence.

Target Bit Rate (Kb)	SSIMPlus (no QMs)	SSIMPlus (Default HEVC QMs)	SSIMPlus (Proposed QMs)	Minimal SSIMPlus (no QMs)	Minimal SSIMPlus (Default HEVC QMs)	Minimal SSIMPlus (Proposed QMs)
2,000	76.82	76.85	78.61	48	48	54
3,000	82.06	82.10	83.48	58	58	65
4,000	84.82	84.87	86.10	65	66	72
5,000	87.20	87.28	88.48	73	73	77

In the next section, another promising approach for increasing video coding gain is discussed. In this approach, “visual masking” is applied [12], which is based on the human visual system (HVS) characteristics.

4. Perceptual Video Masking Framework

As known, HEVC was especially designed for coding of HD and UltraHD video content with a much larger coding gain compared to its predecessor H.264/MPEG-AVC, thereby reducing both spatial and temporal video content redundancies in a much more efficient way, which in turn significantly assisted in compression of the HDR UltraHD video content [1]-[5]. However, coding of the HDR video content still remains challenging due to users’ demands for high visual quality, which in turn requires allocating more bits and increasing a video coding depth (e.g., from 8 bits to 10 bits). In addition, the transmission bandwidth is normally limited due to a typical limitation of the existing network infrastructure, especially in case of the transmission over wireless/cellular networks. As a result, in order to stay within the transmission bandwidth limits, the high-resolution HDR video content is often compressed with visually perceived coding artifacts. Moreover, encoding of the HDR content normally consumes significant computational resources due to a requirement to preserve fine details within the HDR video. Therefore, there is further a strong demand to improve perceived visual quality of the compressed HDR video substantially without increasing its bit-rate [10], [11].

4.1. Background: Visual Masking

One of the promising approaches for increasing video coding gain is applying “visual masking”, which is based on a very interesting phenomenon observed in the human visual system (HVS) [12]. According to this phenomenon, two or more stimuli are presented sequentially to a viewer, with one stimulus acts as a target which has to be detected and described, while other stimuli are used to mask the visibility of that target. With this regard, a good amount of research has been carried out in the video compression field, such as [33],[34] for example, which exploits the above-mentioned phenomenon by providing a psycho-visual algorithm that has been implemented in the x264 encoder [35]. In turn, more advanced studies of are further presented and discussed in [36]. In addition, in the most recent work, such as [37], it is proposed to mask temporal activities that are unnoticeable by human visual system by using a masking coefficient. Further, [38] presents a video Just Noticeable Difference (JND) scheme by employing compound spatial and structure-based temporal masking, further measuring a JND threshold for each transform coefficient of a color video. Also, [39] proposes an improved transform-based JND estimation model considering multiple masking effects.

However, all surveyed existing visual masking approaches, the most interesting of which are indicated above, lead to relatively low bitrate savings. As a result, these approaches have not been adopted in the video streaming/coding industry to date. In addition, computational complexity of existing visual masking schemes is relatively high due to the utilization of relatively complex quantization models [19].

4.2. Forward and Backward Masking Encoding Scheme

In this section, a masking technique for videos is exploited and discussed in detail. Extensive experiments have been carried out for the unidirectional (either forward or backward) temporal masking, but due to the lower coding gains when compared to the bidirectional (i.e. *joint* forward and backward) temporal masking, and to keep the presentation of the experimental results of this work in a clear and simple manner, this paper is focused on the bidirectional temporal masking only. The x265 open source HEVC-based encoder [28] was selected for implementing the proposed joint forward and backward temporal masking framework due its ubiquity in the industry and flexibility in configuration, as well as due to its good coding performance.

With this regard, *Figure 5* presents a schematic illustration of the proposed framework, which includes three forward sub-windows 1 to 3, and three backward sub-windows 4 to 6. Each window can have a different length and for each window, a set of different quantization parameters (QPs) can be assigned by adding the following QP offsets: ΔRef_1 , $\Delta Non-Ref_1$; ΔRef_2 , $\Delta Non-Ref_2$; ΔRef_3 , $\Delta Non-Ref_3$; ΔRef_4 , $\Delta Non-Ref_4$; ΔRef_5 , $\Delta Non-Ref_5$; ΔRef_6 , $\Delta Non-Ref_6$. Also, different QP offsets can be assigned separately to reference (e.g., *P-frames*, *B-frames*) frames and to non-reference frames (e.g., *b-frames*) present inside each masking window. The above-mentioned QP offsets are predefined in the x265 code [28] for reference *B-frames* and for non-reference *b-frames*, the offsets for *P-frames* are automatically reduced by 30%, thereby applying only 70% of the ΔRef offset value, to improve their quality and to increase a coding gain. In addition, no QP offsets are applied to *I frames*, regardless of the fact whether the *I-frame* is a scenecut or not. In case when an *I-frame* is present inside a masking window, the masking is avoided on all frames after this *I-frame* in a given masking direction (either forward or backward). The values of QP offsets can be customized using the x265 command line [28].

Figure 5 – A schematic illustration of the proposed joint backward and forward temporal masking framework.

For evaluating the proposed framework, the authors selected a wide range of cinematic content, mostly in 10-bit UltraHD resolution, which can be characterized as follows: (a) “El Fuente” – includes mixed content, with both fast and slow motion; (b) “Lucy” – includes many action scenes, many fast motion scenes, mixed content; (c) “Warcraft” – includes various computer-generated content, mostly fast motion scenes; (d) “Everest” – includes mountains views, snow scenes, mostly slow motion scenes; (e) “Regatta” – includes water scenes, many fast motion scenes. Main technical parameters of the above-mentioned cinematic content are presented in *Table 8* below:

Table 8 – Test Sequences.

No	Sequence name	Resolution	Frame count	Frame rate	Duration (sec.)	Bit depth
1	El Fuente	3840x2160	1500	60	25	8
2	Lucy	3840x2160	480	24	20	10
3	Warcraft	3840x2160	495	23.98	~20	10
4	Everest	3840x2160	480	23.98	~20	10
5	Regatta	3840x2160	1199	59.94	~20	10

The test environment, lighting, and the rest of requirements for obtaining optimal viewing conditions were set according to [40].

4.2.1. Experimental Results and Brief Discussion

The experiments were conducted according to [40],[41]. Due to the COVID-19 restrictions, viewing sessions were done remotely, and strict instructions were provided to all participants in accordance with [40],[41]. The video playback was done on high-end consumer 4K TV displays capable of playing HEVC-encoded video content with a minimal screen size of 55” (OLED TV). High-quality 32” professional SDI reference/grading displays were used as well.

Table 9 – Bitrate Savings in Terms of BD-BR.

Sequence Name	CRF	Without Masking (Reference)		With Masking (Tested)		BD-BR Savings
		Bitrate	MOS	Bitrate	MOS	
El-Fuente	20	23960.64	88	18266.86	89	-10.7%
	24	14701.49	85	11378.59	82	
	28	9013.59	80	7115.96	79	
	32	5629.3	73	4560.42	72	
	36	3616.78	64	3054.72	64	
Lucy	20	14074.81	89	11390.49	88	-5.6%
	24	8042.85	85	6677.24	84	
	28	5003.31	74	4210.82	75	
	32	3211.48	69	2737.33	62	
	36	2113.21	63	1832.32	55	
Warcraft	20	7092.24	88	6655.14	88	-2.3%
	24	4082.99	85	3852.15	85	
	28	2572.63	82	2436.43	83	
	32	1705.72	73	1621.98	71	
	36	1171.32	66	1121.69	58	
Everest	20	13420.24	85	11418.12	85	-14.8%
	24	5738.53	83	4943.96	82	
	28	2516.55	76	2224.67	78	
	32	1480.22	69	1335.23	70	
	36	1007.73	65	922.89	65	
Regatta	20	34769.29	83	26042.09	84	-26.3%
	24	21264.06	80	15836.46	82	
	28	13164.48	82	9791.08	79	
	32	8342.09	76	6249.4	72	
	36	5349.47	66	4192.14	61	
Average				-11.9%		

As seen from *Table 9*, the largest bitrate savings of more than 26% are for “Regatta” sequence, which has the highest bitrate, on average.

On the other hand, the smallest bitrate savings of 2.3% are for the “Warcraft” sequence, which has the smallest bitrate, on average. Further, there is a substantial decrease in the overall computational complexity in terms of encoding times (for simplicity, the results are not presented).

One of the *important findings* is that the proposed joint backward and forward temporal masking framework tends to perform better for higher bitrates and frame rates, as well as for content that includes textures, such as water and snow.

In this paper, two approaches have been presented and discussed in detail: perceptual quantization matrices and visual masking. Future directions with this regard are discussed at the next section.

5. Future Directions for Perceptual Video Coding Optimizations

In spite of the fact that the HEVC standard was especially designed for the HD and UltraHD video content, more efficient video compression techniques are still desired, especially for streaming UltraHD video content as well as Panorama video content (so called 360° video content) from concerts, shows, sport events, etc. Therefore, in order to fulfill this demand, the exploration phase for future video coding technologies beyond HEVC (ITU-T H.265 | ISO/IEC 23008-2) started in October 2015 by establishing a Joint Video Exploration Team (JVET) on Future Video Coding of ITU-T VCEG and ISO/IEC MPEG. In turn, these future technologies were integrated into the Joint Exploration Test Model (JEM), and the official standardization activities for the next-generation video coding standard officially started in April, 2018 - right upon publishing results of the Call for Proposals (CfP) for future video coding technologies (after completing the Call for Evidence (CfE) in 2017).

The emerging video codec under the JVET development was titled “Versatile Video Coding”, or in short, VVC [42].

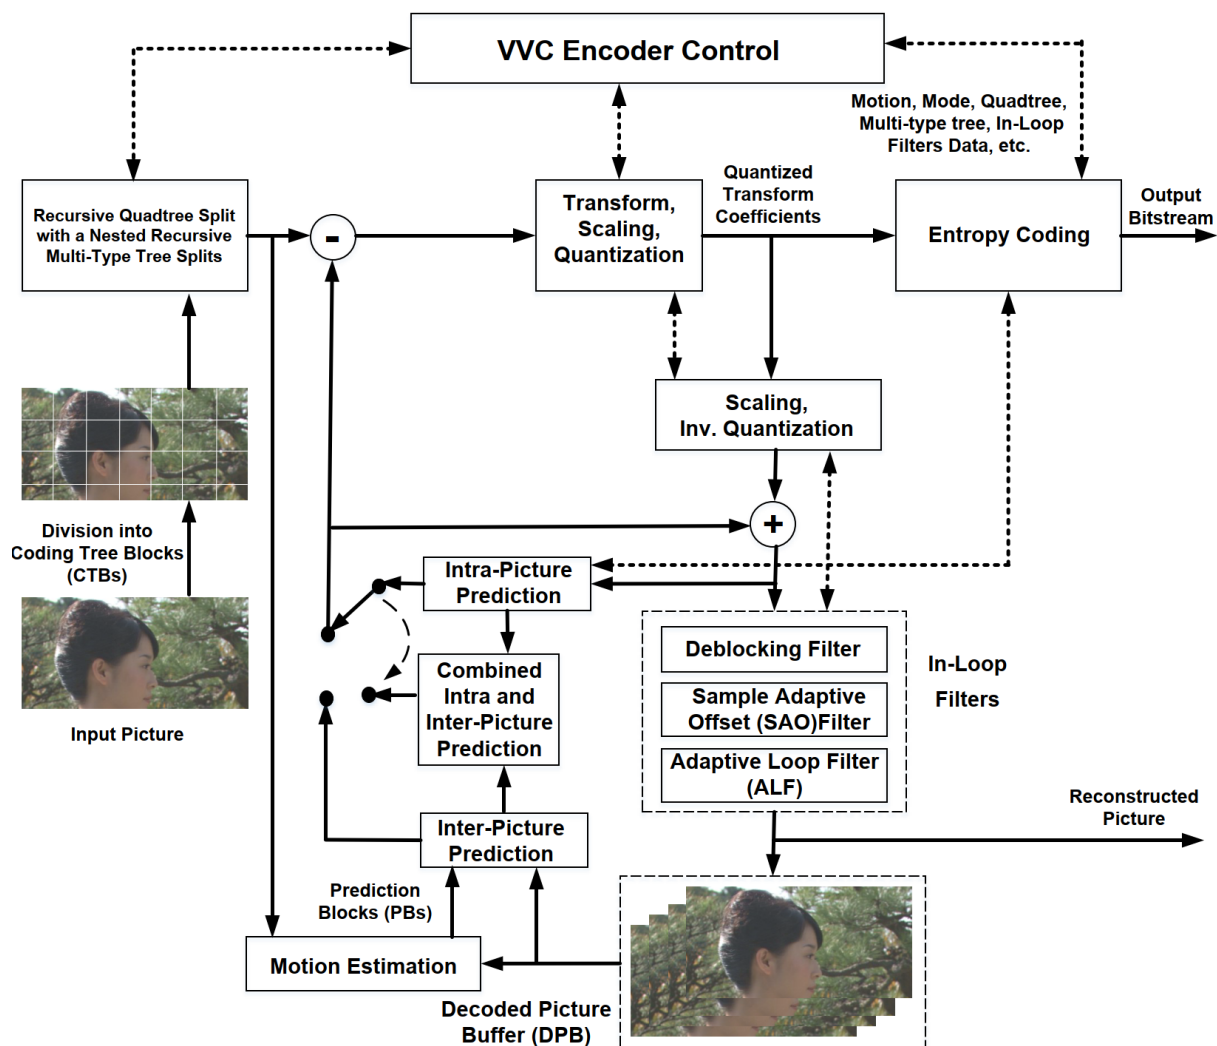

Figure 6 – The schematic block diagram of the H.266/MPEG-VVC encoder.

In turn, the first VVC draft along with the VVC Test Model 1 (VTM1) was published right after the April, 2018 meeting. As one of the main tools that provides a significant coding gain, VVC includes a quadtree with nested multi-type tree by using a coding block structure of binary and ternary splits. Further, additional tools and features include: Intra-mode coding with 67 Intra-picture prediction modes; Intra Block Copy (IBC); Bi-Directional Optical Flow (BDOF); Adaptive Motion Vector Resolution (AMVR); Geometric Partitioning Mode (GPM); Combined Inter and Intra Prediction (CIIP); Adaptive Loop Filter (ALF); *and many others*. The first version of the VVC standard (i.e., VVC v1) was officially finalized during the 19th JVET meeting, which took place between June 22 and July 1, 2020, and the VVC codec is currently starting to be widely deployed worldwide [42]. The schematic block diagram of the H.266/MPEG-VVC encoder is presented in *Figure 7*.

Therefore, the perceptual quantization matrices and masking encoding schemes described in this paper, can be applied during the VVC encoding process as well, thereby leading to even larger coding gains.

In addition, the presented perceptual video coding optimizations can be applied to the framework of [43], as described below. According to this framework, the x265-based multi-resolution encoding architecture is leveraged to significantly speed-up the encodes through sharing the analysis information from lower to higher resolutions. For example, the encodes that generate representations at the 960x540 resolution (i.e., 540p) can share information to those that generate representations at the 1920x1080 resolution (i.e., 1080p, a dyadic multiple of 540p), which in-turn can speed up the 3840x2160 resolution encode (i.e., 2160p, a dyadic multiple of 1080p). In addition, the encodes that generate representations for the 1280x720 resolution can share information to the encode that generates a representation at the 2560x1440 resolution.

Therefore, a framework can run efficient encodes, which generate both the reference and dependent representations in parallel, while also efficiently handling dependencies with the sharing analysis information among these presentations. In turn, the Adaptive Bit-Rate (ABR) ladder allows the more efficient sharing of the aforementioned analysis information among the representations at different resolutions.

Further, *Figure 7* schematically presents a high-level block-diagram of the proposed framework for the efficient usage of the x265-based [28] adaptive multi-resolution encoding architecture, thereby enabling the efficient sharing of analysis information across representations. As shown in *Figure 7*, the proposed framework is being used for converting an input video source, which has the $W \times H$ resolution, to n representations, each representation having a scaling factor of L_i (*with $i = 0$ to n*) and bitrate B_i . This framework uses a configuration file in order to define the encoding graph and the degree of encoder decision reuse between a dependent and a reference representation. In addition, it is possible to add representation-specific parameters to the configuration file, such as limiting the Coding Tree Unit (CTU) size for lower resolutions.

For the more detailed description regarding the syntax of the x265 configuration file, the reader is referred to [28].

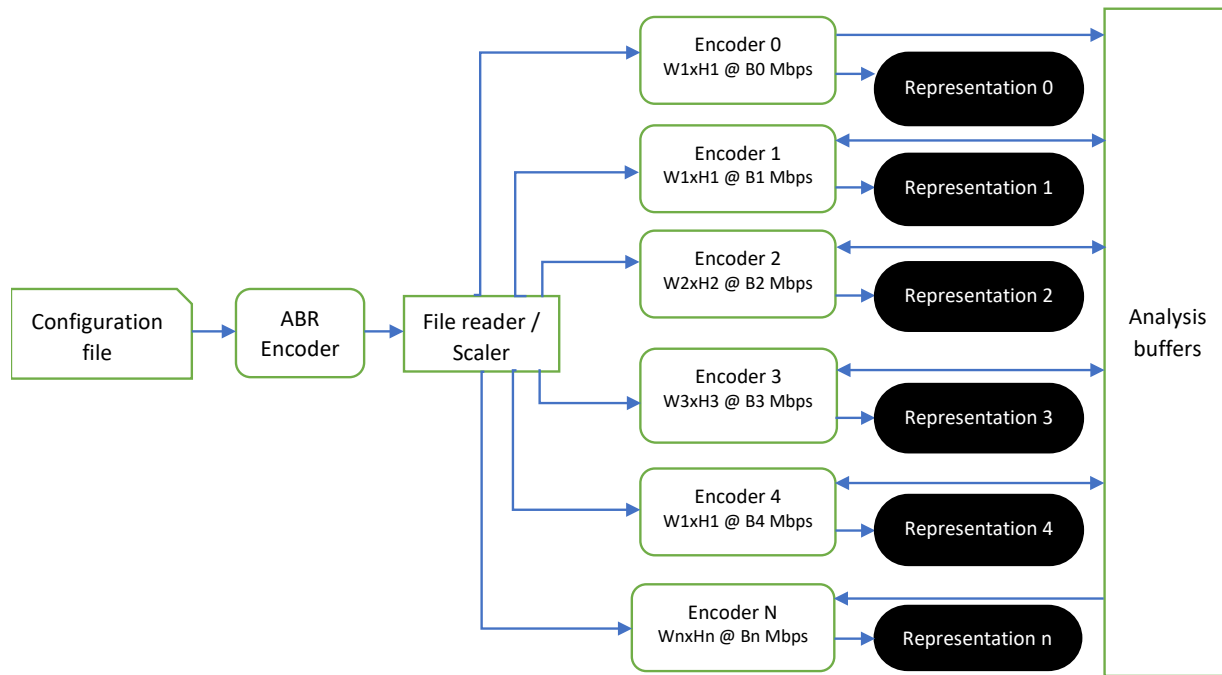

Figure 7 – A multi-resolution encoding framework for enabling efficient sharing of analysis information across representations.

By such a way, i.e. by utilizing perceptual quantization matrices and masking encoding schemes with VVC and with the above-mentioned multi-resolution encoding framework, further significant bit-rate savings can be achieved.

6. Conclusion

In this paper, perceptual video coding optimization techniques, including most recent trends and future directions, have been discussed in details. A special emphasis was made on the UltraHD resolution, such as the 3840x2160 (4K) resolution in terms of luma samples, and on the most recent, and currently the most advanced, H.265/MPEG-HEVC video coding standard. The development of the perceptual quantization matrices has been motivated by the Daly HVS-based perceptual model, which was further fitted into the more advanced and more complex Barten model (that incorporates a variety of HVS parameters) for much more accurate generation of these matrices. As a result, the video transmission bit-rate for UltraHD displays was reduced up to 11.3% in terms of SSIMPlus, while keeping the visual quality at substantially the same level. On the other hand, for smaller size mobile device displays, the video transmission bit-rate was reduced up to about 25% in terms of SSIMPlus objective quality metric, while keeping the visual quality substantially at the same level. In addition, a joint backward and forward temporal masking framework was presented, which considers temporal distances between frames and the closest scenecuts. This framework has been implemented in the popular x265 HEVC-based encoder. Based on the extensive subjective quality assessments, significant bitrate savings of up to about 26% are achieved for substantially the same perceived visual quality. The future direction mostly refer to implementing the presented framework with the most recent VVC video coding standard, further getting benefit from the presented x265-based multi-resolution encoding architecture.

Abbreviations

ABR	Adaptive Bit-Rate
ALF	Adaptive Loop Filter
AMVR	Adaptive Motion Vector Resolution

1. Introduction

As the largest broadband company in the US, Comcast serves millions of customers and businesses with a reach that stretches coast to coast. All of this is the result of a large optical network that spans core, metro and access layers with multiple intersecting points all intended to increase capacity, reduce latency, and enhance reliability.

In this paper, we describe for the first time an end-to-end view of our optical network including the core, metro, and access layers. At the core and metro, we increase capacity with a move towards flexible 400G connections and reduce latency and enhance reliability with an infrastructure that meshes color-less, direction-less, and contention-less reconfigurable multiplexers thru to each of our headends. At the access layer that connects these headends to customers and businesses, we discuss capacity increases with our move to all-digital fiber links and the distributed access architecture paradigm. Of note is a cost effective environmentally hardened dual laser bidirectional coherent 100G system and the converging all bidirectional access transmission formats on one single optical fiber. Reliability enhancements accrue with real-time continuous and pervasive optical monitoring of all these access assets. We then briefly describe the infrastructure that helps provision, visualize and event these layers. Finally, we will venture into the future of optical technology at Comcast and its positive impact on network robustness and enhancing the customer experience.

2. The Big Picture

Photons flood into the Comcast backbone network from giant Internet routers and reach the various metro routers. At the metro center, photons reincarnate and course thru the highly meshed Converged Regional Area Network infrastructure that terminates in the thousands of our headends. At the various headends, photons reincarnate again, traverse access fibers and light up the many homes, businesses and fiber nodes eventually completing their journey in the downstream. A similar process ensues in the upstream where photons transmigrate thru the access system to the various headends and mesh metro circuits before making their way back thru to the internet.

2.1. Backbone, Metro and Access

Presented below is a picture that illustrates the reach of our backbone and access systems in Comcast [1].

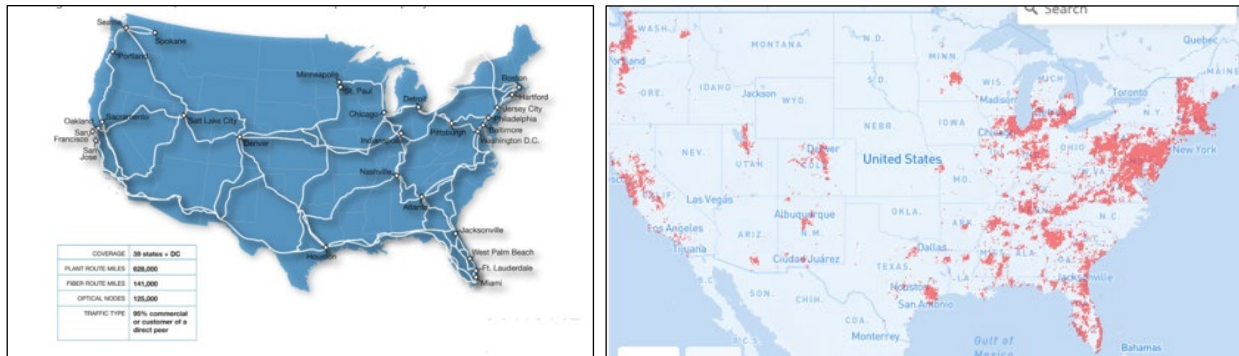

Figure 1 – Comcast Backbone and Access Networks

With the breadth that reaches coast to coast connecting important Internet Data sites and the depth of reaching 60M homes and businesses, the Comcast communications system comprising the Backbone, Metro and Access sub-systems today is now all under one single group in Comcast.

Internet sites located at Chicago, Atlanta, Ashburn and others are connected to the Backbone and via route redundancy reach all our Metro sites that interconnect hubs and headends within individual cities. At the extremities of the Metro network, residential access network interconnect with Metro and via vCMTS (virtualized Cable Modem Termination System) connect to Remote PHY based digital fiber Nodes. Commercial/Business services which were always closely connected to Metro are now converging with Residential access networks and are sharing common connectivity and fiber assets.

The residential access network is orchestrated by Comcast own provisioning, monitoring and fix agents and provide an end-to-end view. The Metro and Backbone orchestrations for provisioning, monitoring and fix are more closely related to the vendors of choice.

Figure 2 – Comcast Architecture

With this understanding in the next few sections, we describe a more detailed view of each of the subsystems along with a brief history evolving to the current state and potential innovations that we are looking into for meeting capacity and performance and transform Comcast into the leading communications provider in the country.

3. The Backbone

The early days of the Comcast network began as 28 separate networks or islands connected using Transit connectivity and leveraging local access interconnects. Comcast's network needs dramatically changed in the early 2000's. The company was looking to centralize video downlinks in order to distribute them terrestrially, which coincided with the initial roll out and testing of Broadband cable modems. Between the needs of nationally distributed video, transit for high-speed internet access, and the birth of data centers for VOD / back-office systems, there was an obvious need for a national network. The decision was made to build a National Backbone that enabled more control over the products and services Comcast would deliver by acquiring the Indefeasible Right of Use to a 2-fiber national footprint. The footprint touched all 28 Comcast metro networks and had a presence in the majority of all the tier 1 cities that enabled easy connectivity to our transit provider(s). Since the fiber passed close to Comcast buildings, but not through Comcast buildings, short fiber laterals would need to be constructed to attach metros to the Backbone.

3.1. Comcast Backbone History

Each of the 28 metros chose 2 locations for Backbone connectivity, and core locations were also strategically selected in major cities. Each core location was given a core router for Comcast "internal video" and a core router for "external" or "internet" services. Although multiple "networks" were built from a routing perspective, fiber availability, and cost, drove the need for a single transport platform to carry all traffic and lines of business. The original Backbone was designed and built as a greenfield taking advantage of new MEMS based reconfigurable add, drop multiplexers (ROADM) technology. ROADMs were placed at each metro aggregation points, core location, and fiber branch. This created an 88 channel, fixed 50GHz, meshed network, that allowed channels to be turned up between ANY add/drop locations. A large portion of the footprint contained amplifier sites that didn't serve any add/drop purpose. These sites were built as amplifier only sites, unless optical regeneration was needed in which the site was built as an add/drop.

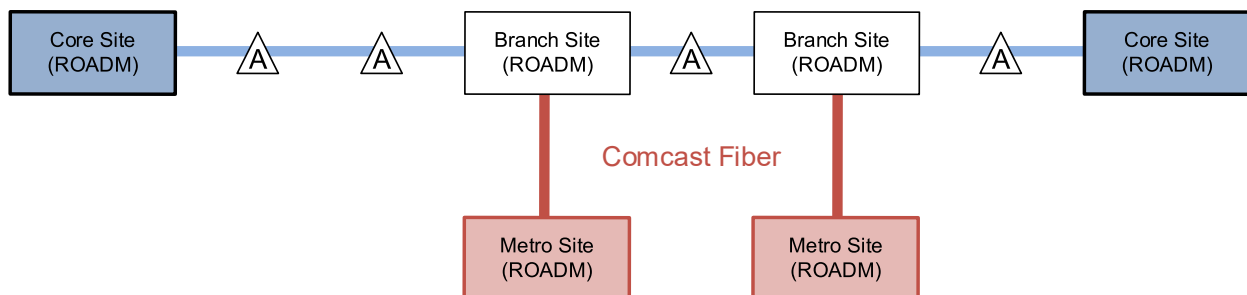

Figure 3 – Comcast Backbone Architecture - 1

Traffic was then turned up using 10G DWDM transponders. Initial calculations arrived at each metro requiring a 10G channel for “internal” Comcast video traffic, and a 10G channel needed for “external” data/internet traffic. To support this in the core, all core routers were also connected via 10G channels per supported service.

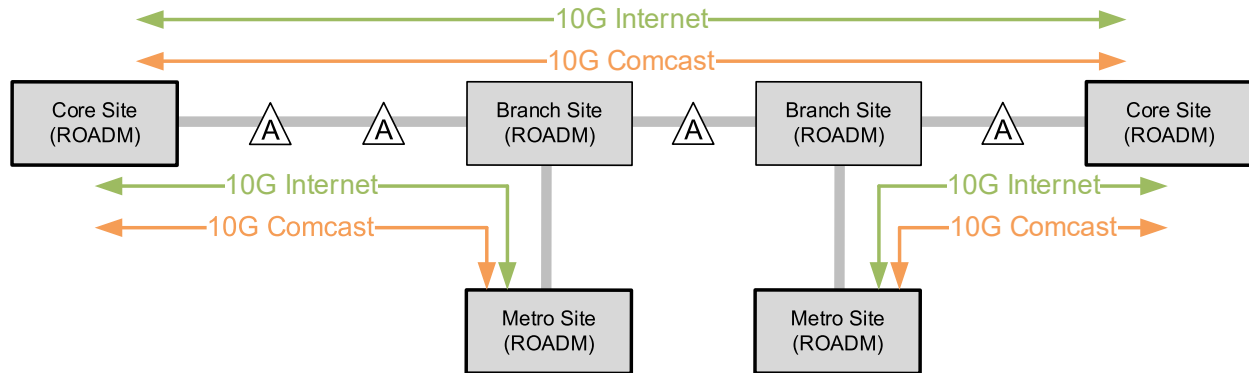

Figure 4 – Comcast Backbone Architecture - 2

Before the entire greenfield was even completed, it became VERY obvious that the exponential growth of the internet would quickly drive 2 changes.

First, Comcast needed to transition from leveraging a transit provider, to becoming a full-service provider. Core sites needed to move to locations that were more conducive to Settlement Free Interconnects. “Carrier Hotel” sites were chosen, and “Edge” router ports now faced offnet Settlement Free Interconnects and customers.

Second, the Compounded Annual Growth Rate (CAGR) growth far exceeded Comcast’s ability to deploy technology such as 10G transponders. We quickly realized that in order to support our growth that we would need to drive Optical Technology roadmaps to support higher Optical speeds. The move to 40G (2006) and then to 100G (2011) was required to manage our optical spectrum efficiently to avoid exhaustion on the original line system.

By 2015, the original fixed grid system was full and unable to utilize the new 400G transponders that required flex grid. Comcast chose to acquire more fiber and construct a 2nd line system instead of trying to upgrade the existing system. The 2nd backbone optical system was completed in 2018 and was almost exclusively 400G from the start with built in capabilities to expand to 800G and beyond.

3.2. Optical Innovations in the Backbone

The tremendous CAGR growth realized over the last 15+ years, drove many optical industry innovations in an effort to keep pace. In addition, these innovations had to be economically viable driving Watts per Bit efficiencies.

The primary obstacle that separates backbones from other optical networks is simply the fiber distance. Fiber Distance drove the initial 10G and 40G NRZ deployments to install over 40 optical regen sites across the country. The first big break in technology was the arrival of the

40G coherent modem. It not only quadrupled speeds per channel, but just as importantly, it more than doubled the reach. Cost per bit dropped, and with regens reductions dropping into the teens, network costs were reduced significantly. Within a few years, Comcast was then able to augment longer spans with Raman amplifiers, move to the industry's first 100G coherent modem, and reduce Optical regen sites to 4.

The second backbone built in 2017-2018 was built utilizing colorless direct attach (CDA), flex grid ROADMS, with a flexible add/drop structure. Combining low loss fiber and 2nd Gen Raman amplifiers, Comcast is now able to cross every link without regen at a minimum of 200G and maximum of 800G. Additionally, all shelves were deployed with L-band amplifiers, so L-band channels can be added in the future without any service interruption.

Finally, the integration of an OTDR into the optical line system must be mentioned. When your network spans 18,000 route miles, knowing exactly where an outside plant problem occurs is invaluable with the hopes of reducing the Mean Time to Mitigate. (MTTM)

3.3. Capacity of the Backbone

The most valuable commodity in National Optical Networks is long haul fiber and the efficient use of optical spectrum management. Fiber longevity within the access and metro networks is also important, but typically more feasible and economical than acquiring and deploying national fiber where such options are very limited. Any fiber, if available, usually comes at an exorbitant cost.

Comcast has historically been a proponent of partnering with the Optical Industry to drive key technology innovations and continues to collaborate on next generation Optical capacity and efficiencies innovations.

Table 1: Fiber Capacity

Year	Line System	Modem	Fiber Capacity
2005	50GHz Fixed	10G	880GB
2009	50GHz Fixed	40G Coherent	3.5TB
2013	50GHz Fixed	100G Coherent	8.8TB
2018	CDA Flex	400G Flex	12.8 - 25.6TB*
2021	CDA Flex	800G Flex	16.8 - 33.6TB*

* C-band only (all fibers are L-band capable which should double capacity when modems are available)

3.4. Future of the Backbone

There is no denying the need for long haul networks to interconnect metro networks and peers, both in footprint and offnet. Even with the overall CAGR slowdowns after the Pandemic, the need to scale efficiently and economically will not disappear anytime in near the future. Moving forward, it is critical to drive software, tools, automation and integration in addition to the speeds and feeds of the typical hardware innovations. It is important that as an Industry we continue to partner and drive these Optical technology evolutions in support of future network products and services.

3.5. Purpose Built Networks

Comcast traffic contains 2 basic types. The majority (>95%) is very predictable internet destined traffic between the metro aggregation shelf and the edge. The smaller portion is very unpredictable traffic that has varied source and destination points. The large portion emphasizes the need for lowest cost per bit, while the other demands flexibility over cost. A point-to-point network of a flexible CDA line system with state-of-the-art modems would really push capacity up, and costs down, but with almost no flexibility. Where a CDC network can move traffic between any location, but at a lower capacity, and at a higher initial cost. Since the original Backbone was full and reaching end of life, a replacement was needed. Comcast utilized the luxury of having more than 1 fiber pair and decided to build 2 purpose built networks instead of one Swiss Army knife of a network. This allows the cost-effective network to grow quickly, while preserving the life of the costlier one.

3.6. Power Consumption

Power consumption is an industry wide concern. However, this is amplified in peering locations (BB Core sites) specifically. Peering locations are needed to interconnect with other service providers, and they are independently owned by facility managers. This forces Comcast and other service providers to rent space and power. Network growth has forced these locations to fill and make space and power very scarce. If a space fills, a migration to a new facility is needed. To avoid (or delay) the high cost and complexity of moving a core peering location, driving power consumption down is a must. Comcast has seen watts per optical bit fall from 7.3 in 2005 to below 0.5 today. Unfortunately, growth has outpaced the reduction in power consumption, so this continues to be a hot topic.

3.7. IPoDWDM and Alien Waves

IP over DWDM, primarily led by ZR+ plugs, is getting serious testing in Comcast. Although they are not as applicable in the Backbone as the metros, there is still some key use cases. The Comcast Backbone network tried this in 2006-2007 with a 40G optic being placed in our core routers. Engineering limitations were understood and overcome, but operational limitations ultimately ended the experiment. The same operational shortcomings were identical to alien wave issues. Comcast continues to seek operational solutions both internal and external in hopes of taking advantage of the possible cost reductions of alien transponders and plugs.

3.8. Automation

Turn up of new bandwidth and services across large national networks can seem like it happens at a snail's pace. Equipment and resources tend to be needed in several locations, often very far apart. Planning, deploying, testing, and turn up requires a lot of time. This time is stretched even longer as they sit on long waiting lists seen in very large networks. Comcast has been able to streamline and automate some of the predictable, business as usual (BAU), bandwidth growth, but much more is needed. Commercial and wave services will, due to their unique and custom designs, amplify this need. Comcast continues to drive automation from planning to turn up and utilize more flexible equipment to drive down equipment installation times.

4. The Metro Network

Designed to support multiple lines of business (LOB) with a variety of bandwidth needs and traffic patterns, however, to say designed is a bit of a misnomer. This would imply the metro was conceived and deployed from day one in a greenfield manner to meet all the needs of today. What had actually happened is that over the last 25 years these networks came to be through mergers of smaller cable television (CATV) providers into multiple system operators (MSO). There were technology evolutions from passive transport systems with amplifiers (AMP) and multiplexers (MUX) to what is present today with reconfigurable add, drop multiplexers (ROADM) colorless add / drops, and flex grid technology. The type of data and rate has also dramatically changed. The earliest deployments were to support video to areas that were beyond the reach of long coaxial (COAX) trunk runs, followed by hybrid fiber-coaxial (HFC) and 1 gigabit ethernet (GbE) commercial customers. Today 100G to 800G wavelengths are the norm! The more than 60 metro networks at Comcast have now either been upgraded or planned to go to colorless, dispersion less designs with flex grid ROADMs optimized for coherent wavelengths. Additional paths have been added between sites (referred to as degrees) for resiliency and latency reduction as well. The Metro networks are unique in that they are intentionally not purpose built to support a single demand but are LOB agnostic. The Swiss Army Knife of transport at Comcast!

Figure 5 - The beginning of the Metro network. 3 independent CATV providers

Figure 6 - Metro network today. One MSO. Flex grid and ROADMs. The Swiss Army Knife

4.1. The 28 CRANs of Comcast

The largest consumer of metro transport bandwidth are the Comcast regional area networks (CRAN). These networks are the core of the internet protocol (IP) infrastructure consisting of a pair of large aggregate routers (AR), residential U routers (RUR) and commercial super U routers (SUR). Each edge site is U ring with a pair of RURs with one router connecting to one market AR and the other connecting on diverse path to the other AR. If there are commercial services at the site, the same topology is applicable but with SURs in addition to the RURs. Each CRAN has two ARs which are connected to two backbone connections on diverse routes. This topology ensures failures of equipment or fiber will not impact customers. They are called U rings because the shape of the letter U describes the topology. The top of each leg of the U is an AR location and the bottom being the RUR / SUR site.

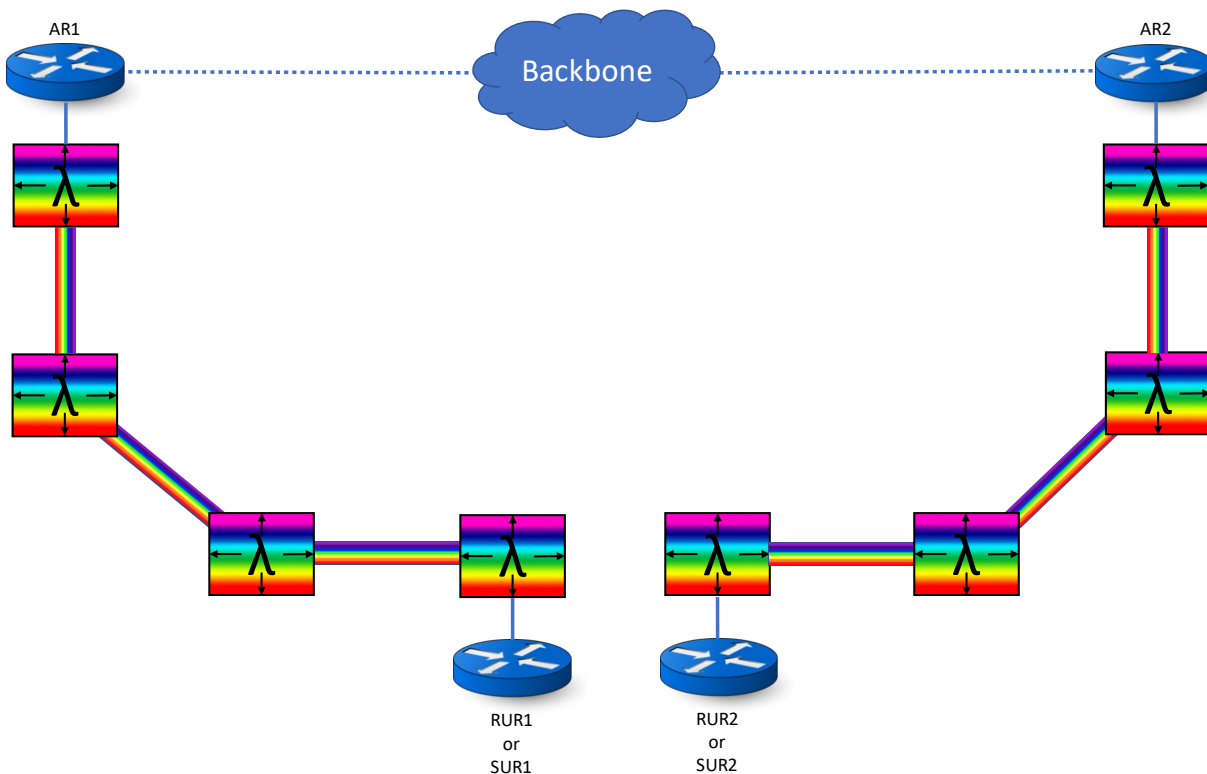

Figure 7 - U Ring Topology

4.1.1. In the beginning. Video on demand (VOD)

The Metro Transport Network tends to evolve to meet the needs of the routed network. The original iteration was dense wave division multiplexing (DWDM) and coarse wave division multiplexing (CWDM) uni-directional 10GbE optics placed directly in routers with MUXs and AMPs as needed. This was to support VOD and was also the birth of the U ring at Comcast. The routers we aptly named U routers (UR). A major difference in the topology compared to today is that that these URs to support VOD were configured hop by hop. Each router was connected in a chain. Since the circuit never had to go more than one span this allowed the use of point to point amplified optical links referred to as passive transport

4.1.2. Next up! High-speed internet (HSI).

If all routers need the same amount of capacity the hop-by-hop VOD architecture worked fine. With the introduction of high-speed internet (HSI) not only did the traffic need to become bi-directional but also the capacity needs of the routers began to become more fluid based on consumption of the product. For example, if there were five routers in the leg of a U all at 10GbE of demand and the fourth router in the chain grew and needed 20GbE then all the spans between the AR and the fourth router need to be augmented to 20GbE. This applied to both sides of the U. This was not a scalable model to throw away bandwidth along the way to reach a downstream router.

This led to the installation of active transport with ROADMs which allowed each router to get a direct connection to the ARs bypassing sites along the way optically. This first generation of transport had dispersion compensation, fixed grid wave selective switches (WSS), fixed grid MUXs and was optimized for 10GbE. Depending on the era this equipment could be either 50 gigahertz (GHz) or 100GHz spaced. This spacing is not critical for the 10G but would play a role in future evolutions.

As ROADMs were being installed and traffic could be steered at site optically it made sense to start breaking up large rings into smaller sub rings by building degrees between sites and including more remote sites into the network. These new shorter paths began to open the door for commercial services like cell backhaul (CBH).

4.1.3. 10 x the bandwidth and then some!

The next substantial change was to 100GbE interfaces on routers and the 100G coherent wavelengths required on transport. This was a huge leap! Fortunately, the metro transport was able to carry this traffic without upgrading the line system. A typical 100G coherent wavelength is ~37.5GHz wide. With most of the technology at this time being deployed with 50GHz spaced ROADMs and MUXs the 100G wavelength fit without issue. In fact, up to a 200G wavelength can fit in these networks.

At this point the transport was one step ahead of the routers. With 400G line rates right around the corner and the router interfaces to follow the transport needed to maintain this lead and be ready for 400G as soon as possible.

In an interesting twist some of the oldest ROADM transport networks were the first ones capable of supporting 400G. As mentioned above both 50GHz and 100GHz systems were deployed with the 100GHz typically the first generation. With a 400G wavelength being ~75GHz wide it fit in the oldest technology deployed allowing another entire evolution of bandwidth increases to be deployed without an upgrade to the photonics. This is however the end of the road. 800G is already being deployed and with its ~112GHz wide wavelength it can only be deployed using flex ROADMs and a colorless add / drop structure. Given the fixed 50GHz systems are not capable of 400G and the networks that can are the oldest, the standard has been set to only deploy new networks as colorless and Flex grid to ensure any size future wavelength would be supported. Having also learned that there can never be enough available capacity a decision has been made to design all new networks to be C+ L band capable as well. Adding the L band doubles the capacity of the fiber! A final benefit to deploying all colorless networks going forward is the availability of Layer 0 (L0) control plane. This sets the stage for further resiliency by offering protection and restoration at the optical level.

4.2. Optimizing further - Capacity vs. Connectivity

Now the network is well prepared for bandwidth expansion by being able to support any width wavelength and the addition of L band has doubled the capacity. The construction of new degrees and creation of sub rings improves resiliency, latency and provides new routes for commercial customers. This architecture is the new performance baseline. Can it be optimized further though?

Of the traffic on the CRANs the largest and most predictable is residential. RUR U rings are high capacity with many being over 1 terabit (Tb). Although the physical flow of the traffic is passing through several ROADMs the logical circuit looks like point-to-point. With the large and predictable growth of these U rings does it make sense to go back to the original VOD architecture and build large, simple point to point networks? The answer might be yes, but not exactly.

4.2.1. Internet protocol over dense wave division multiplexing (IPoDWDM)

Much of the focus on technology advancements has been on creating larger wavelengths that consume less spectrum, however the transport is now outpacing the IP platforms with up to 1.2TB line rates while the routers are just starting to adopt 400GbE. To best utilize and align the IP and optical platforms the answer could be IPoDWDM. Simply put, this is making the source of the DWDM wavelength a pluggable optic and placing it directly in the router, thus eliminating the transponder. Sound familiar? This is exactly how the first generation of transport to support VOD was deployed as described previously. This may make sense again but with several important caveats.

The optic that has been developed for this application is called a ZR+. It has a 400GbE rate and like other 400G transport interfaces has a spectral width of ~75GHz. It does have roadblocks to overcome before being deployed at scale.

4.2.1.1. Form factor and transmit power

The first two issues are related. They are form factor and optical transmit power. There are two current versions of the optic. C form factor pluggable (CFP) and quad small form factor pluggable (QSFP). The form factor is directly related to optical transmit power. The CFP is larger and can house the components required to achieve ~0 decibel-milliwatts (dBm) optical transmit power commonly seen in transponders. However, IP host platforms that use CFP are no longer common at Comcast. They have been replaced by devices that use the much smaller QSFP optic. The issue is given the smaller size of the QSFP optic it can only produce ~ -10dBm transmit power with the current technology. This is as much as 14dBm lower than transponders! To allow the high-power transponder and low power optic to coexist in the same ROADM they need to have a similar input. There are two options. Either turn down the transponder and greatly reduce its performance or amplify the low power ZR+ optic. Neither of the solutions are acceptable in a brownfield environment. Fortunately, both problems are remedied by high power ZR+ optics in a QSFP form factor becoming available in late 2022. In fact, Comcast is collaborating with an optical partner to be one of the first to get this optic in the lab in advance of the general availability release.

4.2.1.2. Reach and ROADM limitations

The third issue is the reach of the optic. The ZR+ optic not only has distance limitations but every ROADM it passes through adds penalties and decreases the reach. In the end all the ROADMs that were added to increase flexibility in steering traffic and reducing latency now could be preventing the use of these optics. One solution being explored is to build ROADM bypass express paths to decrease the number of ROADMs and increase the reach.

Figure 8 - ROADM impact on 400GbE ZR+ optics

4.2.1.3. Operational support

Finally, the largest issue is the operational and engineering support of these optics. By disaggregating the DWDM source from the optical line system the topology connection between the DWDM wavelength source and add / drop structure is no longer known. It is not possible to know what the pluggable is connected to. This splitting of the optical network into two domains essentially makes the link an alien. This was the case also in the VOD era however with only a handful of links to support per market it was manageable with static documentation. Today with thousands of links this is no longer possible. Comcast engineers and software developers and the industry in general are currently working on solutions to operationalize aliens which would make the use of ZR+ optics possible.

If these challenges can be overcome ZR+ optics do not replace transponders everywhere nor do the ROADM bypass express paths displace the multiple path options of many meshed degrees. Instead, it becomes yet another layer, optimizes further and solidifies the Metro Optical Networks role of being the do it all, Swiss Army Knife at Comcast.

4.3. Leaveraging access and metro together to support commercial services

Where the metro ends the access starts. Unlike other networks that are completely independent and do not converge the metro and access are different. They can and do and have a symbiotic relationship.

Comcast combines the metro optical network, optical transport network (OTN) tails over the access fiber, small optical shelves at customer sites called network terminating equipment (NTE) and dedicated commercial shelves at hub sites called wave integration shelves (WIS) to support multiple types of commercial business.

As seen in the above network evolution diagrams the metro transport has become more meshed and better able to support an any to any traffic pattern. The access has also gone through evolutions but what has stayed the same is the fact that it stops at the hub site. What has been found is that most commercial customers can connect to the access and be brought back to a hub site where metro is present, but how can they be connected to each other if their fiber terminates at different hubs? Or in the case of ethernet dedicated internet (EDI) how do they get to the router that provides internet access? This is where the access and metro can work together by using OTN tails.

OTN is taking an Ethernet (or other protocol) payload and encapsulating it in a wrapper to be carried across an optical transport network. It is completely transparent, and a standard governed by International Telecommunication Union (ITU) G 7.09. An OTN tail is transmitting that wrapped payload over dark fiber or a channel on a MUX over fiber. Using this tail and transponders (or Muxponders) in the NTE and WIS facing each other can extend the metro core over the access without using ROADMs or even AMPs.

This tail is then transmitted over the metro by a second card in the WIS with an optical transport unit (OTU) client to client connection to the card facing the NTE. This back-to-back configuration allows a DWDM OTN signal to face the NTE and the add / drop structure of the metro. The client-to-client connections have been made in the past as ethernet where a similar design was used for regens. In this case, keeping them OTN so that the circuit remains transparent from end to end has been selected as the standard. There is no conversion to ethernet and back to OTN. One advantage of this is that a trail trace identifier (TTI) remains intact from end to end even if the circuit crosses to another network or even to another vendor. You can transmit a trace on the A end and read it on the Z end. This is particularly useful for trouble shooting and topology verification.

This Unified Optical Architecture to Support Wavelength and High Bandwidth Ethernet Services is now a common way the metro and access work together at Comcast and is fully detailed in another paper being presented at the SCTE Cable-TEC Expo 22. [1]

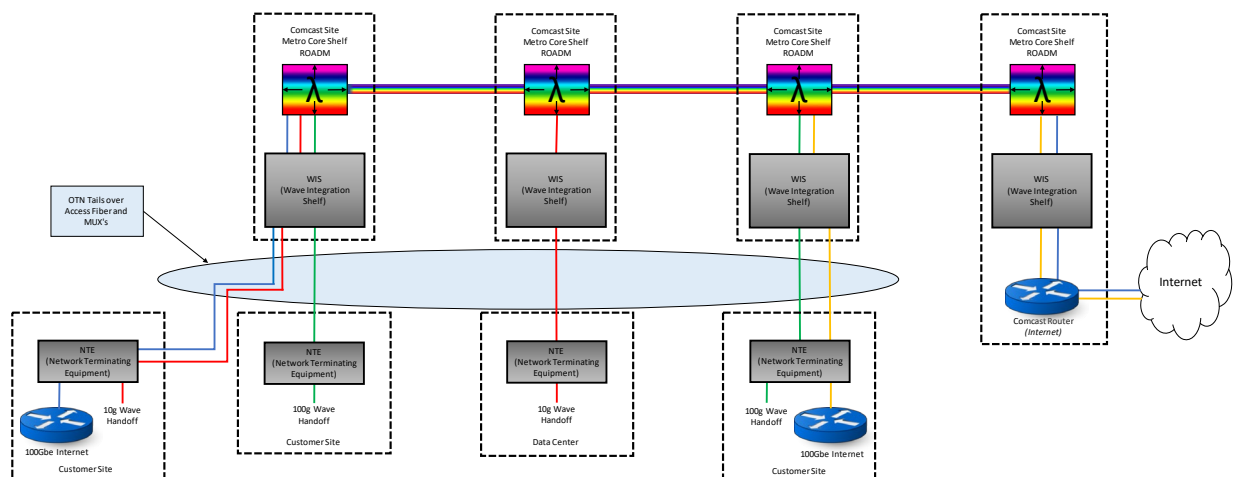

Figure 9- Metro and Access used together to support commercial customers

5. The Access Network

The Comcast Access network consists of a myriad set of architectures some organic, some acquired and many augmentations over the years. Some of these architectures are the traditional 1310nm/1550nm analog and digital/analog return nodes connected to traditional CMTS. Others are DWDM QAM Overlay solutions and yet others are the latest distributed access architecture (DAA) based nodes.

Comcast has pioneered the DAA that has virtualized the CMTS functionality and separated the PHY layer from the CMTS and distributed it out into nodes in the field. These are now called the Remote PHY Device (RPD) nodes. In Comcast virtually all of the traditional nodes and CMTSs will be replaced by the DAA in the next couple of years. For this reason, this paper will concentrate of the DAA system but will address other systems along the way as needed.

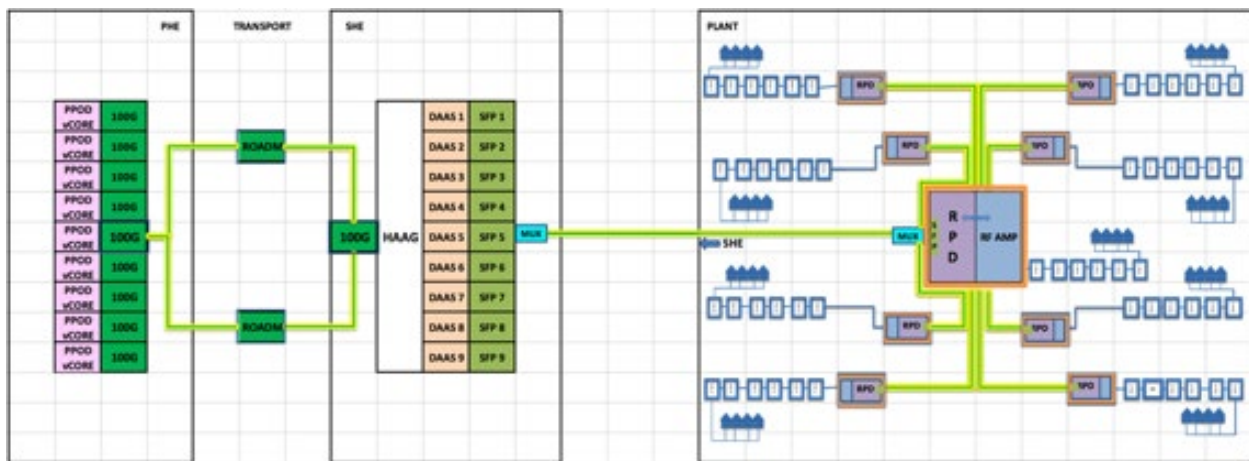

Figure 10 – Illustrating the DAA Network of Comcast

Shown above is a simplified version of the DAA system. vCMTS cores from the Primary headend are connected to DAA switches (DAAS) in the secondaries. Note here that these connections are typically done via the Comcast's own Metro networks described in the above sections. While the Primary to Secondary connections are based on 100G or higher capacity coherent optics, the connections from the DAAS on wards in the access domain are always 10Gbps DWDM based signals. The aggregating switches called HAAGs typically combine US signals and de-combine DS signals to the respective DAAS ports.

Once out of the DAAS, both the US and DS 10G wavelengths are multiplexed on a single strand of fiber and sent over into the field, where they are demultiplexed at an OSP enclosure location. For there, dual strands of fiber carry the 10Gbps signals over to the various RPDs in the immediate location. The distance from the Secondary to the field OSP mux is called the trunk fiber, while the fiber from the OSP Mux location to the various RPDs is called the distribution fiber. On the trunk fiber Comcast has a 100GHz ITU WL Plan standard that has adjacent odd and even pairs of ITU channels serve each node beginning at ITU 61/60 pair to ITU 15/14 pair. Thus, all in all, 24 pairs of wavelengths are available on each trunk fiber capable of serving 24 different remote devices.

While distribution fibers are new fibers sometimes put in explicitly for newer nodes, the trunk fibers are in extremely short supply as they were installed decades back and augmented over the many years to serve nodes that sprung up as population centers sprung up. It is for this reason that all DAA trunk fibers are bi-directional as that relieves pressure on the trunk fibers and promotes fiber efficiency across the organization.

Figure 11 – Typical Secondary to Node distances in the Access Plant

Generally, primary headends also supply node signals directly from their location to the local nodes as well. It is for this reason that the distance between a headend and the node is around 10km, but a fair number of nodes extend up to 40km. This is illustrated in a Comcast survey of optical links from a couple of year back [2]. In general, distribution links are on average 0.5km and as discussed construction crews may build this fiber for some of the newer nodes which arise due to node splits or fiber extensions from the OSP Mux. For this reason, there are multiple fibers connecting OSP Mux to fiber nodes. It must be mentioned here that most of access field infrastructure requires Industrial-Temp operation, this means that all optics actives and passives must be qualified up to 85C. Therefore, the field trunk fibers are standardized to 100GHz spacing utilizing thin-film based optical filtering and all the SFPs used in remote devices are Industrial-Temp qualified tunable SFPs.

Our fiber to the home (FTTH) offering comprises initial RFoG deployments but that is expected to move over to 10G EPON offerings for all the newer builds. The 10G EPON DS is at 1577nm while its US is at 1270nm. With the advent of SFP based OLT and ONUs, it is expected that current RPD nodes that have the capability to received 10G signals will receive 10G signals from their respective DAAS ports and convert via the SFP based OLT to the 10G EPON standard and serve the FTTH customer base. A lot of attention has been paid to enable the convergence of conventional RPD devices that can serve residences via standard HFC plant AND the FTTH customers thru the remote OLT (also called virtualized broadband network gateway or vBNG).

The vBNG line puts out 1577nm in the DS and accepts 1270nm in the US one single fiber and thus enables centralized or decentralized splitting as it serves homes via single fiber stands.

5.1. Converging the Access Network

The previous has been a simple description of Comcast network, but while the direction of digitization and distributed access is clear Comcast still has various older architectures comprising analog DS wavelengths and potentially analog or digital US wavelengths and they must all be accommodated as the DAA transition takes place. In addition, one interesting aspect of access plant is that most of the businesses that require separate optical wavelengths are also interspersed among the residential customers. The ability to have analog and digital WLs coexist on the same fiber has been described in earlier papers and is summarized here. Briefly, full spectrum analog WLs in the C-Band require a comprehensive WL plan to minimize optical non-linearities such as 4WM, XPM, SRS and overcome dispersion and imperfections of the optical passives. For this reason, they are not on a uniform spacing, but rather non-uniformly spaced. In Comcast, we have carved out Analog and 10G WLs in DS and, 10G and DRT WLs on the US on the same single strand of fiber.

Our current business base is a mix of single and dual fiber CWDM and DWDM connections that reflects the years of organic and acquired growth. Many of our current business customers that require fiber to their premises require 1G to 10G services (discussed in the Metro section of this paper) and could be in the vicinity of existing OSP Mux enclosures. For a go forward plan, since these are digital signals, these customers can be served by the same strand of trunk fiber as would connect analog and digital nodes. This is an important way to relieve stress on our fiber assets by enabling a more effective use of our fiber assets. In addition, it enables a common way to continuously and pervasively monitor optical assets which is described in a subsequent section.

But what is interesting in the figure below is that we have now been able to incorporate Coherent optics in the access plant in much the same way as direct detect has been deployed. This type of convergence requires game changing technology of bidirectional dual laser pluggable optics conceived and implemented in Comcast in recent years and is described in this section.

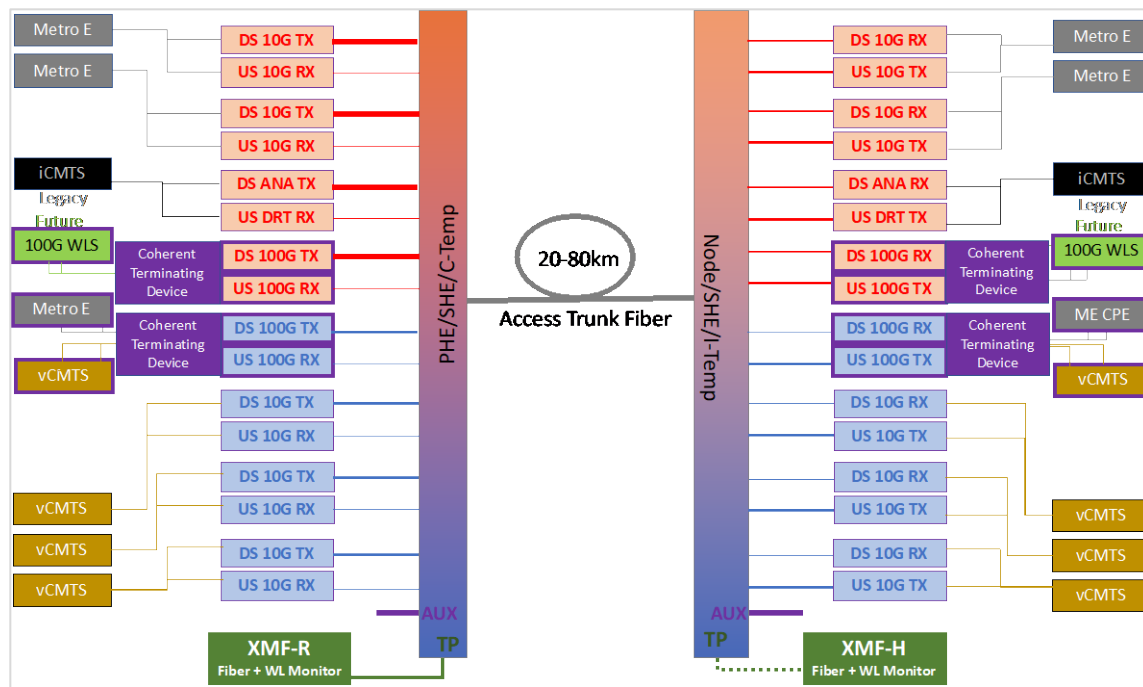

Figure 12 – Illustrating the Converged Comcast Access Network

Since ROADM cascades are not used in our DAA access networks due to modest fiber lengths, the design of high-capacity (100G – 800G) solutions could be elegant since there is no degradation due to these devices. Furthermore, these links can support bidirectional transmission quite easily since there are no non-reciprocal elements in the fiber path. Indeed, the relaxed relatively modest fiber reach required in DAA enables us to innovate on optical devices as well as reduce cost, oftentimes by innovating on the trailing edge of technology, which is discussed next.

Figure 13 – Converging Direct detect and Coherent bi-Directional Wavelengths

Presented above is a measured plot of the various direct detect and coherent optical signals overlaid with the optical passband of typical filters being deployed in Comcast [3]. It is seen here that 10Gbps direct detect as well as 100Gbps QPSK Coherent all the way to 400Gbps 16QAM Coherent optical signals fit within the optical passband of deploying optical filters. Although there is little concern for data rates up to 400Gbps, we still need to further investigate the case for 800Gbps where, even with higher QAM modulation orders and with higher OSNR requirements, it is expected that the occupied bandwidth will start to encroach into the WDM passband and impose power penalties that need to be considered, particularly over temperature. More generally, a skillful use of optical passives express/upgrade ports with a contiguous C-Band can easily be dedicated for higher capacity/bandwidth modulations or for flex grid type applications.

5.1. Dual Laser Bidirectional Coherent Transmission

Coherent optics relies on having a laser at the transmitting end send out phase and amplitude information in the form of QAM constellations to a receiver. At the receiver, the incoming signal is ‘beat’ up against a laser that has in effect the exact wavelength of the transmitting laser and it teases out the phase and amplitude information out. Since information is coded in phase and amplitude, as opposed to only amplitude in direct detect systems, the information carrying capacity of the coherent system is vastly superior to that of direct detect systems for the same amount of bandwidth available.

To reduce cost and also to ensure that the wavelengths are identical, most of the plugs available in the market use just one laser in each plug and split its light to do double duty, in effect to act as the encoding transmitters and the decoding receiver. This is illustrated in the top half of the picture below.

The industry has gotten quite good at this type of design and has successfully used it to provide 100s of Tbps over 1000s of kms in core and metro networks. Unfortunately, this approach always requires two separate fibers, one for downstream and another for upstream information. When a fiber can be fully loaded with data, say for 100s of Tbps, this approach seems reasonable. But when the fibers are unable to be fully loaded, like what happens in access networks, an approach of this kind is very inefficient with fibers and can cause severe fiber exhaustion.

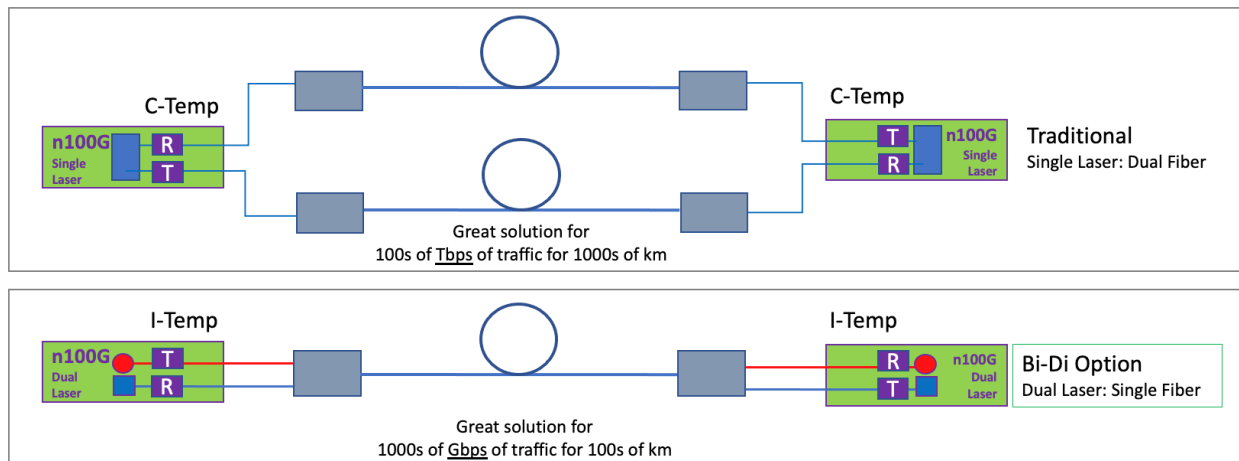

Figure 14 – Illustrating Bi-Directional Coherent systems

It is for this reason that a new approach had to be thought of for accommodating Coherent optics in the access domain and enable high-capacity wavelengths to feed our residential DAA systems and as standalone high-capacity wavelengths for our business customers.

We note here that the use of optical circulators is a valuable option and could potentially allow the same wavelength to traverse in opposite directions, but that approach can be prone to reflections in the fiber plant and also to fiber Rayleigh backscattering that could limit the link budget. A more robust solution is needed for wide bi-directional deployments that envision the use of existing fibers with other bi-directional signals already running on it.

Such a robust solution to this problem is to have a separate laser for the transmitter and one for the receiver at each end. Doing this would enable the two wavelengths to be multiplexed (or combined) together and transmit bidirectionally (Bi-Di) on the same single strand of fiber. In fact, many Coherent optical wavelengths could be multiplexed on the same fiber along with direct detect wavelengths thus leading to a converged system that was described in the previous section.

Interestingly, low earth orbit (LEO) satellite communications systems have also come up with the same requirement of dual laser bi-directional transmission. In free space, coherent optical modules communicate with adjacent satellite and hop signals from satellite to satellite to minimize the need for ground stations. But the vast speeds of the LEO satellites and their relative speeds to other satellites create the familiar doppler shift in frequency sufficient to thwart the use of a single laser design. So, in this effort of defining a dual laser plug, we have had the unusual conjoining of space requirements as well.

With this in mind, Comcast have specified dual laser bidirectional fully C-Band tunable industrial temperature CFP2 plugs for use in access networks much in line with the CableLabs point to point Coherent specification [4]. Current systems support 100Gbps rates with QPSK modulation at 32GBaud with a 25dB link budget, enough to support point-to-point links up to 100kms. As mentioned previously there are no ROADMs in the access plant and there are no

non-reciprocal elements in the system, this allows for relaxation of certain specifications and needs for chromatic dispersion compensation that enable these new innovative devices to be cost effective as well.

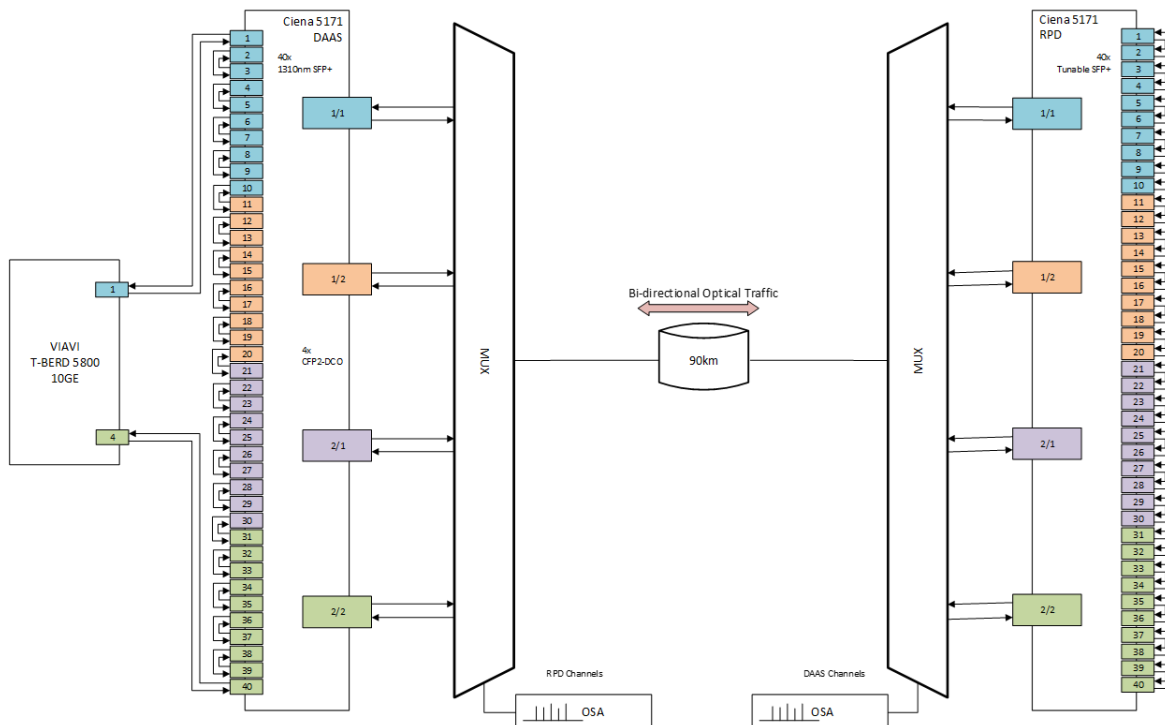

Figure 15 – Hybrid Loop testing the Coherent Optics in the Access Plant

While 100G coherent systems can exist on their own and support individual wavelength services for our commercial customers in the converged access architecture described in the previous section, a particularly important application of the dual laser bi-di system is to support DAA systems. Often these DAA systems have to operate out of smaller OTN or secondary cabinets that make direct metro transport system connections difficult due to limited critical infrastructure. And adding fiber to the trunk line is an expensive and time-consuming effort. In such cases, we have developed a system that takes in 10 of the 10Gbps streams and electronically converts to 100Gbps stream that modulates the CFP2 which is then multiplexed to a single fiber and sent over to the secondary. At the secondary the 100Gbps stream is split back to its constituent 10Gbps streams and serves DAA nodes from there.

To test this system for its robustness, we set up a hybrid loop test where 10Gbps signal was injected into one of the 10Gbps port that then entered the 100Gbps CFP2 which then traversed 90km of SMF fiber and was converted to its constituent 10Gbps stream and looped back via the CFP2 and traversed the 90km. In this way the traffic traversed $90\text{km} \times 2 \times 40 = 7200\text{km}$ before closing the loop. In our tests this was done with zero errors and with latency that was predominantly dictated by the optical fiber time of flight.

The system designed and shown above can support up to 40 10Gbps streams each way that modulate 4 of the 100Gbps streams in each of the two locations. In effect, 6 such systems can be optically multiplexed together and serve up to 240 10Gbps Nodes all on a single strand of fiber. As we have said before these our efforts at innovations will be to extend to higher capacity systems cost effectively over the coming years.

5.2. Convergence Continuous Pervasive Monitoring

Our current business base is a mix of single and dual fiber CWDM and DWDM connections that reflects the years of organic and acquired growth. Many of our current business customers that require fiber to their premises require 1G to 10G services (discussed in the Metro section of this paper) and could be in the vicinity of existing OSP Mux enclosures. For a go forward plan, since these are digital signals, these customers can be served by the same strand of trunk fiber as would connect analog and digital nodes. This is an important way to relieve stress on our fiber assets by enabling a more effective use of our fiber assets. In addition, it enables a common way to continuously and pervasively monitor optical assets which is described in a subsequent paragraph.

In the figure below we have shown a converged system that is a combination of residential and commercial services, incorporating coherent and direct detect systems, all capable of running on a single fiber. Since all services can be multiplexed on a single fiber, the current series of optical passives in Comcast have consolidated test ports that provide access to view forward and return wavelengths of live links. Furthermore, the test ports also allow unrestricted 1611nm access for use of OTDRs to shoot over live links and provide fiber impairment and cut information.

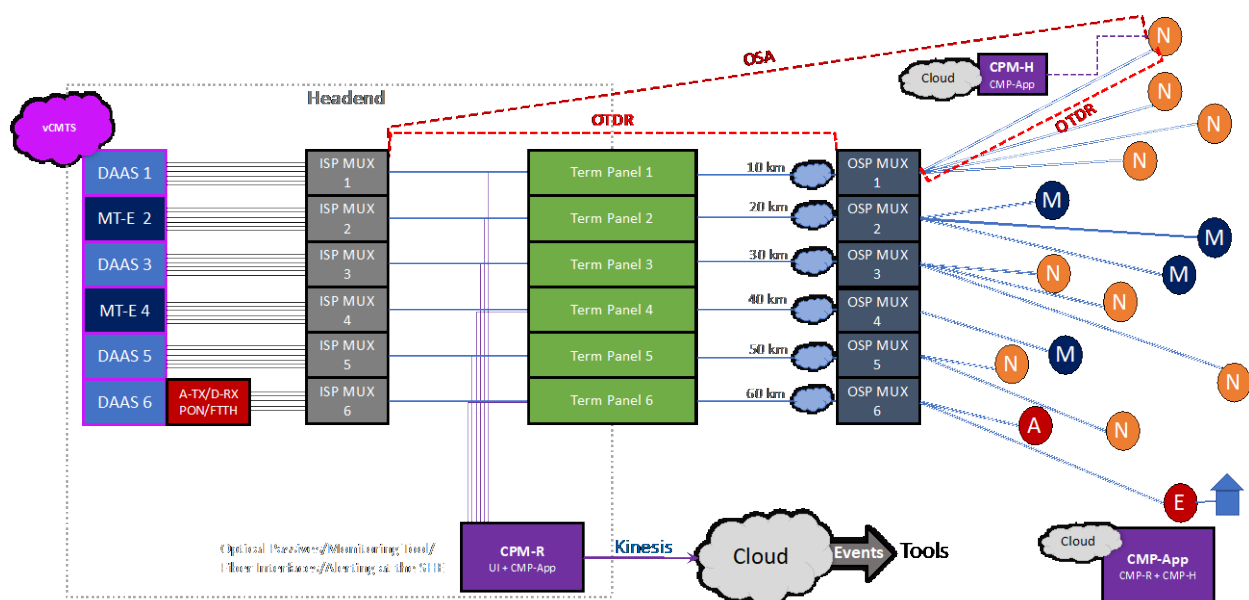

Figure 16 – Illustrating Continuous Pervasive Monitoring

Detailed description of the continuous and pervasive monitoring paradigm in Comcast was described in earlier SCTE papers. By way of summary, all optical passives are connected to a continuous monitor comprising an OSA and OTDR and an optical switch. This arrangement

continuously monitors all connected fibers in a round robin fashion and generates fault information comprising either fiber impairments or individual wavelength impairments on average within 90 seconds. The entire information set is sent into the cloud and alarms and events are sent to fix agents.

To promote a common language between headend and field technicians, a version of the monitor is available as a handheld device that has the same cloud connectivity as the headend version. Connecting the headend unit or the hand-held unit or both to the cloud now enables the entire region, division or company tie in and view all events in real time and strive to achieve closure on important customers impacting issues. This is a real game changer with the net effect of providing continuous monitoring on residential, commercial, direct detect and coherent optical signals across the access network.

6. Conclusion

In this paper, we described for the first time an end-to-end view of our optical network including the core, metro, and access layers. A brief history of the organic and acquired properties and technologies at play in Comcast was described. At the core and metro, we have increased capacity with a move towards flexible 400G connections and continue to reduce latency and enhance reliability with an infrastructure that meshes color-less, direction-less, and contention-less reconfigurable multiplexers thru to each of our headends. At the access layer that connects these headends to customers and businesses, we discussed capacity increases with our move to all-digital fiber links and the distributed access architecture paradigm. The vision shared here is part of a larger commitment that leverages Comcast's technical and business expertise to deliver cutting edge and reliable services to our residential and commercial customers combining a robust and scalable core and metro network with a converging range of access networks ranging from wavelength services to traditional HFC to FTTH solutions.

1. Introduction

1.1. Problem Statement

Planned maintenance is a daily activity for any number of complex systems, including cable plants. It is important to think of a cable plant as a living, breathing organism that requires care and feeding, involving replacing parts that are continuously exposed to the elements. Repairs often include identifying problems, making repairs, and replacing parts while temporarily interrupting a customer's service. A service interruption event (SIE) averages between five to ten minutes. In an ideal world, all SIEs would be performed during the evening maintenance window, but in practice, most short-duration SIEs must be performed outside of this maintenance window. Currently, SIEs are scheduled without the benefit of knowing which hours would have the least or the highest amount of subscriber impact. This information would be invaluable in optimizing the ideal time to perform an SIE.

We set out to find if a data-driven system could be developed to determine the best time to conduct SIEs. Performing SIEs during times when they will have the least impact on subscribers would not only provide a better subscriber experience but also could potentially cut the expenses incurred by responding to customer interactions (CI), such as calls to our care agents, unnecessary truck rolls, chat sessions, and other triaging events.

1.2. Proposed Solution

Our research involved identifying data that would have sufficient signal to indicate the least and the most impactful times to perform an SIE for the set of subscribers that each SIE would impact; we chose to calculate recommendations on each subscriber's hourly high speed data usage, which we will refer to, here, as customer usage information (CUI).

The main objective of our research was to develop a Planned Maintenance Tool (PMT) to assist with field operations. The algorithm that drives the PMT evaluates the hourly customer usage information (CUI) for each set of customer accounts that an SIE will impact. Then the PMT returns the hours when the SIE will be the least impactful toward those customers. We assessed the validity of our algorithm with historical SIEs and corresponding CI data from a geographic area that we will refer to as the 'test region.'

We have found that CIs typically increase when there is an unexpected SIE. We theorized that if we could create an algorithm to identify the best time(s) to perform an SIE, we would see a less severe CI increase around the hour the SIE is performed. Our assessment, though limited in breadth, appeared to follow this expected trend, and the findings pinpointed subsets of CIs we could monitor and assess periodically for financial and customer impact.

In the following sections, we discuss the constraints that motivated the initial version of the PMT user application and the refinements we think would be necessary further to improve the user experience and reliability of the PMT.

2. PMT Core Components

At its core, the PMT tool comprises two components that provide the data-science backbone of the system. They are the data processing and the recommendation algorithm, which are described in detail in this section.

2.1. Data Sources

It was posited that the best time to perform SIEs with the least impact on customers would be the hours when the least amount of data was consumed. We aggregated data from the following sources to collect a good source of data consumption for a group of homes.

2.1.1. Customer Usage Information (CUI)¹

Customer usage information is aggregated, in bytes, for upstream and downstream traffic for each DOCSIS (Data Over Cable Service Interface Specification) -capable device at hourly intervals.

2.1.2. Device to Network Mapping (DNM)

We needed to map individual MAC addresses to the network elements, including nodes, regions, and CMTS (Cable Modem Termination System). DOCSIS-capable network infrastructure allows the implementation of a system that polls all devices six times a day to check for any impairments, noise, and other factors. This data also records all devices connected and active in the network, along with their mapping to customer account numbers, location, and elements in the network.

2.1.3. Plant Topology Information (PTI)

The plant topology information includes data from various source systems to provide a hierarchical view of multiple elements in the network, such as head-end devices, CMTSs, RF cables, power supplies, taps, nodes, drop cables, and customer devices in the network. Although not used in the initial assessment, plant topology will be used by the developed application.

2.1.4. Service Interruption Events (SIE)

Service interruption events are initiated when an interruption in the plant is needed to correct RF system impairments, if the plant needs to be disconnected to replace a network component, or if periodic maintenance needs to be performed. Data about service interruption events is recorded and includes the time they occurred, the length of time that service was interrupted and a list of accounts that were affected.

2.1.5. Customer Interactions (CI)

Customer interaction events are identified as indicators of the impact SIEs could have on customers. Customer interaction events consist of logs of activity in a customer's timeline. They include billing, communications, customer chats, customer request tickets, inbound calls, tech appointments, speed tests performed, and equipment orders. The events selected for this analysis were limited to inbound customer

¹ We collect, store, and use all data in accordance with our privacy disclosures to users and applicable laws.

2.2. Data Processing

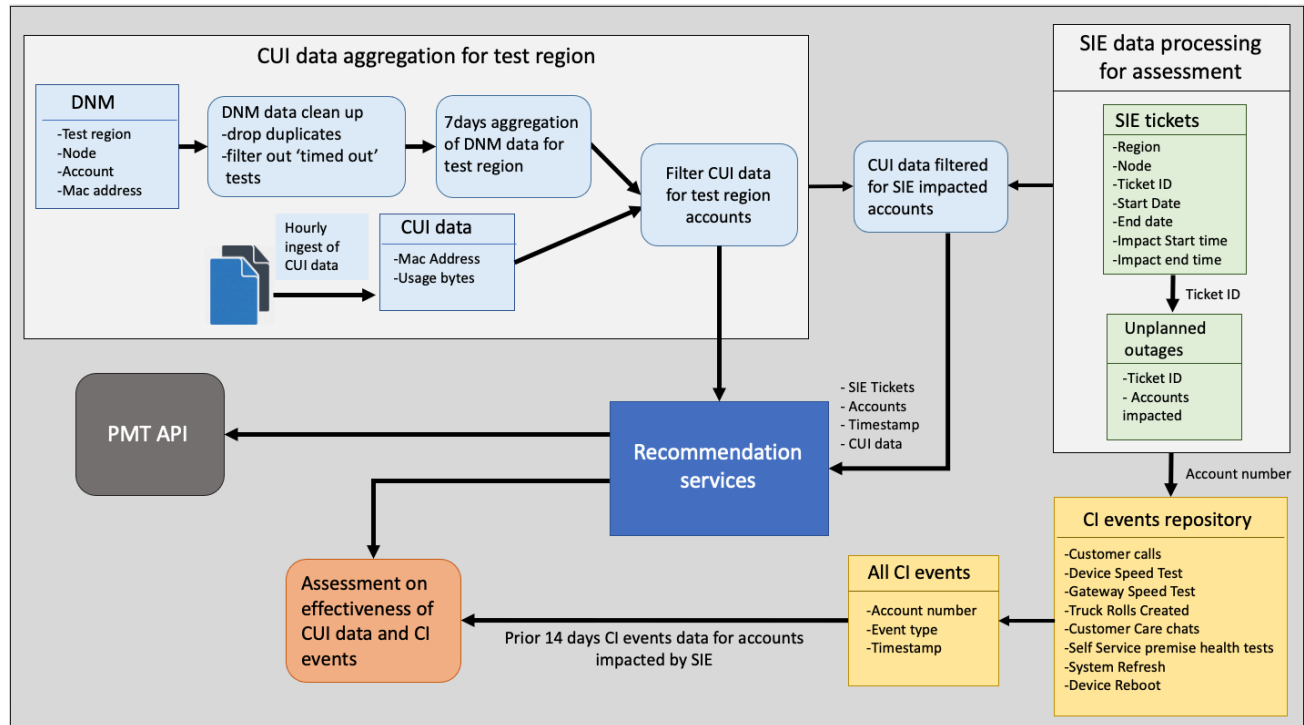

Figure 1 - Data Processing Workflow for the PMT Recommendations Process

2.2.1. CUI data filtering for test region

Daily polls of the DNM from the test region are collected and cleaned to filter out ‘timed out’ and inactive devices. A 7-day aggregate of DNM data is performed to accommodate account additions or deactivations changes. This seven-day aggregated DNM is then used to filter the stream of hourly CUI. We derive an hourly aggregate of CUI at account levels for the total 24 hours daily, which serves as the input into the PMT algorithms for any accounts (households) likely to be impacted by a network SIE.

2.2.2. Selected Accounts for Recommendations

Based on CMTS and node segment ID from PTI data, the geolocation latitude/longitude for customer service addresses are derived. The latitude/longitude information is passed to a Grouping Service (see section 4.3.1) to find all field topology information such as cables, taps, buildings, and addresses inside the node boundary. Accounts are then formed into multiple groups based upon the topology information by performing a fuzzy comparison of street addresses. Additionally, it was found useful to resolve some addresses by comparing their latitudes/longitudes using proximity. The account groupings² are further used in generating recommendations (See section 2.3.1).

² In Section 3 where we detail the assessment of the CUI and PMT algorithm, these “account groupings” are simply the set of SIE-impacted accounts, derived directly from SIE logs.

2.2.3. SIE Data Processing for Assessment

We collected SIE data for the test region for this assessment. The accounts impacted by each SIE are derived from an ‘unplanned outages’ dataset. For each account affected by an SIE, we collected customer interaction events from 14 days before the onset of a SIE, which we used to derive 3 different CI baselines. The SIE ticket information and CI events were then used to create the assessment detailed in Section 3.

CI event types include:

- Customer calls
- Virtual assistant chats
- Device speed tests
- Gateway speed tests
- Truck rolls created
- Customer care chats
- Self-service premise health tests performed through a web application
- System refreshes
- Device reboots

We summarize the various data processing pipelines in Figure 1.

2.3. Recommendation Algorithm

The PMT Tool uses existing network usage data to create a historical picture of how customers interact with our services within their homes. This section details the two main components of our recommendations: Data Analysis and the Ranking-Based Algorithm.

2.3.1. Data Analysis

CUI data is ingested and filtered down to Account ID, Timestamp, and Total usage on a given Hour (upstream bits + downstream bits = total). Then, Data Aggregations are performed on the filtered dataset. The important fields to note are those that are shown in Figure 2.

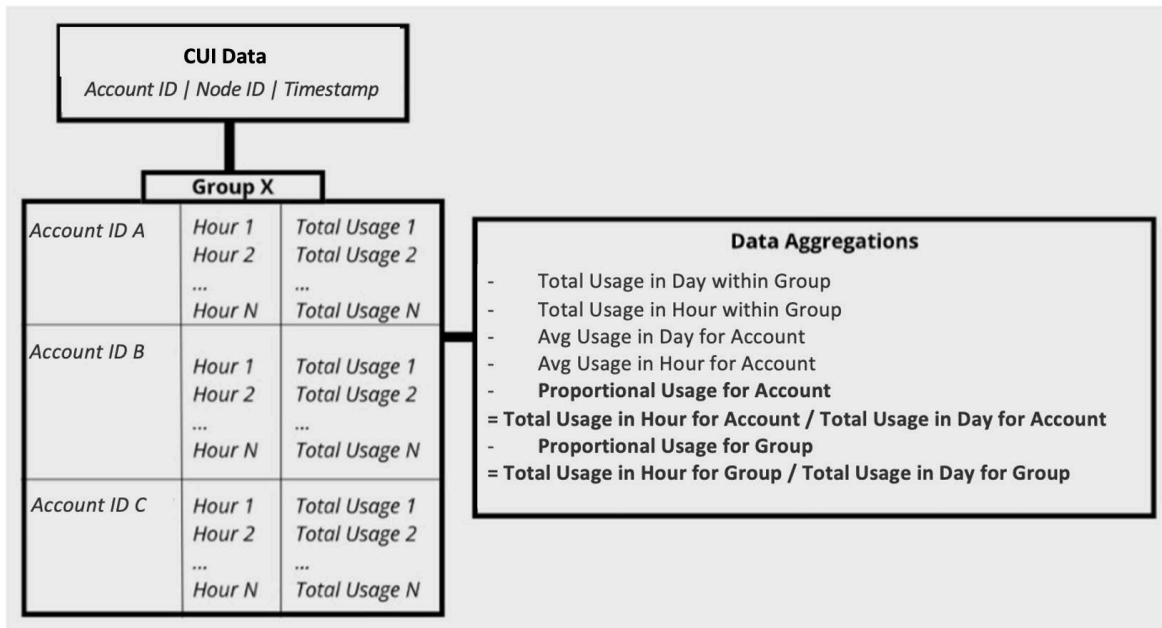

Figure 2 - How CUI data are aggregated to derive proportional usage for account and selected accounts

Proportional Usage for Account: We take the total usage seen in an hour for each Account ID and divide it by the sum of the total usage for the Account ID over the entire day (or however many hours are being considered in the comparison).

Proportional Usage for Group: We collect the total usage seen in an hour for the selected accounts (abbreviated as ‘Acct’ in the following Examples); this selected set of accounts is also referred to as a “Group”. We then divide it by the sum of the total usage for the Group over the entire day (or the specific hours considered in the comparison).

Consider Example 1 for an applied example of calculating the Proportional Usage per Account:

Acct A (Proportional Usage)	Acct B (Proportional Usage)
<i>Total Usage for Day = 99</i>	<i>Total Usage for Day = 102</i>
Hour 1 = 10 / 99 = 0.101	Hour 1 = 9 / 102 = 0.088
Hour 2 = 40 / 99 = 0.404	Hour 2 = 6 / 102 = 0.059
Hour 3 = 3 / 99 = 0.03	Hour 3 = 5 / 102 = 0.049
Hour 4 = 15 / 99 = 0.151	Hour 4 = 12 / 102 = 0.118
Hour 5 = 20 / 99 = 0.202	Hour 5 = 10 / 102 = 0.098
Hour 6 = 5 / 99 = 0.051	Hour 6 = 20 / 102 = 0.196
Hour 7 = 6 / 99 = 0.061	Hour 7 = 40 / 102 = 0.392

Example 1 - Calculating Proportional Usage per Account

With Proportional Usage (PU) per Account derived, we can move on to describe how we ranked an account's PU relative to others within the selected set of accounts ("Group" and "Acct" are used interchangeably).

2.3.2. Ranking-Based Algorithm

Scoring $N = \# \text{ Hours in Group} // 2$	
Best Hours Hours ~ N LOWEST Total Usage / Acct % of Acct for each Hour Returned	Worst Hours Hours ~ N HIGHEST Total Usage / Acct % of Acct for each Hour Returned

Figure 3 - Scoring of best and worst hours

Figure 3 outlines the theory behind making recommendations based on CUI usage data. All recommendations are made according to the number of hours to be considered before creating the recommendation. The defined hour arrangements are as follows:

Morning Hours: 6 am-5 pm (inclusive)

Extended Working Hours: 6 pm-11 pm (inclusive)

All Day: 6am-11pm (inclusive)

The number of hours being compared in each arrangement is divided by 2 (dropping any remainder) to get N .

Morning Hours: $N = 5$

Extended Working Hours: $N = 2$

All Day: $N = 8$

N is used to determine the best and the worst hours to perform maintenance for each Account ID. For example, looking at a 7-hour window of time, N would be equal to $7 // 2 = 3$. We apply this in *Example 2*.

Acct A (Total Usage)	Acct B (Total Usage)
Hour 1 = 10	Hour 1 = 9
Hour 2 = 40	Hour 2 = 6
Hour 3 = 3	Hour 3 = 5
Hour 4 = 15	Hour 4 = 12
Hour 5 = 20	Hour 5 = 10
Hour 6 = 5	Hour 6 = 20
Hour 7 = 6	Hour 7 = 40
N Best Hours Acct A = Hours 3, 6, 7	N Best Hours Acct B = Hours 3, 2, 1
N Worst Hours Acct A = Hours 2, 5, 4	N Worst Hours Acct B = Hours 7, 6, 4

Example 2 - Determining Best and Worst Hours according to CUI

Next, the results are accumulated to get the percentage of each Account ID returned for each hour within a group. *Example 3* is expanded to demonstrate this:

Group AB (Acct A and Acct B)	
Best Hours Group AB:	Worst Hours Group AB:
Hour 1 = 0.5	Hour 1 = 0.0
Hour 2 = 0.5	Hour 2 = 0.5
Hour 3 = 1.0	Hour 3 = 0.0
Hour 4 = 0.0	Hour 4 = 1.0
Hour 5 = 0.0	Hour 5 = 0.5
Hour 6 = 0.5	Hour 6 = 0.5
Hour 7 = 0.5	Hour 7 = 0.5

Example 3 - Proportional Network Usage According to Group

We now take our example's Proportional Users (PU), where $PU = \% \text{ Accts at Best Hour} - \% \text{ accounts at the worst hour}$. *Example 4* breaks this down:

Best Hours Group AB:		Worst Hours Group AB:	(PU):
Hour 1 = 0.5	-	Hour 1 = 0.0	= 0.5
Hour 2 = 0.5	-	Hour 2 = 0.5	= 0.0
Hour 3 = 1.0	-	Hour 3 = 0.0	= 1.0
Hour 4 = 0.0	-	Hour 4 = 1.0	= -1.0
Hour 5 = 0.0	-	Hour 5 = 0.5	= -0.5
Hour 6 = 0.5	-	Hour 6 = 0.5	= 0.0
Hour 7 = 0.5	-	Hour 7 = 0.5	= 0.0

Example 4 - Calculating Proportional Users

We define the Weight of our Prediction based upon the summation of the Proportional Usage for the accounts over each of the Hours in Best Hours and Worst Hours, as briefly explained in *Example 1*. We then combine that with the results from *Example 2* to get the Proportional Usage of Accts across the Best Hours and the Proportional Usage of Accts across the Worst Hours. This is written out in *Example 5*. The Best Hour results corresponding to each Account are marked with a “*”, while the Worst Hours are denoted with a “-” minus sign.

* Best Hours for Mac - Worst Hours for Mac			
Mac A	Mac B	B-Level	W-Level
*Hour 1 = 0.101	*Hour 1 = 0.088	$(0.088 + 0.101) = 0.189$	$(0) = 0$
-Hour 2 = 0.404	*Hour 2 = 0.059	$(0.059) = 0.059$	$(0.404) = 0.404$
*Hour 3 = 0.03	*Hour 3 = 0.049	$(0.03 + 0.049) = 0.079$	$(0) = 0$
-Hour 4 = 0.151	-Hour 4 = 0.118	$(0) = 0$	$(0.151 + 0.118) = 0.269$
-Hour 5 = 0.202	-Hour 5 = 0.098	$(0) = 0$	$(0.202 + 0.098) = 0.3$
*Hour 6 = 0.051	-Hour 6 = 0.196	$(0.051) = 0.051$	$(0.196) = 0.196$
*Hour 7 = 0.061	-Hour 7 = 0.392	$(0.061) = 0.061$	$(0.392) = 0.392$

Example 5 - Calculating Account Level Prediction Weights

Finally, we get the Weight of Our Prediction (WP) by taking W-Level – B-Level, shown in Example 6.

Hour	W-Level		B-Level	(WP)
1	0	-	0.189	= -0.189
2	0.404	-	0.059	= 0.345
3	0	-	0.079	= 0.079
4	0.269	-	0	= 0.269
5	0.3	-	0	= 0.3
6	0.196	-	0.051	= 0.145
7	0.392	-	0.061	= 0.331

Example 6 - Calculating Prediction Weights

Our final step is to take our PU from *Example 4* and subtract the WP to get our overall recommendation. This final step is calculated in *Example 7*.

<i>Recommendation = (PU) – (WP)</i>			
Hour	(PU)	(WP)	Recommendation
1	0.5	-0.189	= 0.689
2	0.0	0.345	= -0.345
3	1.0	0.079	= 0.921
4	-1.0	0.269	= -1.269
5	-0.5	0.3	= -0.8
6	0.0	0.145	= -0.145
7	0.0	0.331	= -0.331

Example 7 - Final Recommendation Values

The recommendation value is then divided into three separate categories: Do-Not-Recommend (DNR), Caution (CAU), and Recommend (REC). To be categorized as DNR, the recommendation value will be ≤ -0.1 . Conversely, a REC result will be ≥ 0.1 . This leaves “CAU” to be between -0.1 and 0.1.

Figure 4 summarizes the above Examples as our PMT algorithm:

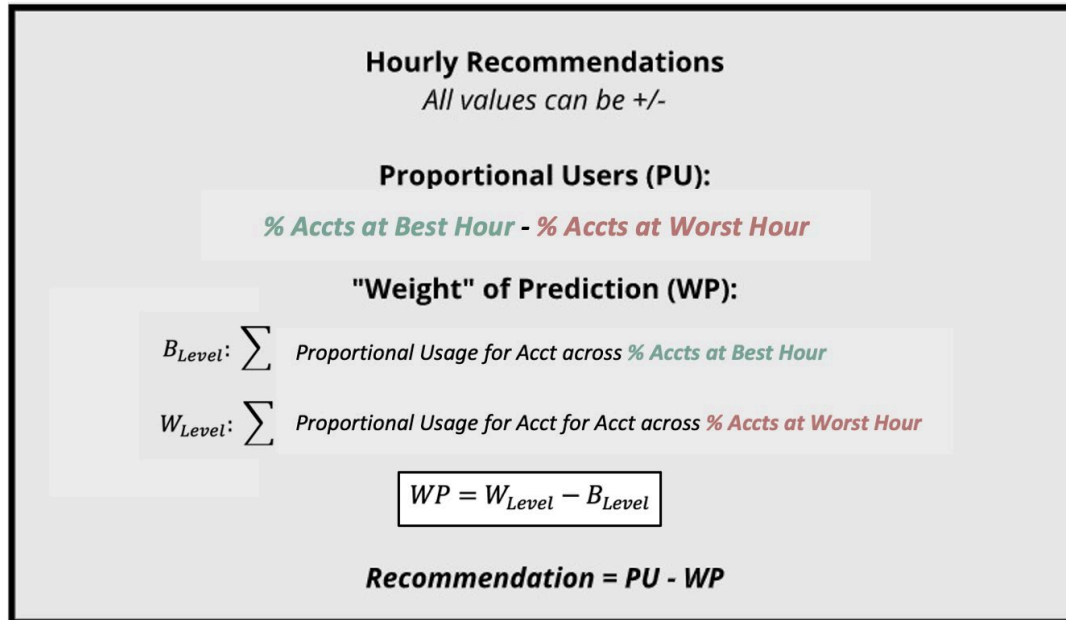

Figure 4 - PMT Algorithm Formula

3. Assessment

The PMT algorithm leverages CUI to find the optimal times when customers served by the same branch of a network have the lowest usage pattern levels relative to other hours of the day. This algorithm assumes that customers will likely experience less service impact during periods of proportionally lower data usage relative to their respective total use across the day. Identifying a collective lower usage pattern helps drive the recommendation towards the most optimal hours for a group of customers whose network branch requires planned maintenance.

3.1. Aim

Since the PMT algorithm is dependent on the CUI, we must determine if the identified CUI has sufficient signal to allow the PMT to make meaningful recommendations.

Specifically, we want to ensure that PMT suggestions of REC, CAU, or DNR for performing an SIE show variation in customer impact (approximated by the volume of CIs). We anticipate that if CUI has sufficient signal, SIEs occurring during PMT's "recommended" hours will show less relative CI increase than SIEs performed during PMT "do-not-recommend" hours. Otherwise, we would expect that the difference in these relative SIE increases across different PMT recommendations is negligible.

3.2. Method

We took advantage of the availability of historical CUI, CI, and SIE data to perform the assessment. This approach mimics an "idealized" scenario because we already know i) the SIE occurred, ii) the exact set of households impacted by the specific SIE, and iii) have access to the household's corresponding CUI for the same day as the SIE, which is used to derive the PMT recommendation for the hour each SIE occurred. Given that we were planning to trial an application based on the PMT algorithm in one of the

regions of our service footprint (aka the ‘test region’), we focused our assessment on the same region of interest from February 01 to March 11, and April 14, 2022. This time period avoids date ranges that could potentially be affected by daylight savings in 2022 (13th March (USA) and 27th March (UK)) as well as 2021 winter holiday seasonal effects³.

A total of 3341 SIEs in the test region occurred during our collected data sample's assessment period of interest. We derived PMT recommendations for each SIE and its set of corresponding households' CUIs for each hour from 6 am to 11 pm ET on the day each SIE took place. The hourly recommendations for the same day as the SIE allowed us to determine if the start of each SIE occurred at an hour the PMT yielded i) REC, ii) CAU, or iii) DNR result.

Categorizing the time of SIEs onset by PMT recommendations allowed us to compare the average volume of CI associated with each set of affected households during the start hour of SIE relative to their corresponding mean CI baseline across these PMT categories of SIEs. We refer to this metric of relative change in the mean volume of customer interactions as our ‘delta ratio’ ($dRatio_{CI}$):

$$the\ dRatio_{CI} = \frac{CI_{SIE_{startHr}}}{CI_{baseline}}$$

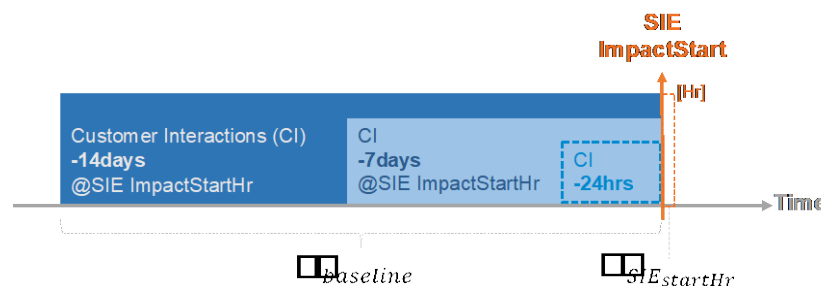

Figure 5 - Three different CI baselines were considered in our assessments.

For each SIE, the start of SIE impact (denoted as SIE ImpactStart) is used as a reference to derive the average CIs from the prior 24 hours, the average CIs from the same first hour since the start of SIE impact (denoted as a dotted orange bar) in the prior 7 or 14 days.

We derived the *delta ratio* metrics using three different CI baselines (see Fig 5): 24hrs prior, seven days prior, and 14 days before the same SIEs. It is helpful to get a sense of the fluctuations in CI in the 24hrs before the SIE, as it can show the potential time-of-day effects of customer interactions (e.g., customers may tend to interact at certain hours of the day). This comparison also prompted us to consider the volume of CI in the last 7 or 14 days during the same period as the hour following the start of the service impact event (@SIE). At the same time, this does not fully account for potential day-of-the-week effects (for which we needed a sample of historical CI data going back for more weeks than we were able to

³ There is a +5hrs (before 13th March) +4hrs (13-26th March) +5hrs (27th March onwards) UTC – EST/EDT difference. While there is potentially no differences in terms of Service Interruption Event (SIE) impactHr timestamps, the associated Customer Interactions (CI) events would include some days with +4/+5 ET depending on number of days or hours (7 or 14days | 24hrs baselines) one looks back relative to the CI data time zone. As such, the date-range we work with is primarily to avoid dealing with daylight savings conversions.

sample at the time of writing). We at least established a prior seven or 14-day baseline for the same period as the hour following each SIE.

3.3. Findings

3.3.1. Comparison of REC and DNR delta_ratios

We are particularly interested in the difference between DNR and REC delta_ratios. Specifically, if a DNR delta_ratio is more extensive compared to REC delta_ratio, we can infer that the SIE at a PMT REC hour is a less customer “impacting” time.

Figure 6 illustrates how delta_ratio(s) are derived for the three PMT categories of SIEs for the assessment using 24hrs before baseline with all customer interaction types considered. The analytical approach is similarly applied for the evaluations performed using the same SIE for each day in the previous 7 or 14 days as baselines (Figs 9—11).

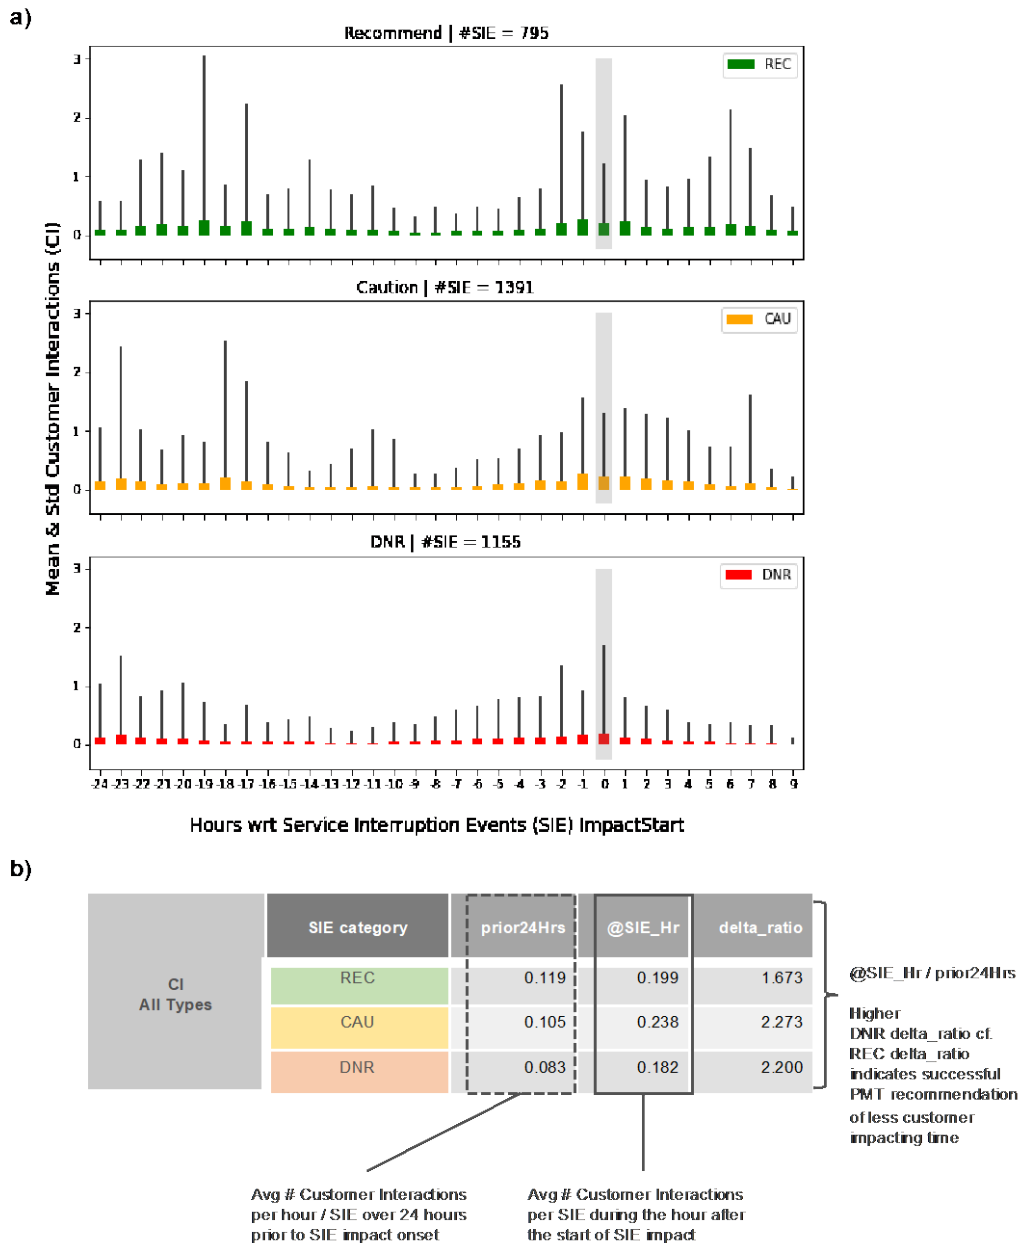

Figure 6 - CIs relative to SIE_ImpactStartHr and derived delta_ratios for the PMT categories of SIEs with prior 24hrs as a baseline

a) Hourly mean and standard deviation of CI across all SIEs concerning impact start hour (i.e., 1—24 hours prior and 1—9 hours after). All types of CIs are considered. The prior 24 hrs as a baseline is denoted with SIE categorical shading, relative to SIE start hour, as indicated by the grey vertical bar; b) Summary of average CI i) across all hourly means of prior 24 hours (prior24Hrs), ii) for an hour after SIE impact start (@SIE_Hr), as well as the respective delta_ratio for each SIE category.

Figures 7 and 8 provide the summary of customer interactions 24 hours before the SIE impact start hour for assessments with sub-types of customer interactions.

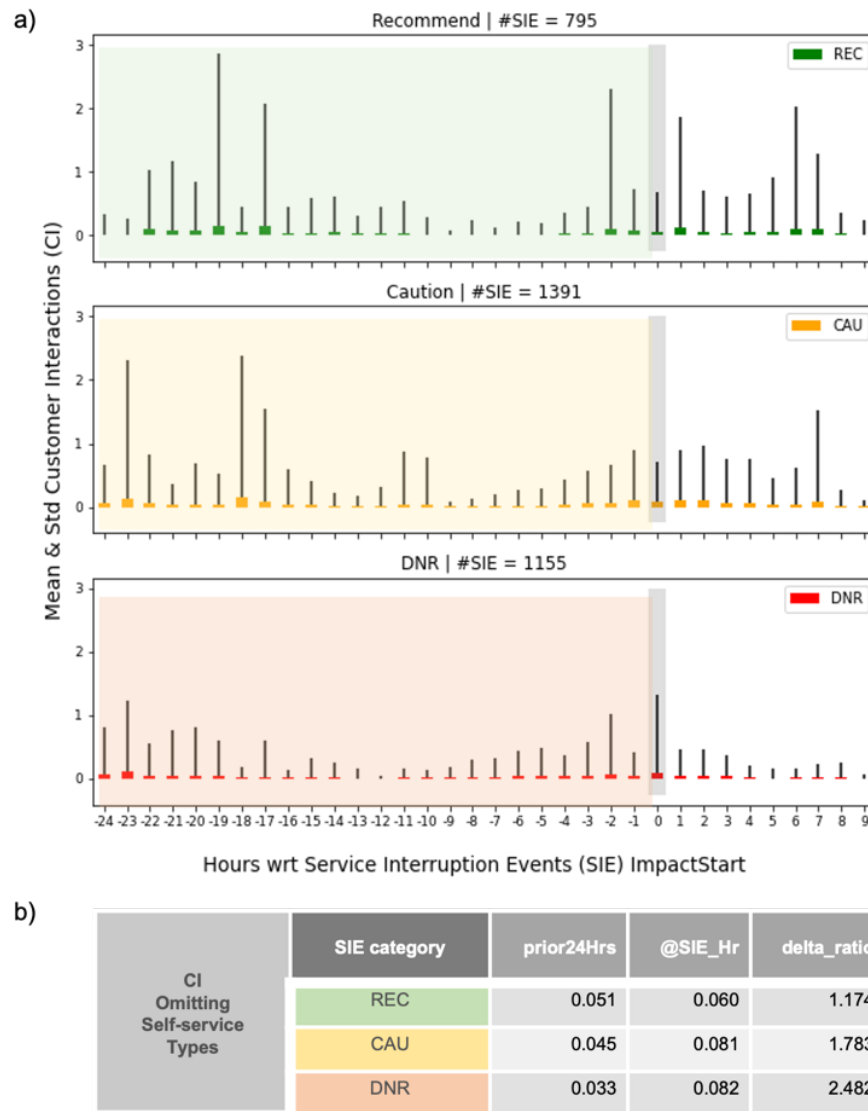

Figure 7 - Non-self-service CIs relative to SIE_ImpactStartHr and derived delta_ratios for the PMT categories of SIEs with prior 24hrs as a baseline.

a) Hourly mean and standard deviation of CIs across all SIEs concerning SIE impact start hour (i.e., 1—24 hours prior and 1—9 hours after). CIs without self-service event types are considered. The prior 24hrs as a baseline is denoted with SIE categorical shading, relative to SIE start hour, as indicated by the grey vertical bar; b) Summary of average CI i) across all hourly means of prior 24 hours (prior24Hrs), ii) for an hour after SIE impact start (@SIE_Hr), as well as the respective delta_ratio for each SIE category.

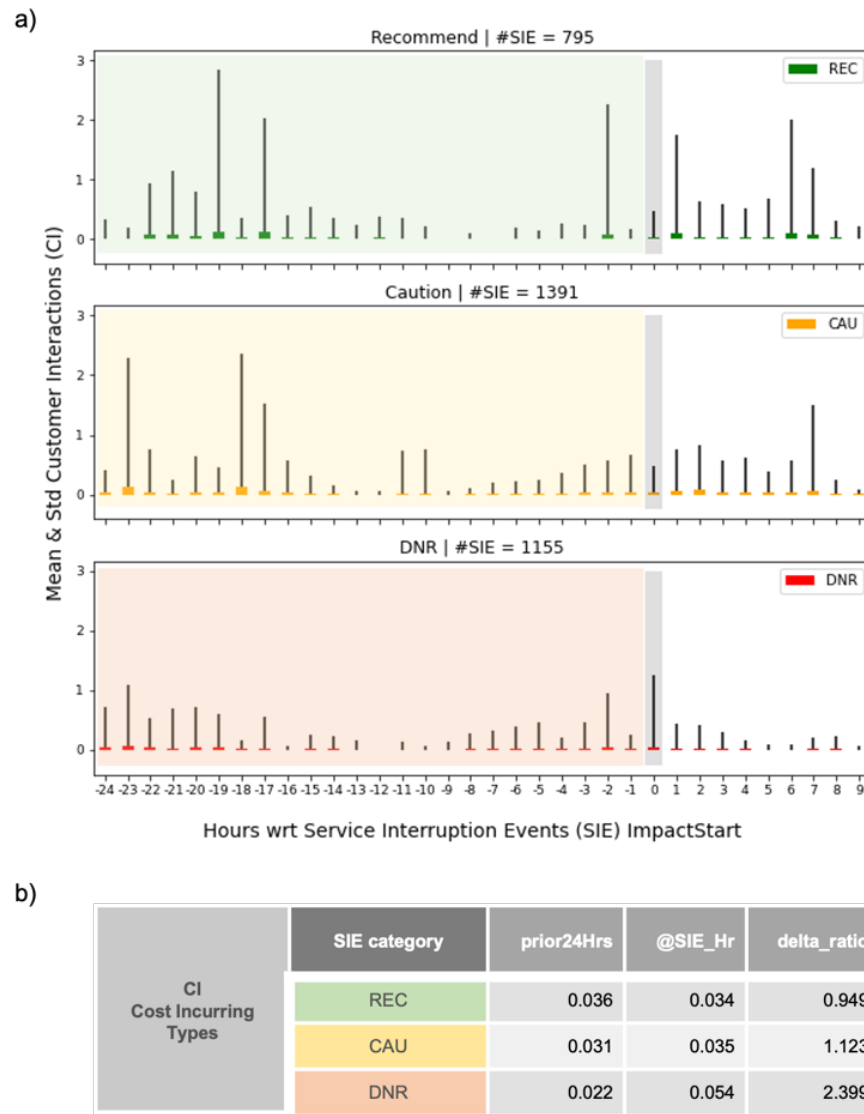

Figure 8 - Cost-incurring CIs relative to SIE_ImpactStartHr and derived delta_ratios for the PMT categories of SIEs with prior 24hrs as a baseline

a) Hourly mean and standard deviation of CI across all SIEs concerning SIE impact start hour (i.e., 1—24 hours prior and 1—9 hours after). Cost-incurring CI types (e.g., technician visit scheduling; repair call/chats) considered. The prior 24hrs as a baseline is denoted with SIE categorical shading, relative to SIE start hour, as indicated by the grey vertical bar; b) Summary of average CI i) across all hourly means of prior 24 hours (prior24Hrs), ii) for an hour after SIE impact start (@SIE_Hr), as well as the respective delta_ratio for each SIE category.

Similarly, the baselines of assessments performed using the same SIE in the prior seven days and 14 days are summarized in Figures 9—11.

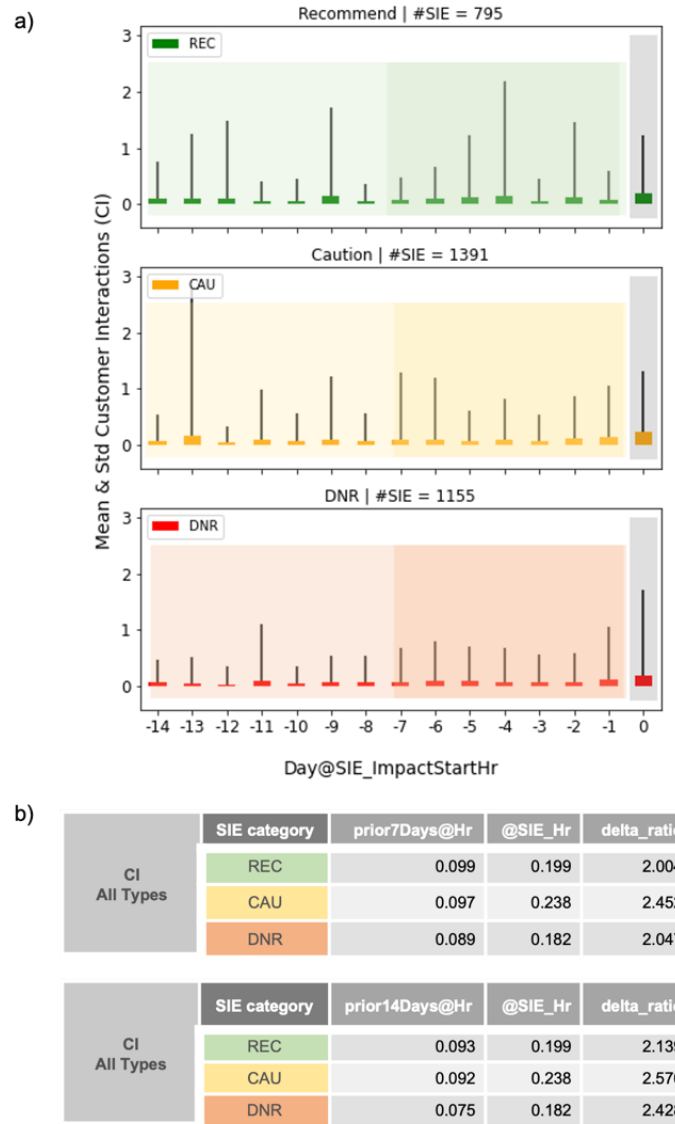

Figure 9 - CIs relative to SIE_ImpactStartHr and derived delta_ratios for the PMT categories of SIEs with SIE_ImpactStartHr in prior 7 or 14 days as a baseline

a) Daily mean and standard deviation of CI (at SIE impact start hour across all SIEs. All types of CIs are considered. The prior 7 or 14 days CI at SIE impact start hour as a baseline is denoted with SIE categorical shading, relative to SIE start hour, as indicated by the grey vertical bar; b) Summary of average CI i) across all hourly means of prior 7 or 14 days, ii) for an hour after SIE impact start (@SIE_Hr), as well as the respective delta_ratio for each SIE category.

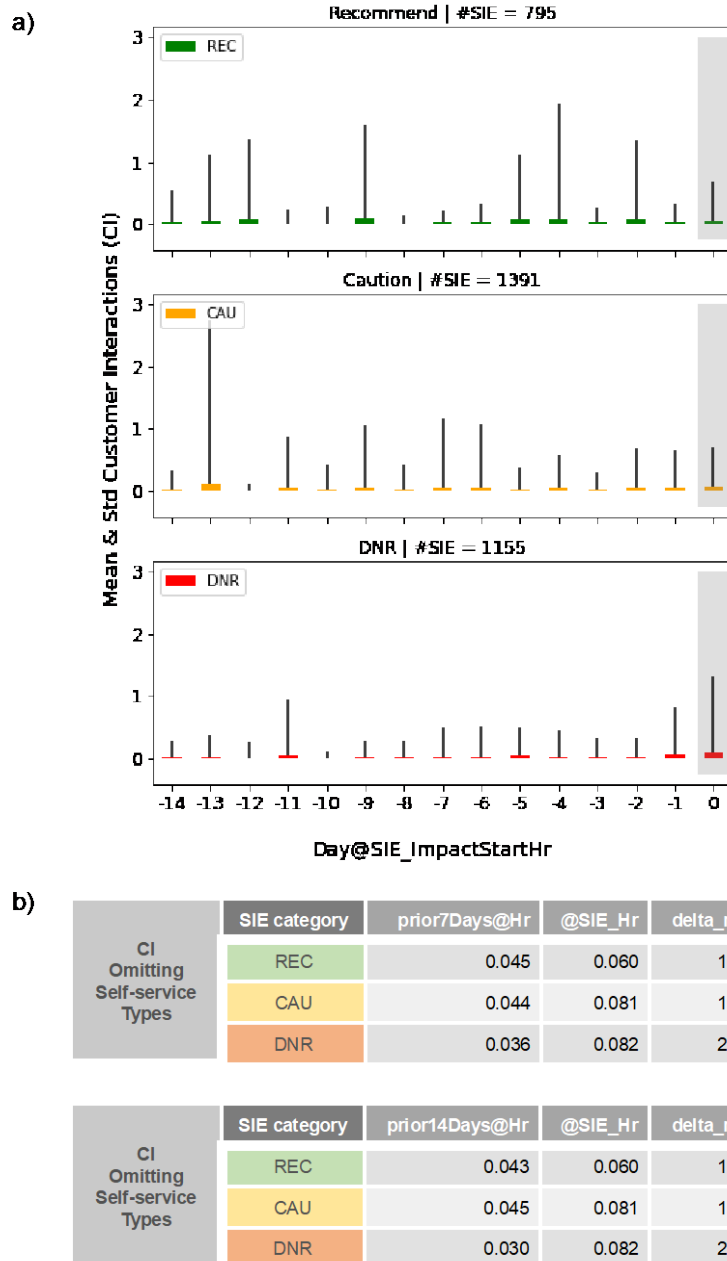

Figure 10 - Non-self-service CIs relative to SIE_ImpactStartHr and derived delta_ratios for the PMT categories of SIEs with SIE_ImpactStartHr in prior 7 or 14 days as a baseline.

a) Daily mean and standard deviation of CI at SIE impact start hour across all SIEs. CIs without self-service event types are considered. The prior 7 or 14 days CI at SIE impact start hour as a baseline is denoted with SIE categorical shading, relative to SIE start hour, as indicated by the grey vertical bar; b) Summary of average CI i) across all hourly means of prior 7 or 14 days, ii) for an hour after SIE impact start (@SIE_Hr), as well as the respective delta_ratio for each SIE category.

Figure 11 - Cost-incurring CIs relative to SIE_ImpactStartHr and derived delta_ratios for the PMT categories of SIEs with SIE_ImpactStartHr in prior 7 or 14 days as a baseline.

a) Daily mean and standard deviation of CI at SIE impact start hour across all SIEs. Cost-incurring CI types (e.g., technician visit scheduling; repair call/chats) considered. The prior 7 or 14 days CI at SIE impact start hour as a baseline is denoted with SIE categorical shading, relative to SIE start hour, as indicated by the grey vertical bar; b) Summary of average CI i) across all hourly means of prior 7 or 14 days, ii) for an hour after SIE impact start (@SIE_Hr), as well as the respective delta_ratio for each SIE category

We observed that our assessments across the different baselines (24hrs prior; 7 days prior; 14 days prior) and the various combinations of customer interaction types (e.g., all types; excluding self-service trouble-

shooting; inclusion of only cost-incurring types) all show a consistent trend: Service Interruption Events (SIEs) performed during PMT “recommended” hours show less relative customer interaction (CI) delta_ratio increase compared to SIEs performed during PMT “do-not-recommend” hours (see Tables 1—3).

Table 1 - Derivation of delta_ratios for comparison across SIE categories using 24hrs prior CIs as a baseline.

a)	CI All Types	SIE category	prior24Hrs	@SIE_Hr	delta_ratio
		REC	0.119	0.199	1.673
		CAU	0.105	0.238	2.273
		DNR	0.083	0.182	2.200
b)	CI Omitting Self-service Types	SIE category	prior24Hrs	@SIE_Hr	delta_ratio
		REC	0.051	0.060	1.174
		CAU	0.045	0.081	1.783
		DNR	0.033	0.082	2.482
c)	CI Cost Incurring Types	SIE category	prior24Hrs	@SIE_Hr	delta_ratio
		REC	0.036	0.034	0.949
		CAU	0.031	0.035	1.123
		DNR	0.022	0.054	2.399

Table 2 - Derivation of delta_ratios for comparison across SIE categories using CIs in the prior 7 days at the same impact start hour as a baseline

a)	CI All Types	SIE category	prior7Days@Hr	@SIE_Hr	delta_ratio
		REC	0.099	0.199	2.004
		CAU	0.097	0.238	2.452
		DNR	0.089	0.182	2.047
b)	CI Omitting Self-service Types	SIE category	prior7Days@Hr	@SIE_Hr	delta_ratio
		REC	0.045	0.060	1.333
		CAU	0.044	0.081	1.828
		DNR	0.036	0.082	2.293
c)	CI Cost Incurring Types	SIE category	prior7Days@Hr	@SIE_Hr	delta_ratio
		REC	0.036	0.034	0.955
		CAU	0.031	0.035	1.140
		DNR	0.024	0.054	2.249

Table 3 - Derivation of delta_ratios for comparison across SIE categories using CIs in the prior 14 days at the same impact start hour as a baseline

a)	CI All Types	SIE category	prior14Days@Hr	@SIE_Hr	delta_ratio
		REC	0.093	0.199	2.139
		CAU	0.092	0.238	2.576
		DNR	0.075	0.182	2.428
b)	CI Omitting Self-service Types	SIE category	prior14Days@Hr	@SIE_Hr	delta_ratio
		REC	0.043	0.060	1.415
		CAU	0.045	0.081	1.798
		DNR	0.030	0.082	2.777
c)	CI Cost Incurring Types	SIE category	prior14Days@Hr	@SIE_Hr	delta_ratio
		REC	0.034	0.034	1.005
		CAU	0.035	0.035	1.012
		DNR	0.020	0.054	2.704

What is particularly interesting to note is that when omitting self-service CI types or considering only cost-incurring CIs – such as scheduling a technician visit and calls and chats with a customer agent – we observed relatively larger differences in DNR—REC delta_ratios. Although the differences in delta-ratios observed were not statistically significant ($p > 0.05$ ⁴; likely due to data sample sizes), these findings are encouraging because they point to specific CIs that we could potentially monitor and assess for the financial and customer impact on an ongoing periodic basis.

3.3.2. Time-of-day Effects

In addition to deriving and assessing the DNR—REC delta_ratios, categorizing the time of SIEs onset by PMT recommendations also allowed us a view into when different categories of PMT recommended SIEs tended to occur over the period of 06:00 hrs—23:00 hrs in the test region. Figure 12(a) shows the distributions of SIEs for each PMT recommendation category over time.

Additionally, our assessments highlighted a time-of-day effect: hours that the algorithm would recommend tended to occur earlier in the day (06:00-14:00hrs), while the caution hours shifted to later (08:00-15:00hrs), and for hours that PMT yielded a do-not-recommend, we saw the latest (09:00-19:00hrs).

Combining the separate categorical plots in Fig 12(b) as a relative proportion of all SIEs performed during the onset hour of service interruption across the period of 06:00 hrs—23:00 hrs, we can begin to appreciate the time-of-day effects together with the previously described trend in delta-ratios. Specifically, we observe that performing an SIE after 15:00 hr almost always is associated with high customer impact compared to performing an SIE before 08:00 hr when it shows low impact for customers.

⁴ Our t-tests were performed with probability (p) significance test against the threshold $\alpha = .05$; we assume and allow for a 5% chance level of how extreme our observed results must be to reject the null hypothesis of no delta_ratio difference. At the set threshold of $p < .05$, an observed test probability p below 0.05, would indicate the alternative hypothesis of a delta_ratio difference is ‘statistically significant’ and that we could reject the null-hypothesis. In our case we observe that the t-test performed on the delta_ratios derived from our limited sample exceeds the set threshold of acceptable chance level, and we conclude that the observed trend is not statistically significant.

Figure 12 - Distribution and relative proportion of SIEs for each PMT category.

- a) Hourly distribution of SIEs for each PMT recommendation category – REC; CAU; DNR – over time;
b) Relative proportion of all SIEs in data sample during onset hour of service interruption across the period of EST 06:00 hrs—23:00 hrs.

3.4. Assessment Summary

Overall, the assessments for the test region over the date range highlighted the following:

- 1) CUI has sufficient signal to drive the PMT algorithm;
- 2) Different categories of PMT recommendation are associated with a consistent trend: SIEs performed during PMT “recommended” hours show less relative customer interaction (CI) increase (as measured by delta_ratio) compared to SIEs served during PMT “do-not-recommend” hours;
- 3) Operationally, a simple and effective way to improve customer experience is by retroactively measuring CI for SIEs in defined geographic regions and using the results to provide guidance. PMT recommendation is most effective if it is run:
 - i. Only when a planned maintenance job needs to be scheduled (i.e., beforehand, before being in location)
 - ii. Derived with CUI of the exact SIE-affected accounts

We reiterate that our data-driven assessment approach mimics an idealized scenario, which may not be easily achieved in the field without a robust data ingest and computational platform. To approximate the idealized system, future customer usage information must be forecasted. This relies on the stability of historical data, which may be affected by seasonal events – an area of research we hope to pursue.

Notwithstanding, the findings discussed provide valuable insights and recommendations for how the PMT could be applied in the field. Importantly, given that the data sampled was over a short period in the current year and for only the selected test region, periodic assessments would be needed to monitor if our observed delta_ratios and time-of-day trends hold across seasons, time, and indeed, if there may be regional differences in such movements.

Next, we discuss practical considerations of applications in the field and how our findings could be best incorporated into deploying an early version of the PMT.

4. Application

An application was developed, for use by technicians, to determine the best time to perform SIEs, specifically for ‘planned maintenance’ events to be performed during regular and extended working hours. For better or worse, the application was developed with scalability and performance, which means that its function does not match that of the Assessment described above in Section 3. Although much further testing would be required to measure its effectiveness, it helped expose the challenges faced by developing a field tool that would rely on data generated by various corporate systems. A description of the application follows.

4.1 Architecture

4.1.1. Overview

The application is divided into three major systems, including the same Recommendation Service (Section 2.3) developed for the Assessment (Section 3). The additional components include a Grouping Service (Section 4.1.3), designed to help with performance, and an Application Programming Interface (API), where aggregated data and field tech requests were processed. Figure 13 provides an overview of the PMT Application and its different components.

As described earlier, the Recommendation Service uses CUI metrics and groups of selected accounts to calculate recommendations. However, in the PMT application, we created a ‘Grouping Service’ that pre-determined groups of up to 40 accounts for which recommendations would be calculated. This approach allows the recommendations to be calculated before the technicians need them, thus minimizing query latency, unlike systems that must perform data pulls and calculations on-demand. We provide a summary of this in Figure 14 and Section 4.1.2.

The Grouping Service (Section 4.1.3) consumes data about the structure of the cable plant (see description of PTI in Section 2.1.3) from each CMTS down to each account. It then creates groups of up to 40 accounts on the same network branch. This is then stored in the MySQL database via the API, which is used to fetch this data by the Recommendation Service. These pre-created groups are approximations of areas that could be affected by a representative SIE event based on their connectivity to the cable plant.

The application is built with a RESTful web service that takes requests from the Field Tech’s Laptop through a user interface, which helps them generate a list of accounts that would be involved in an SIE. This list of accounts is then sent to the API, which determines the group it best represents, looks up the pre-calculated recommendations for that group, and returns the result to the user interface on the Field Tech’s laptop, as illustrated in Figure 13.

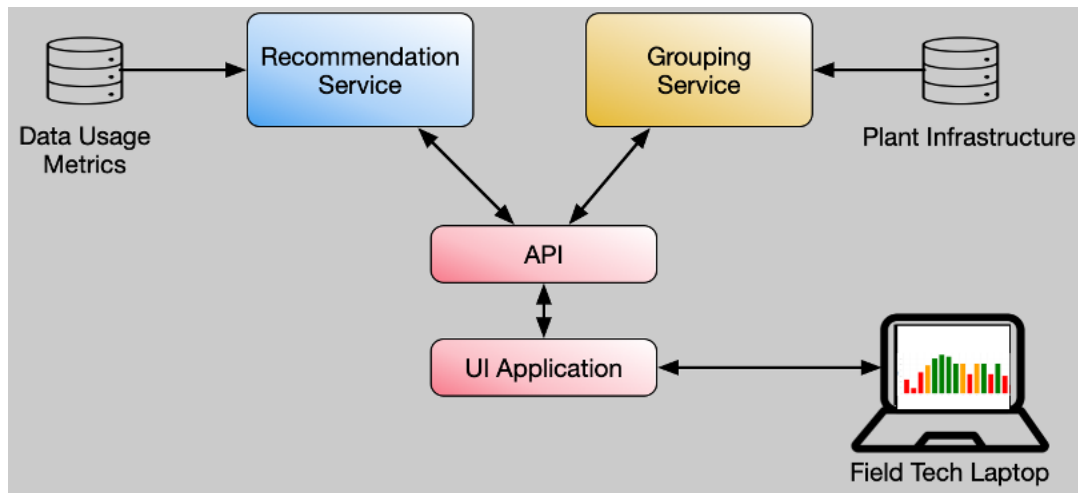

Figure 13 - Overview of PMT Application and its different components.

Detailed descriptions of each of these components are now discussed, except for the Recommendation Algorithm (Section 2.3), which has already been described.

4.1.2. Process Flow

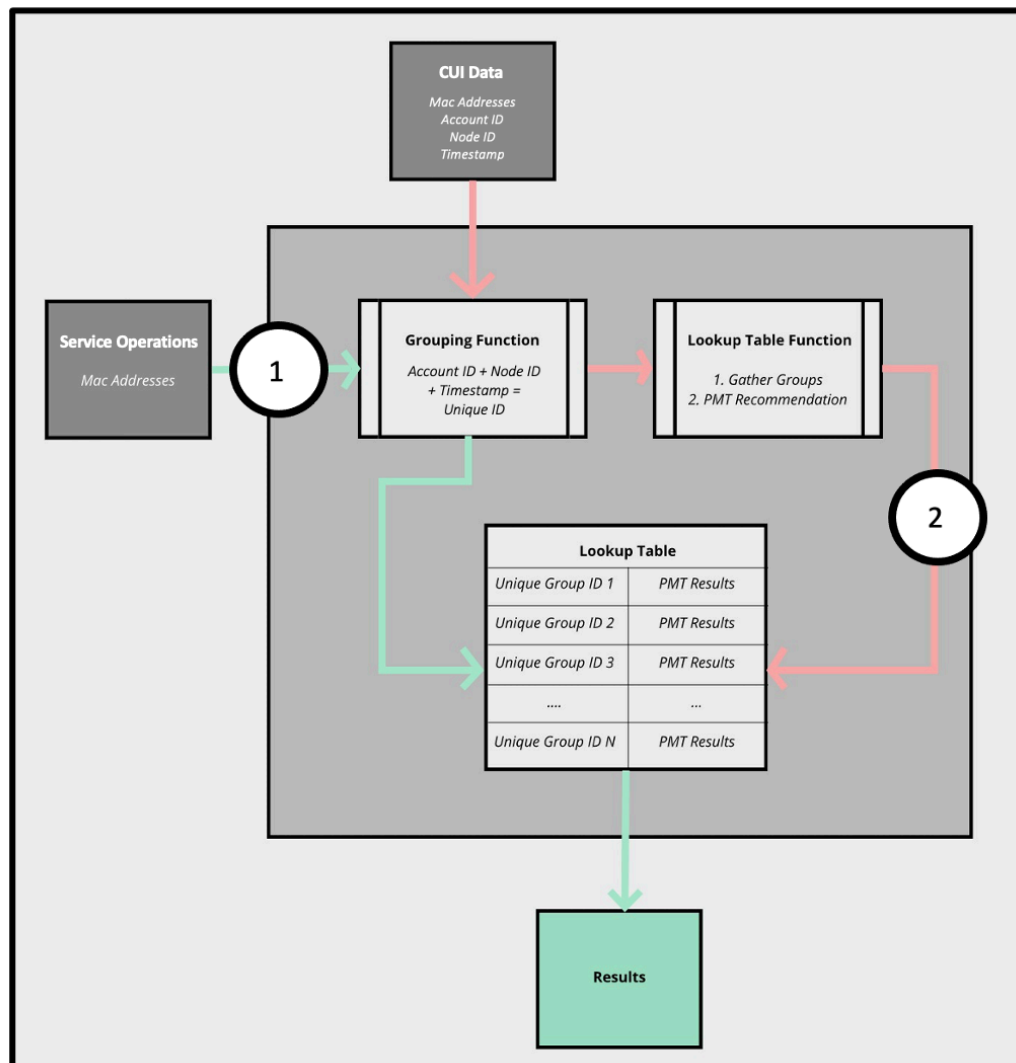

Figure 14 - High-Level Overview of PMT Recommendation Service

Flow 1, described by the **green** arrows, represents a technician's process when scheduling a job. It takes Mac Addressees provided by our Service Operations Tool and then matches them to Account and RF Node IDs. This data then gets passed through the Grouping function to create a Unique Identifier for the group. That Unique ID goes to the Lookup Table, and the PMT Result tied to the Unique ID is returned.

Flow 2, described by the **red** arrows, represents the backend flow where data is processed and prepared for a technician to query. It takes in CUI Data, comprised of Upstream and Downstream rates, and creates a unique ID using the same Grouping function as Flow 1. Then, this ID and CUI Data are passed to the Lookup Table Function, making a PMT Recommendation. The results are then populated into the Lookup Table to await a technician to access the results.

4.1.3. Grouping Service

An assumption was made that given a neighborhood where our services are provided, customers within closer proximity and/or customers who share a pedestal or an amplifier may experience similar plant activity. For example, fiber connects the CMTS to the RF Node in a neighborhood; there would be actives and amplifiers downstream. From there on, there would be taps with up to 8 ports that supply our services for up to 8 households in a residential neighborhood. If the amplifier is faulty, every household connected downstream from that amplifier would be affected. This led to creating groupings of 5-40 accounts.

An internal geographical topology tool, which is built on top of the Geographic Information System Framework (GIS), provides geographical and physical connection information regarding the plant's infrastructure: CMTS, Nodes, Actives, Passives, Amplifiers, Taps, and houses that have been set up to receive our services. Once information regarding a particular CMTS is retrieved, PMT's Grouping Service creates the groups based on common ancestors (such as taps or amplifiers) and geographical proximity within the infrastructure tree. It saves it into a graph database using a graph framework (See Figure 15 below). The last step in the Grouping Service process is to send lists of accounts for all the identified groups and underlying information, including account numbers, MAC addresses, and physical addresses, over to the MySQL database via the API. This information is then pulled into the Recommendation Service via an automated pull.

Figure 15 - Example groupings determined by Grouping Service.

Two groups being calculated based on their geographical proximity by the Grouping Service

There are tradeoffs in assuming that the data usage patterns are similar between customers sharing a common ancestor or geographical proximity. It would be more accurate for the PMT application to evaluate each account's statistically considered data consumption when calculating a recommendation for a SIE.

4.1.4. User Interface

Due to expediency and the fact that technicians use a smartphone or their in-truck laptop, we decided to use a browser-based solution. In the PMT application, the UI was created with ReactJS, and the backend was developed via NodeJS, Express API, and MySQL as a database. This was done to provide a visualization of the recommendations to a technician that would be concise and relatively quick to read.

As mentioned in section 4.1.3, the input for the area affected by the SIE is acquired via an internal GIS-based tool in which the accounts within the impacted area are identified and provided to the PMT application. Within the UI, the technician selects future dates (as far as two days in the future) in which they desire to view the recommendations for that area. These inputs go to the API, which determines which accounts belong to which groups via a “majority rules” filter to select which pre-determined group has the most accounts for an assigned area. Using a graph, PMT then fetches the recommendations for the identified group from the MySQL database and displays them on the ReactJS frontend.

Figure 16 - Example PMT application recommendations

After the accounts are input by the user, PMT would run its microservices and reveal the hourly recommendation based on the hours of the day and the date selected.

Figure 16 shows the displayed recommendations in three color categories: green for REC, yellow for CAU, and red for DNR. In addition, the bar graph’s magnitude is determined by the values calculated by the Recommendation Service. Additionally, a user can look at today’s, tomorrow’s, and the day after tomorrow’s data to find an ideal time to perform an SIE.

5. Discussion

5.1 Learnings from the field and insights from the assessment

We discuss the learnings from our small-scale field trial and the insights derived from assessing our algorithm with historical SIE and CI data.

5.1.1. Trial

The PMT application was trialed in a limited area (0.15% of total nodes in the region), or approximately 30 nodes in a test region with tens of thousands of nodes. While the trial is ongoing, we have already discovered that deployment of the PMT on a fraction of the regional network plant does not generate sufficient data to concretely determine if the use of the developed PMT application improves customer experience.

We note that the assessment described in Section 3 was performed on a sample of a few thousand SIEs across the whole test region. As just mentioned, the application trial covered a small fraction of the test region by comparison. Therefore, to match the integrity of the assessment, the trial would need to be expanded to include the entire region. However, such an expansion would be equivalent to creating a large-scale production-level application deployment, which would require committing resources to an unverified design.

As of this writing, we determined it would be best to extend our assessment approach within the same region, as well as to the other areas, to verify that findings in the test region: scale up in volume of historical SIEs and CIs, and check if they are consistent across the geography of different regions and over time.

5.1.2. Learnings and Observations

We acknowledge that our assessment of derived PMT recommendations, based on historical data, simulated an *idealized* scenario wherein customer usage information was extracted for the set of SIE-affected accounts and all hours on the same day (that is still unfolding) when the SIE occurred. In a real-world scenario, this application would have to reliably and efficiently estimate future customer data used to calculate recommendations for any set of accounts and any day. Building such an application will require:

- Reliable forecasting of future customer data usage from historical CUI;
- Adequate computing and data ingest resources to continuously store, fetch and compute the stream of available CUI data;
- Adequate computing resources to calculate and return recommendations, at scale, in a performant fashion when a field technician makes a request;
- A system to continuously monitor system effectiveness to provide feedback for improvements.

A noteworthy finding is the time-of-day pattern of SIEs and their associated PMT recommendation category observed in our assessment: SIEs with PMT REC hours tended to occur earlier in the day. In contrast, an SIE during hours that PMT would yield CAU or DNR occurred at higher frequencies later in the afternoon. Field operations groups can immediately use this time-of-day insight to guide them to make sensible choices and possibly even schedule directives on when to perform investigations and preventative maintenance that results in a SIE.

5.1.3. Considerations

In the future, it may be prudent to store data about SIE's impact on customers for an entire year to understand annual patterns. Correlations could be based on locality, especially given the different schedules that universities, K-12 schools, and local holidays, among other events, will affect data usage. For example, university towns have transient populations that drop significantly between terms. K-12 schools have schedules imposed by local governments and are typically published before each school year. Knowing when children are not going to be at school means knowing that they're probably going to be at home sharing bandwidth with parents who may be working from home.

Moreover, events like the COVID pandemic have significantly impacted the use of residential gateways, making knowledge of data usage patterns even more critical as livelihoods have been, and continue to be, made from home offices. Although epidemics and pandemics do not have a known schedule, local health directives and infection rates could be studied and used for predicting increases in residential data usage.

6. Conclusion

Insights from our assessments can be used to recommend how a PMT user application could be architected, deployed, and used in real-time to guide technicians to the optimal time to schedule an SIE. While it should be cautioned that the data used in our assessments were limited in sample size, within one northeastern region in our national footprint, and over a limited time range (February 01 – March 11 and April 16th onwards), the findings we observed suggest that customer usage information could be a good indicator of potential customer impact during SIEs.

Observing trends using the assessment method described in section 3 can help simplify the deployment of the PMT application across our service footprint. It offers a way to standardize its use and potentially roll out randomized field trials across multiple regions for a more robust assessment of the value of using the PMT application in the field.

We also know that the recommendation algorithm may not always yield the expected trend during the year. This could be due to many factors, including:

- seasonal customer data usage patterns
- customer experience campaigns rolled out in parallel
- changes in data usage patterns due to pandemics or natural disasters

Overall, we learned that it helps to employ “hindsight,” using retrospective analyses as we did in assessing our algorithm with historical SIE and CI data. We suggest this as good practice before building a field application for trial. The insights derived from a data-driven analytical approach can help guide how such an application would be best used and deployed. Since there is no way to predict which nodes in our network will require the most SIEs in the future, we determined retroactive data was the most efficient way, albeit idealized, to validate our assumption that customer usage data at particular times during the day would be indicative of customer impact.

In conclusion, we entered this trial with the premise that the best time to interrupt the network with a SIE is when nobody is using it. This premise was assessed using the methodologies described in this paper. The measurable reduction of CIs during SIEs that occurred during times recommended by the PMT indicates that a data-driven model to predict the best times to conduct invasive maintenance is possible and deserves further development.

1. Introduction

A Profile Management Application (PMA) is a critical component of DOCSIS downstream and upstream for both speed and reliability. This is especially true with increased bandwidth demands in recent years. As such, it is critical to react quickly to issues in order to provide the best customer experience. Faster mitigation of network issues reduces customer impact and call volumes. The profile recommendation interval was lowered from 6 hours in the previous system (Harb, 2020) to 5 minutes in the DOCSIS 3.0 (D3.0) upstream (US), and from 3.5 days to 1 day in the DOCSIS 3.1 (D3.1) US and downstream (DS), while reducing operational costs and improving capacity.

Ingesting and analyzing large amounts of data at a high rate creates high demand for both storage and CPU. The technology stack was refactored and costs were lowered by eliminating redundancy and leveraging streaming, batching, cloud computing, and parallel processing. Aligning the polling and PMA processing using Simple Storage Service (S3), Simple Notification Service (SNS), and Simple Queueing Service (SQS) allows for processing of a single batch of related data immediately after polling. Storage demand was reduced by moving components from a relational database to S3 with a large batch size. CPU demand was reduced by moving the analysis logic from a large Apache Spark cluster to a smaller Elastic Kubernetes Service (EKS) cluster. CPU demand was further reduced by refactoring the clustering algorithm to use Single Instruction Multiple Data (SIMD) parallel processing.

Making PMA recommendations more often improves capacity to an extent, but larger capacity gains were made by making changes to the profile selection and clustering algorithms. For D3.1, the Modulation Error Ratio (MER) data model was improved by using histograms and a time decay function. Better utilization and capacity estimates were created by using the model and the added time dimension. Optimal percentiles and corresponding weights are generated for each modem and used as inputs to the clustering algorithm. The result was capacity gains of greater than 8% and 5 Tb/s.

2. US D3.0 Profile Management

Capacity gains were increased primarily by decreasing the recommendation interval from 6 hours to 5 minutes. To do this, the data granularity was also changed, and the operating model changed from batch to streaming. Additionally, some changes were made to the profile recommendation business logic. Finally, costs were reduced by eliminating redundancy in the polling and data ingest pipeline.

2.1. Data Granularity

Per-modem SNR and Forward Error Correction (FEC) statistics were replaced with interface-level aggregates in the data ingest pipeline. Interface-level data is orders of magnitude smaller than the equivalent per modem data, which allows for more frequent collection and the incorporation of more historical data for making profile recommendations. Data ingested includes interface level FEC, MER, Profile, and Utilization metrics.

2.2. Collection and Recommendation Interval

Interface-level aggregate SNR and FEC is ingested in 5-minute intervals. The incoming data is retrieved from AWS S3 storage and an SNS notification informs of the availability of new data. The data is written to a time series database. There is minimal lag between the poll and the ingest, and a new set of profile recommendations is made immediately. This allows the system to respond quickly to a change in the plant conditions and results in a better customer experience. As a result, a 60% reduction in major alarms and a 50% reduction in minor alarms was achieved.

2.3. Recommendations

US profiles for D3.0 channels are comprised primarily of a modulation order from Quadrature Phase Shift Keying (QPSK) to 64-Quadrature Amplitude Modulation (QAM), and data and parity lengths for short and long grants. A recommendation is then made and implemented for each upstream channel on a Cable Modem Termination System (CMTS). Recommendations are made by choosing the most appropriate profile for the channel from a fixed set of available profiles. The chosen profile minimizes FEC error rates while maximizing throughput. Additional consideration is given to interfaces with high utilization, e.g., a profile change won't be made if it would increase the utilization above 80%.

To reduce profile flapping (repeated profile changes downgrading and upgrading the same channel), the algorithm will lower the profile more readily than it will raise it. It also takes into consideration past profiles and their corresponding MER values.

2.4. Downgrade Profile

The decision to downgrade a profile is made when the channel uncorrectable FEC rate is impaired (> 1%) for 20 minutes.

2.5. Upgrade Profile

The profile is upgraded after 30 minutes of clean uncorrectable and correctable FEC rates (< 0.0001%) and MER > 36 dB, or 75 minutes of Uncorrectable FEC < 0.1%, and a +2 decibel (dB) improvement in MER and a 50% reduction in correctable FEC.

2.6. Capacity Gain

On average, the capacity gain is measured at 16.6 %. This is about a 1.5% capacity improvement vs. the previous version of US D3.0 PMA. Gains in various markets vary from 14% to 22%. US D3.0 PMA adds about 4.2 Tb/s in total capacity to the upstream, which represents an average gain of 3.1 Mb/s per channel. System performance and capacity gains are continuously monitored via dashboards and automated alerting.

Overall Profile Stats				
cmts_count	gainpct	interface_count	rawgain	avgintgain
3756	16.6	1304932	4.18 Tb/s	3.05 Mb/s

2.7. Dashboards

The dashboards provide insight into the performance and health of the system. Figure 2 shows a dashboard view of the performance of the US3.0 PMA system, showing statistics for the Mountain West region, including profile distribution, capacity gain, interface degradation, and the number of changes applied by the PMA System.

Figure 3 shows a dashboard view of the health of the US3.0 PMA system. Metrics shown include processing time and volume, message lag, and quantities of profile changes.

Figure 2 - Example US D3.0 PMA Stats for Mountain West Region

Figure 3 - Example US D3.0 PMA Monitoring Dashboard

3. DS D3.1 Profile Management

Capacity was increased while lowering cloud computing costs, by improving the data model, improving the clustering algorithm, and making performance improvements to the clustering algorithm. Additionally, the processing model was changed from batch-oriented to streaming. The performance improvements allowed the recommendations to be made more frequently as compared to the prior version, lowering the recommendation interval to 1 day from 3.5 days. As a result, approximately 8% more OFDM capacity was gained, more than 5 Tb/s in total.

3.1. Model

The MER data model was changed to use a two-dimensional histogram, or heatmap, incorporating an exponential decay function. Figures 7 and 8 below show representative histogram rendered using a color scale. This allows for the quick computation of any percentile value between 1 and 100 without sorting. The purpose of the decay function is to age out older data over time and introduce a recency bias. A half-life of 4 days was chosen for the decay function. An entire CMTS worth of compressed JSON data is stored in a single S3 file, organized by interface. On average, the data for a modem (with a single 96 MHz wide Orthogonal Frequency Division Modulation (OFDM) channel, 25 kHz subcarrier spacing) takes up only 75 kilobytes of space, or about 20 bytes per subcarrier. This space savings is the key to cost savings in cloud storage, as the full dataset is both read and written hourly.

Modem level per-subcarrier MER data is ingested on an hourly basis. The polling system produces a single S3 file per CMTS and sends an SNS notification when the file is ready. The large batch size minimizes costs for reading the incoming data. Due to the streaming nature of the system, there is a minimal delay between the poll completion and the processing.

The previous system (Harb, 2020) used a static MER percentile and a weight of 1 for each modem. Using a static 10th percentile of MER of each modem as an input to the clustering algorithm was insufficient to achieve optimal gains. This is based on the observation that more than 90% of the time the modem MER is higher than the 10th percentile MER and could thus be using a higher profile. On the other side, up to 10% of the time the MER is lower than the 10th percentile MER, and the modem might be using profile 0 (see below). As a result, the system under-estimated capacity gain.

The changes to the model allow for a more accurate estimation of capacity gain, which in turn allow for greater capacity gain. A fixed profile 0 at 64 or 256-QAM is used, and PMA generates 3 additional dynamic profiles. Depending on the MER distribution, a modem may spend a percentage of time on a single profile or a subset of all the profiles. Using the time percentages as weights, the estimated capacity for a modem is calculated as the weighted average of the profile bit-loading. The estimated capacity for an OFDM interface is then calculated as the average of the per modem estimates. Further increases of estimation accuracy at the OFDM interface level could be obtained by weighting the average by per-modem utilization. This would result in larger capacity gains and would be useful for comparing the predicted capacity against actual capacity but could unfairly punish lower utilization users. This is because modem utilization is not equal. For example, a modem with a high utilization on a low profile would skew the actual capacity downwards as compared to the estimate.

A single, optimal profile for a modem can be computed by iterating over the percentiles 1 – 100, estimating the resulting capacity as above, and choosing the percentile that maximizes capacity in conjunction with profile 0. Similarly, a set of N optimal profiles can be computed for a modem by choosing N percentiles of increasing value such that the chosen percentiles maximize capacity.

3.2. Clustering Algorithm

The clustering algorithm as described in (Harb, 2020) already minimizes capacity loss. The inputs were a profile per-modem (computed from the 10th percentile of MER values), with a weight of 1 for each profile. The clustering algorithm reduces the input to the desired number of profiles, e.g., 3, by merging the two profiles together that result in the lowest capacity loss. The improvements to capacity gain were achieved primarily by improvements to the inputs. Versus the previous inputs of a single profile for each modem, 2 optimal profiles are instead computed for each modem (as described above), as well as an additional input representing profile 0. Rather than a weight of 1.0 for each input, varying weights are used. The weight used for each input represents the estimate of the percentage of time spent on the profile, as mentioned above. The weight for profile 0 is the sum of the percentages of time each modem is estimated to use profile 0. Including its contribution to the profile 0 weight, the sum of the weights for each modem's inputs equals 1.

Rather than excluding modems with low MER prior to the clustering, the clustering algorithm merges those inputs as appropriate into the profile 0 cluster. As such, depending on the distribution of MER values, some modems may be ultimately assigned 0, 1 or 2 profiles.

Table 1 – OFDM Profile MER Thresholds, 5 dB more aggressive than DOCSIS 3.1 spec

Bits	Modulation	MER Threshold (dB)
2	QPSK	6.0
4	16-QAM	12.0
6	64-QAM	18.0
7	128-QAM	21.0
8	256-QAM	24.0
9	512-QAM	27.5
10	1024-QAM	31.0
11	2048-QAM	34.0
12	4096-QAM	38.0

3.3. Performance

The core clustering algorithm was made 25 times faster. The biggest speed increases were due to rewriting the distance function using SIMD parallel processing via the Advanced Vector Extensions 512 (AVX-512) instructions on Intel CPUs and in Java via the `jdk.incubator.vector` package. This allows for 16 integer operations to run in parallel on a single core. The next largest boosts came from switching the internal representation from double to int, and from immutable Scala Array types to primitive arrays, which was also necessary to take advantage of SIMD. Finally, upgrades to versions of the Java Virtual Machine (JVM), Scala, and Spark software were made.

Some of the performance gains were offset due to doubling the number of inputs. As the algorithm has an $O(N^2)$ complexity, doubling the inputs results in 4 times slower performance. The net speed increase of more than 6 times faster directly results in lower cloud computing costs. Rather than a single large batch, the work is spread throughout the day. This lowers cloud computing costs by keeping a smaller number of cores continuously busy. The cycle time was reduced from twice a week to daily, and is expected to be reduced to hourly on an as-needed basis, matching the MER ingest rate. As it was also observed in the

D3.0 US, faster response to changes in the plant result in greater capacity gain / and or less capacity loss. However, and an important difference: because the model and clustering account for MER changes over time, and the CMTS assigns profiles periodically throughout the day, a daily cycle is sufficient in most cases.

3.4. Capacity Gain

Greater gains are possible on OFDM than on D3.0 channels, due to the higher modulation orders available. The average capacity gain on OFDM is 43%. Actual capacity gain is measured vs a static 8-bit (256-QAM) modulation profile. As the maximum modulation is 12-bit (4096-QAM), the maximum gain possible on a perfect network would be 50%. This is about an 8% improvement to capacity vs the previous version. This represents an average bits / symbol across all OFDM channels of 11.47, compared to 10.83 on the prior version. In terms of raw capacity, the new DS D3.1 PMA is adding 27.1 Tb/s of total DS capacity, about 5 Tb/s more than the previous version.

3.5. Dashboards

The dashboards for DS D3.1 PMA show the system performance and health. Figure 4 shows the overall performance of the system, including the capacity gain, as well as a break-down by CMTS, and a view of the poorest performing interfaces.

Figure 5 shows a dashboard view of the performance of a specific OFDM interface. Metrics shown include traffic distribution by profile, channel speed by profile, interface statistics, etc.

Figure 6 shows a dashboard view of the health of the DS D3.1 PMA system, focused on AWS resources. Metrics shown include CPU utilization of the components, and metrics for the various notification topics and queues used by the system.

Figures 7 and 8 show example modem MER histograms, the optimal percentiles chosen as inputs to the clustering algorithm, and the resulting segmented profiles.

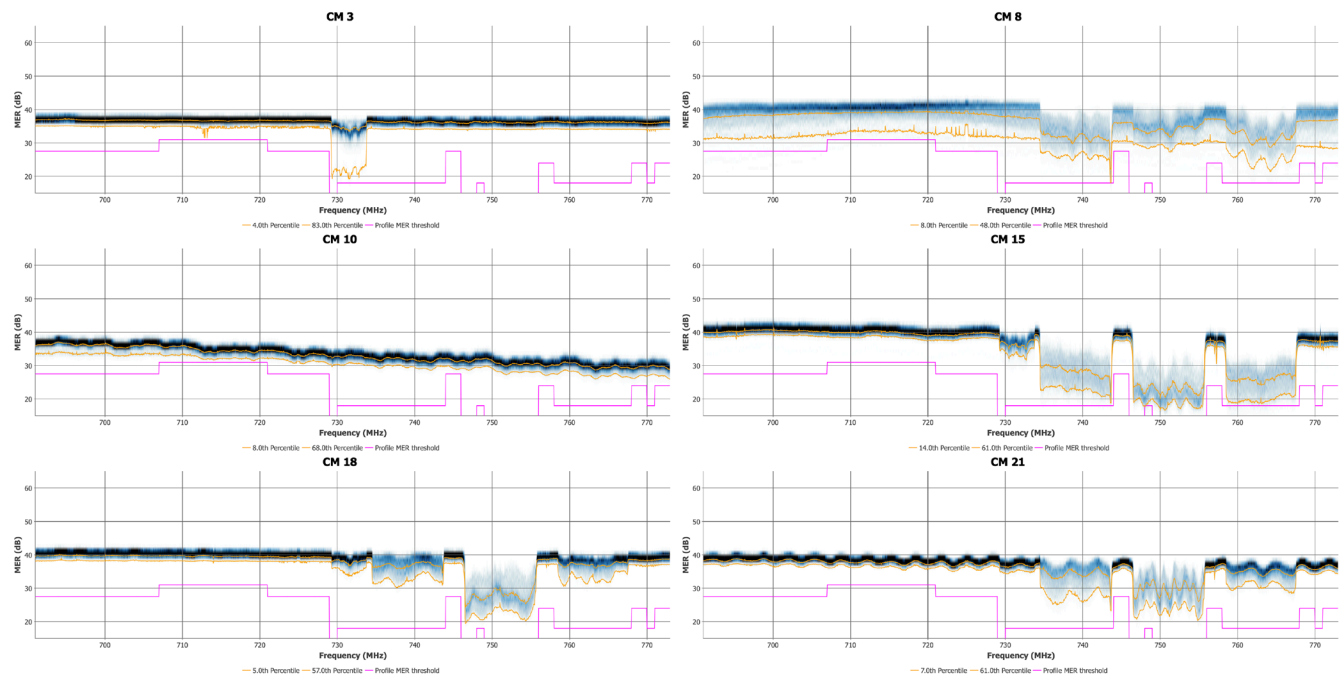

Figure 7 – Example profile 1 modem MER histograms, percentiles, and MER threshold

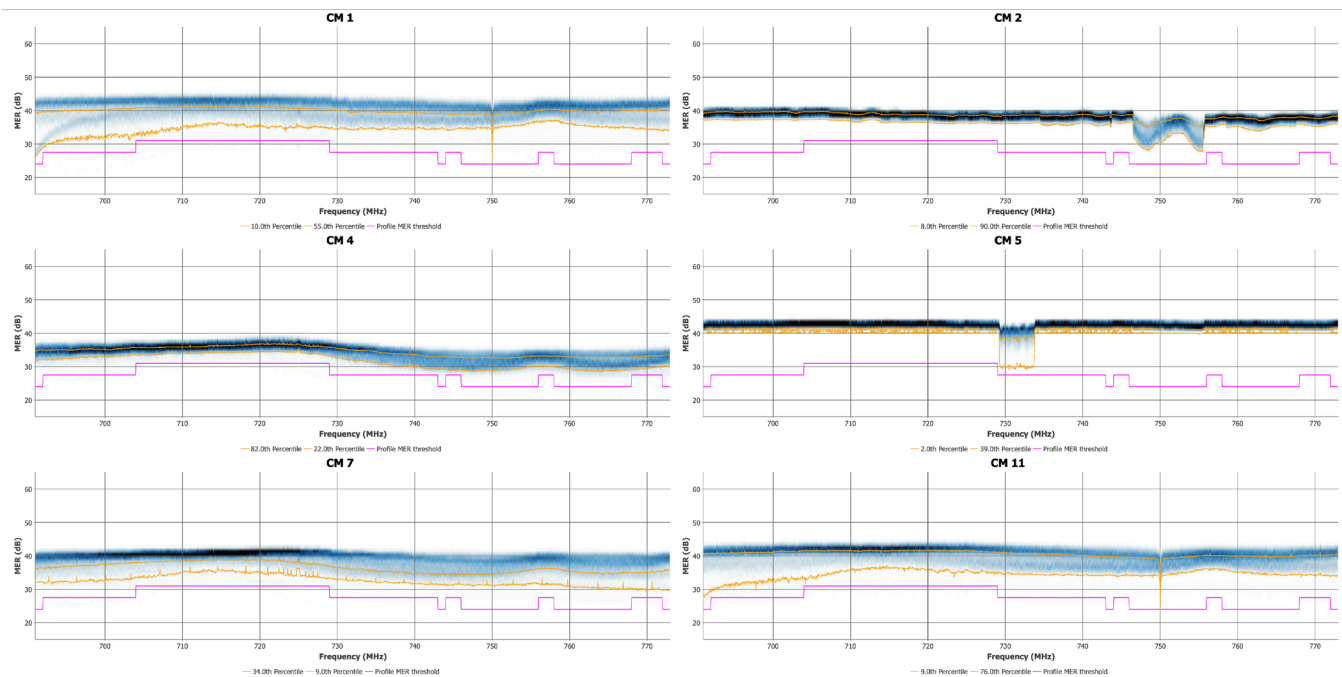

Figure 8 – Example profile 2 modem MER histograms, percentiles, and MER threshold

4. US D3.1 Profile Management

Profile Management for Orthogonal Frequency Division Multiple Access (OFDMA) on US D3.1 is similar to OFDM with a few notable differences. The MER values are per-minislot (400 kHz) instead of per subcarrier. The data is ingested at a 5-minute interval instead of hourly. The increased rate of collection helps offset the loss in granularity. The upstream uses IUCs instead of profiles, and more of them (7 vs 4). A single, static 10th percentile of MER per modem is used as the input to the clustering algorithm. This appears to be sufficient as there is less volatility in the MER values within a single modem as well as across the population of modems on an OFDMA interface. Having less volatility is a factor of the averaging of subcarrier MER into minislots, the upstream funnel effect, the ability of modems to adjust transmit power levels to achieve a desired receive power, and the effectiveness of the pre-equalization process. As of the time this writing, OFDMA PMA is not in full production, but based on trials, capacity gains similar to OFDM PMA are expected.

5. Future Work

Increase the profile recommendation rate for Downstream and Upstream DOCSIS 3.1 from daily to hourly on as-needed basis. Faster reaction to changing conditions would result in even greater capacity gains, or less capacity loss.

Make further performance optimizations and improvements to the clustering algorithms. A better result can be achieved by adjusting the weights accordingly as the clusters are merged, and optimizations can be made to reduce the algorithmic complexity.

Investigate generating more profiles and using profile 0 to a greater effect by modifying it from a flat 64-QAM modulation to a segmented profile. In many cases profile 0 could be made to be more robust, have higher throughput, and automatically handle cases otherwise handled by exclusion zones.

The MER thresholds used in the clustering algorithms to determine modulation are estimates, and appropriate values for the thresholds have been chosen, albeit generally conservative ones. There are cases where more aggressive thresholds can be used without driving FEC rates and using them would result in greater capacity gains. There may also be cases where more conservative thresholds are necessary in order to lower uncorrectable FEC rates. In these cases, the capacity estimates that the PMA algorithm makes would be high, and modems would be using profile 0 at a greater percentage than expected. Lowering the thresholds would lower estimated capacity but increase actual capacity, by shifting traffic to higher profiles. By comparing estimated profile utilization with actual profile utilization, the MER thresholds may be refined, creating realistic thresholds per CMTS, interface, or modem.

6. Conclusion

By making strategic changes to the US D3.0, DS D3.1, and US D3.1 PMA software, the system is able to mitigate issues faster, increase network capacity, and lower cloud computing costs. This was done by eliminating redundancy and leveraging a combination of streaming and batching, cloud computing, and vector processing. Improvements were also made to the underlying data model, business logic, and clustering algorithms. The net result was a reduction in the US D3.0 recommendation interval from 6 hours to 5 minutes, and from 3.5 days to 1 day for DS 3.1 and US 3.1. Capacity was increased by 1.5% for US D3.0 and by 8% for DS D3.1.

1. Introduction

Vendors who make equipment for hybrid fiber-optic & coaxial cable (HFC) networks and cable service providers (also known as “cable operators”) have been discussing high split (HS)—moving the upstream (US) frequency split to 204 MHz—for quite some time now. Over the last few years, vendors have made available the various components required for high-split operation, and they continue to add features and capabilities to simplify the introduction of high split by operators into HFC networks.

The time for talk is over! Some operators have recently taken the brave plunge in deploying high split, while others are busy preparing to migrate to high split in the near-term. This paper will explore the drivers for pursuing high split (204 MHz) on an HFC network. The paper will explore what it takes to deploy high split, including the consideration of architectural issues that need addressing to support high-speed data (HSD), video, and voice over internet protocol (VoIP) services on high-split HFC networks for both residential and commercial services. Furthermore, the paper will explore the considerations for each of the services and the features that are required in the products that comprise the end-to-end solution that enables high split.

The paper will present a unique cross-industry view of a cable operator who is actively deploying high split as well as a vendor who is providing most of the elements to enable this type of migration. The paper will explore the considerations for three of the most popular HFC access architectures today, including Integrated CCAP (I-CCAP) as a Centralized Access Architecture (CAA) as well as the two leading Distributed Access Architectures (DAAs): Remote PHY (R-PHY) and Remote MACPHY (R-MACPHY). There is value in deploying high split in all three of these architectures, and the technology is available today. The paper will explore the main issues which must be addressed in preparation for deployment, as well as key lessons learned from both the preparations and deployments. This paper will position high split as an important steppingstone to DOCSIS 4.0 and explore an HFC network’s evolution through this lens.

2. High Split & Cable Access Architecture Overview

This section will provide an introduction and overview on what exactly high split is, what are the market drivers for high split, and what does high split gain for cable operators in order to lay the groundwork for reviewing the architectural and operational considerations for implementing high split.

2.1. High Split Overview – What is It?

The current return spectrum in HFC networks, typically allocated between 5 MHz and 42 MHz (65 MHz for some geographic regions), has been a critical resource over the years to support the enablement and growth of interactive services. The Data Over Cable Service Interface Specification (DOCSIS) specification versions that define how to provide standards-based high-speed data service up to and including DOCSIS 3.1 have traditionally used frequency division duplex (FDD) to split the upstream (US) and downstream (DS) bands and their associated traffic with a guard band in between the two to prevent interference.

The technology behind the HFC upstream path has grown in complexity and efficiency over time. More recently, DOCSIS 3.1 brought orthogonal frequency domain multiple access (OFDMA) digital modulation technology to the return path along with a higher 204 MHz split. OFDMA improved resiliency to return path noise and impairments, which has resulted in support for even higher speeds and capacities without the need for physical expansion of the return bandwidth spectrum.

However, the 42/65 MHz upstream has become cable's Achilles Heel. With gigabit downstream tiers, it becomes very difficult to pair a complimentary upstream tier with it. This creates the need for upstream bandwidth augmentations which is achieved through implementation of higher frequency splits. DOCSIS 3.1 technology introduced an upstream spectrum of 5-204 MHz, also referred to as a high-split (HS) configuration, with downstream spectrum starting at 258 MHz. The latest DOCSIS 4.0 specification provides an extended FDD option to enable FDD upstream spectrum up to 684 MHz while also providing for incremental downstream bandwidth capacity to offset the expansion of the upstream spectrum.

The vast majority of HFC networks today were built to either 750 MHz or 860 MHz as the maximum DS frequency with sub-split returns in the 5-42 MHz range (5-65 MHz range for some other regions). Expanding services are driving consideration for network expansions to address growing capacity needs in both the downstream and upstream directions. Past expansions were focused on expanding the downstream, while leaving upstream spectrum mostly untouched. As upstream bandwidth expansions are planned, particularly for sub-split and mid-split architectures evolving the return to 204 MHz, a phased approach should be considered that not only considers the impact on downstream bandwidth and services, but also considers the impact of future DOCSIS 4.0 technology options. This will be further explored later in the paper.

In comparison to the upstream spectrum, the downstream spectrum has stretched from 54 MHz (or approximately 87 MHz in other regions) up to 550 MHz, 760 MHz, 860 MHz or, more recently, 1,002 MHz or 1,218 MHz. Whichever is the maximum DS frequency, the DS spectrum clearly has much wider spectrum and supported bandwidth and capacity than the US has. It has been clear for some time that cable operators would need to eventually expand the utilized US spectrum in order to meet the needs of their subscribers as well as to compete in the broadband access market. The drivers for expanding US spectrum will be further described in Section 2.2.

Over time, both the DOCSIS standards and the equipment that implements these standards enabled an ability to expand the upstream spectrum. Up through the DOCSIS 3.1 standard, cable operators can expand the US spectrum to two additional levels:

- (1) Mid split (MS): US spectrum of 5-85 MHz with DS spectrum starting at 108 MHz
- (2) High split (HS): US spectrum of 5-204 MHz with DS spectrum starting at 258 MHz.

Eventually, as DOCSIS 4.0 technologies are widely adopted, additional Ultra-High Splits (UHS) will open the door to even greater upstream bandwidths and capacities with splits that can reach 300 MHz, 396 MHz, 492 MHz, or 684 MHz. However, regardless of which upstream expansion option is selected, operators must recognize certain technical challenges and be prepared to address them as will be explored in the rest of this paper.

An example of the raw total throughput that a cable operator could send in the downstream and receive in the upstream for each service group (SG) is instructive of the relative throughputs that each of the splits outlined above could potentially provide. Table 1 shows three separate implementations, one for each of low split, mid split, and high split. For this example, a mixture of DOCSIS 3.0 single carrier QAM (SC-QAM) and DOCSIS 3.1 orthogonal frequency-division multiplex (OFDM) channels was assumed in the DS, and likewise, a mixture of DOCSIS 3.0 advanced time division multiple access (ATDMA) SC-QAM and DOCSIS 3.1 orthogonal frequency-division multiple access (OFDMA) channels was assumed in the US, as outlined in Table 1.

Table 1 – Raw Throughput Examples for Low/Sub Split, Mid Split, & High Split

US Frequency Split	US Spectrum Usage (MHz)	DS Spectrum Usage (MHz)	US Raw Throughput (Mbps)	DS Raw Throughput (Mbps)
Low/Sub Split	Total: 5-42 ATDMA: 18-42 OFDMA: N/A	Total: 54-860 SC-QAM: 54-588 OFDM: 588-860	87	5380
Mid Split	Total: 5-85 ATDMA: 18-42 OFDMA: 42-85	Total: 108-1,218 SC-QAM: 108-642 OFDM: 641-1,218	575	7812
High Split	Total: 5-204 ATDMA: 18-42 OFDMA: 42-204	Total: 258-1,218 SC-QAM: 258-642 OFDM: 642-1,218	1302	6912

In this example, the maximum DS frequency when operating in low/sub split is assumed to be 860 MHz, a starting point for many cable operators today, and the example also assumes that the operator is utilizing DOCSIS 3.0 SC-QAMs only at this stage in the US, representing yet again another common starting point for cable operators. When moving to high split, the DS loses its lower 204 MHz of spectrum, and a move to 1,218 MHz in the DS is assumed to maximize total spectrum allowed when using DOCSIS 3.1-capable equipment. The example in Table 1 just assumes raw throughput to and from the SG, independent of whether the channel is used for MPEG or DOCSIS QAM.

For the US in this example, usable bandwidth was assumed to be starting at 18 MHz due to noise that typically exists in the 5-18 MHz range caused by noise funneling from the cable plant. However, operators can and have harvested this lower bandwidth utilizing the capabilities of the newer DOCSIS 3.1 OFDMA channels, but that is not explored in this example. Figure 1 shows an overview of the low split, mid split, and high split spectrum and the estimated raw throughput from Table 1. The migration to services that are closer to symmetric is a key driver for cable operators to compete with operators who offer services over a fiber-to-the-home (FTTH), fiber-to-the-premise (FTTP), fiber-to-the-building (FTTB), or generally, a fiber-to-the-X (FTTx) architecture. The competitive drivers for a migration to high split will be covered in Section 2.2.

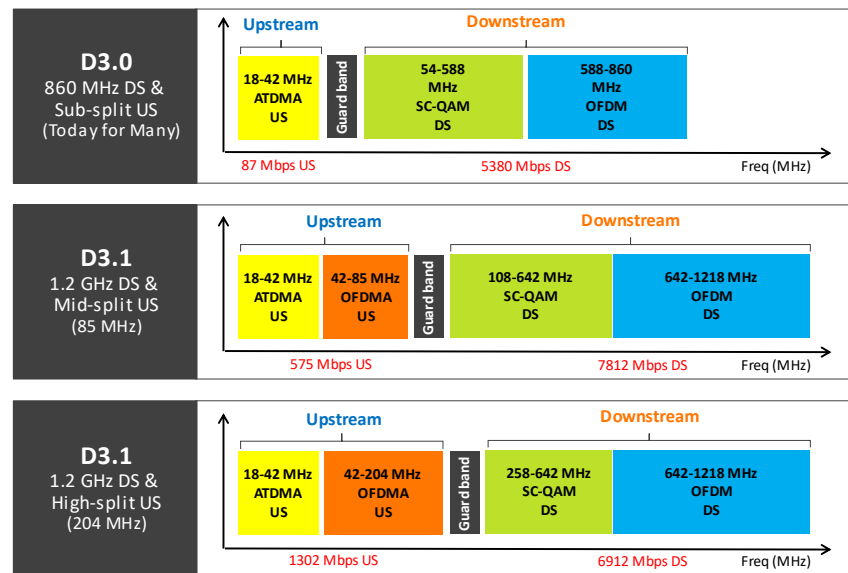

Figure 1 – Example Spectra & Overview of Low/Sub Split (42 MHz), Mid Split (85 MHz), & High Split (204 MHz)

2.2. Market Drivers for High Split

Cable operators face different levels of competition that vary by market. Historically, cable operators had competed against the legacy telecommunication providers (also known as the “telcos”), who initially offered high-speed data utilizing digital subscriber line (DSL) service over twisted-pair copper lines. Many telcos and other alternative operators have opted to implement a fiber passive optical network (PON) for FTTx services. Service providers who are utilizing PON are offering service tiers up all the way up to 5 to 8 Gbps, with many offerings currently in the range of 2 to 3 Gbps as of the writing of this paper. Deploying some versions of PON for FTTx service offerings enables symmetric services, and this distinguishes these offerings from service offerings over HFC.

While cable operators do face tough competition from service providers that utilize DSL, satellite, and fixed wireless access (FWA), the services offered on these technologies generally compete with only specific segments of the broadband internet market either based on location or service availability as well as services that generally fit the lower end of the bandwidth speeds offered, which generally also align with lower cost. Cable operators face much tougher competition from service providers who offer services over FTTx PON due to the higher speeds, potential for symmetrical services, and lower latencies that this technology provides. Therefore, the existence of service providers using FTTx technologies overbuilt on an HFC network and/or the threat of a service provider overbuilding an FTTx network on an HFC network are two of the main market drivers for operators moving their DOCSIS deployments to high split.

Due to the actual or potential competition from FTTx, cable operators need to increase their DS SLA speeds, and when they do this, they also need to increase the US SLA speeds for two main reasons: (1) to have enough bandwidth in the US to support the required Transmission Control Protocol (TCP) Acknowledgements (ACKs) to sustain the offered DS speed and (2) to offer US speeds that may be required or desired by a subset of their subscribers, most notably business/commercial subscribers as well as gamers and video uploaders.

Deploying FTTx services typically comes at high cost whether it is done by cable operators, telcos, or other service providers. Cable operators generally have a key advantage, especially against the potential for a new fiber optic overbuilder: the advantage is the cable network they already have in place! One of the hallmarks of DOCSIS has been the ability to enable cable operators to expand services in an evolutionary manner with incremental investments while maintaining backward compatibility for existing services, as is explored in a separate paper entitled “Network Migration to 1.8 GHz – Operational “Spectral Analysis” Measured in nano-Hertz, a 30-Year Perspective” [Maricevic_2022]. This ability afforded by DOCSIS is a key reason why cable operators are now at the point of implementing or seriously considering a move to high split (204 MHz) in the US and 1.2 GHz in the DS. The decision for an operator to deploy PON or expand with DOCSIS is not an “either/or” situation but can many times be a coexistence story where the operator deploys PON in strategic portions of its network where it makes business sense in addition to high split with 1,218 MHz on HFC. Each operator needs to evaluate its own economic, competitive, cost, strategic, etc. situation to decide which path to go relative to expanding capacity with a pure HFC network implementation, or with a hybrid HFC / PON type deployment.

2.3. Historic & Projected Service Group Capacity of DOCSIS Versus PON

Since FTTx PON competition is a key market driver for cable operators to implement high split, it would be instructive to show how DOCSIS has evolved service group bandwidth over the years and to project how it might grow. This section explores a couple of potential evolutions of an HFC network SG with both spectral changes and channel lineup changes and how that impacts the raw bandwidth per service group (SG) in the DS and US.

Figure 2 shows an example of how SG bandwidth capacity has changed over the years, illustrative of the general DS and US SG bandwidth trends over time. The example only shows an expansion up to DOCSIS 3.1 technology and maximizing out at 1.2 GHz DS and 204 MHz US.

Figure 2 – DOCSIS Service Group Bandwidth Over the Years Utilizing DOCSIS 3.1 Technology

In this example, by 2020, the operator had grown to utilize 32 SC-QAM channels and a single 192 MHz OFDM channel in the DS while the upstream remained at low split (42 MHz). The operator in this example utilized a single 3.2 MHz and four 6.4 MHz ATDMA SC-QAM channels in the US. This yielded just over 3 Gbps per SG DS, which was roughly 25 times what could be achieved in the US.

In 2022, this example added another 192 MHz block of OFDM in the DS and opted to go to mid split (85 MHz). The DS SG throughput grew to nearly 5 Gbps, while adding OFDMA to fill up the remaining 85 MHz of spectrum grew the US SG throughput to approximately 540 Mbps. This reduces the DS:US SG bandwidth ratio to about 10x. Had the operator instead opted to move to high split (204 MHz) and fill the remaining spectrum up to 204 MHz with OFDMA channel capacity, they would have increased the US SG throughput to approximately 1.5 Gbps, further dropping the DS:US SG bandwidth ratio to about 3x. While moving to high split brought the operator closer to symmetrical in DS versus US, the move did not appreciably increase the DS throughput nor efficiently utilize the spectrum that was available.

The final step in this sample HFC SG evolution has the operator moving to 1.2 GHz of spectrum in the DS and 204 MHz in the US, yielding approximately 8.6 Gbps throughput in the DS and 1.5 Gbps in the US with the ratio of DS:US at approximately 5.5x.

By way of comparison, PON offers both asymmetrical and symmetrical offerings, depending on the version of PON in use. Gigabit passive optical networking (GPON) provides 2.5 Gbps DS with 1.2 Gbps US for a 2:1 ratio. The Institute of Electrical and Electronics Engineers (IEEE) specifies a 10 gigabit per second Ethernet passive optical networking (10G EPON) downstream that can be deployed with either a 1 Gbps or a 10 Gbps upstream for either a 10:1 or a 1:1 ratio. The International Telecommunication Union (ITU) Telecommunications Specifications Sector (ITU-T) specifies 10 Gbps PON (10G-PON), which is also known as XG-PON, that pairs 10 Gbps DS with 2.5 Gbps US at a 4:1 ratio and 10 Gbps symmetrical PON (XGS-PON) that provides symmetric 10 Gbps in both DS and US for a 1:1 ratio.

When including the impact of forward error correction (FEC) on throughput, XGS-PON (and other 10G PON technologies) net capacity is ~8.5 Gbps to the SG. Considering traffic engineering, average throughput per user, and a SG size of 64 subscribers, the maximum service level agreement (SLA) that XGS-PON technology can offer at a reasonable subscriber quality of experience is ~7.5 Gbps. Therefore, the 7.5 Gbps potential SLA from XGS-PON sets the bar for the near-term future evolution of DOCSIS and HFC networks to strive for.

Figure 3 below shows an alternative SG bandwidth evolutionary path along with providing a longer future projection of the HFC network SG bandwidths. The example includes those from Figure 2 above through year 2020. In 2022 in the new example, the operator has chosen to jump straight from an 860 MHz DS and low split (42 MHz) cable plant to a 1.2 GHz DS and high split (204 MHz) cable plant, taking a larger leap in an earlier timeframe and skipping the work associated with implementing a mid-split cable plant. Starting from 2025 and later, the operator has chosen to implement D4.0 FDD, which is also known as Extended Spectrum DOCSIS (ESD), to further increase the DS and US SG bandwidth.

Figure 3 – DOCSIS Service Group Bandwidth Over the Years, Including Future Expansion Using DOCSIS 4.0

When the operator moves to D4.0 FDD, even though the maximum DS frequency can be moved up to as high as 1.8 GHz, the DS bandwidth in this example does not grow as much relative to the high split implementation from 2022 because some of what had been DS spectrum is now allocated to the US. The example shows that as the operator moves the UHS to higher frequencies, the US bandwidth grows while the DS bandwidth shrinks as the operator allocates more spectrum to the US at the expense of the DS. In this example, the operator moves through three different UHS settings: 300, 396, and 492 MHz. The example in Figure 3 shows the following:

1. DOCSIS 4.0 can achieve greater than 8.5 Gbps throughput per DS SG, more than what XGS-PON can provide
2. DOCSIS 4.0 can enable the HFC network to offer services that are much closer to symmetrical than prior implementations of DOCSIS
3. Implementing 1.2 GHz DS and high split (204 MHz) US is a clear steppingstone on the path to DOCSIS 4.0 and provides a significant amount of value with equipment that is available today.

The example in Figure 3 focuses the future steps to DOCSIS 4.0 as following the extended spectrum FDD path. A similar story could be laid out for operators who choose to implement DOCSIS 4.0 Full Duplex DOCSIS (FDX). One of the key technical differences between D4.0 FDD and D4.0 FDX is that D4.0 FDX utilizes some portions of the spectrum for both DS and US transmission while keeping the maximum DS frequency set at 1.2 GHz. An operator could chart a bandwidth evolution course to high split and then on to either D4.0 FDD or D4.0 FDX and, in theory, achieve similar results. The factors for

deciding between D4.0 FDD and D4.0 FDX are beyond the scope of this paper, but regardless of that future path, making the step to high split now puts the operator in a better position to compete and set up for the next phase of its network evolution.

At the January, 2019 Consumer Electronics Show (CES), the Internet & Television Association (NCTA), CableLabs[®], and Cable Europe announced an industry initiative generally called 10GTM, which was defined as “the cable industry’s vision for delivering 10 gigabit networks” and “a powerful, capital-efficient technology platform that will ramp up from the 1 gigabit offerings of today to speeds of 10 gigabits per second and beyond – to consumers in the United States and across the globe in the coming years” [NCTA 10G]. DOCSIS 4.0 is clearly one of the key technologies that enables 10GTM, and as high split is a logical steppingstone to DOCSIS 4.0, it is also clearly also one of the smartest steps an operator can take on the Path to 10GTM.

2.4. What Does High Split Buy the Cable Operator?

CommScope has been modeling HFC network operator bandwidth trends for well over a decade now and has utilized this data to project how operators can evolve their plants to meet the projected bandwidth demands of their end subscribers. A separate paper entitled “Broadband Capacity Growth Models – Will the end of Exponential Growth eliminate the need for DOCSIS 4.0?” by John Ulm, Dr. Zoran Maricevic, and Ram Ranganathan [ULM_2022] provides some excellent insights about what implementing high split actually buys the cable operator that will be summarized here.

The completed study performed modeling of a high (21% CAGR), moderate (16% CAGR), and low (linear) DS average busy hour user throughput (Tavg) growth rates on a 1,218/204 MHz plant offering a 5 Gbps DS, 1 Gbps US SLA. It analyzed SG size and the maximum number of subs supported over a 10-year window. The results are shown in Figure 4.

Figure 4 – Max Subs per SG for Low, Moderate & High DS Tavg growth, 1,218/204 MHz

For comparison purposes, Figure 4 also includes the 2018 projections of 43% CAGR “uber growth” – CAGR much higher than the more recent tapering of DS bandwidth growth. The 2018 projections show the max subs per SG supported would drop to 28 subs by 2030. This drove many people to think that FTTx would be required by 2030. However, the reality is that a 1,218/204 MHz plant supporting 5G x 1G tiers can easily last into the next decade, maybe even further if the slower growth projections hold.

In this case, the operator moves to high split in 2024 while simultaneously completing its migration to IPTV in the same year, reducing the legacy MPEG QAM video spectrum to zero. In 2025, the 5G DS tier is introduced and fills up most of the available 1,218 MHz of spectrum. Note that the SG size is still at 400 subs. After 2025, the SG size is reduced as needed to keep within the allotted 1,218 MHz.

Perhaps the key point of this 1,218/204 MHz case study is that a node with 150+ subs can be upgraded to 1,218/204 MHz and support a service tier of 5 Gbps x 1 Gbps for the next decade and beyond. There is no pressing near-term need to push the HFC to very small (and inefficient!) SG sizes, that could be, for example, achieved in N+0 systems. Even if the throughput follows high growth rates, the cable operator is not stuck and can node split further to a smaller SG size to meet the needs of their subscribers and/or migrate to DOCSIS 4.0.

3. Architectural Considerations for High Split

3.1. CMTS Architectures: I-CCAP, R-PHY, & R-MACPHY

There are three predominate Cable Modem Termination System (CMTS) / Converged Cable Access Platform (CCAP) architectures in the market today:

1. **Integrated CCAP (I-CCAP)**
2. **Remote PHY (R-PHY)**
3. **Remote MACPHY (R-MACPHY)**

I-CCAP is a Centralized Access Architecture (CAA) whereby an I-CCAP provides DOCSIS Media Access Control (MAC) and physical layer (PHY) functionality in a single, integrated, highly available chassis that provides high-speed data, voice, and video services on HFC networks. Figure 5 shows an example of an I-CCAP deployment in an HFC cable network.

Figure 5 – I-CCAP Centralized Access Architecture

R-PHY is a DAA whereby the PHY component of the CCAP is moved from a centralized location (in an I-CCAP) and out to a Remote PHY Device (RPD), which is housed in a shelf or a fiber node. Figure 6 shows an example R-PHY architecture implementation. The RPD handles the RF generation and reception of the signals that traverse the cable plant. The CCAP MAC functionality is provided by either a physical CCAP Core, which is typically an I-CCAP that has been evolved to support R-PHY operation, or a virtualized CCAP Core that runs on common off-the-shelf (COTS) servers in the headend. From headend to RPD, the signals typically traverse an Ethernet network and over digital optics. The migration from analog / amplitude modulated optics as utilized in an I-CCAP CAA architecture to digital optics provides benefits by reducing the noise introduced on the HFC plant by the analog optics. Given the reduction in noise on the HFC network and the pushing of the RF signal generation to the edge of the network, the channels can be received typically with higher modulation error ratio (MER) than in an I-CCAP architecture, and this results in the ability to utilize higher modulation orders and a more efficient use of the RF spectrum.

Furthermore, moving the PHY function to a fiber node can reduce the cable operator's rack space, power, and cooling requirements for the cable headends and operator facilities. In this architecture, the RPDs are aggregated by a Converged Interconnect Network (CIN), which is comprised of switches/routers that connect the RPDs to the cores, software systems, and the internet to round out the network.

Figure 6 – Remote PHY Distributed Access Architecture

R-MACPHY is another DAA whereby both the MAC and PHY components of the CCAP are located in a Remote MACPHY Device (RMD), which can also reside in a shelf or a fiber node. Figure 7 shows an example R-MACPHY architecture implementation.

Like R-PHY, R-MACPHY also utilizes Ethernet and digital optics for the fiber optic distribution network and has similar benefits as R-PHY. With R-MACPHY, both the MAC and PHY functionality are moved to the remote location—typically in a fiber node—and this colocation has some additional benefits including better latency performance and, depending on the application and implementation, the potential to remove the need for the IEEE 1588 Precision Timing Protocol (PTP) grandmaster clock and associated timing network, further simplifying the network.

Similar to R-PHY, RMDs are also aggregated via a CIN. In the cable operator headend and similar to R-PHY, the RMDs connect to OSS/BSS, a video core, and, in the newer Flexible MAC Architecture (FMA) as defined by CableLabs, an FMA Core and/or MAC Manager. RMD is the main access component, which is an intelligent device performing the following functions, among others:

- Support DOCSIS MAC functionality, including DOCSIS signaling functions
- Provide all PHY-related circuitry such as downstream QAM & OFDM modulators and upstream QAM & OFDMA demodulators
- Convert downstream MPEG video received from a video core and downstream legacy out-of-band signals received over a digital transport link, such as Ethernet, into analog for transmission over RF
- Convert upstream legacy analog out-of-band signals received over RF into digital for transmission over a digital transport link, such as Ethernet.

R-MACPHY deployments arguably consume less total system power than either the I-CCAP or R-PHY alternatives.

Figure 7 – Remote MACPHY Distributed Access Architecture

The great news for cable operators is that a migration to high split is both possible and can make sense for any of these architectures, and high split deployments are currently in the field on all three architectures using today's technology!

When an operator upgrades the HFC network to high split, the main components that get upgraded in all of these architectures are the actives in the cable plant, including the fiber node and RF amplifiers (line extenders (LEs) and bridger amps (MBs)). Whether deploying a CAA or DAA, the RF tray in the node needs to be upgraded to support high split (204 MHz) operation. Operators may typically want to leverage the fiber node visit to also move the downstream to support up to 1.2 GHz. With a CAA, the amplitude modulated optics can be implemented as analog in the return path, but the use of digital optics in the return path as offered by some vendors provides significantly improved performance. Generally, analog return path is better suited to shorter fiber links (approximately 10 miles or less) while digital return provides even more pronounced benefits at longer fiber links. When implementing a DAA, then the fiber optic link is handled by Ethernet links and digital optics.

Independent of implementing a CAA or DAA, the considerations for the upgrades to the actives and passives in the cable plant between the fiber node and the subscribers are the same. Generally, the RF amplifiers (actives) need to be upgraded to support 204 MHz operation in the upstream path, and most of the options already include support for 1.2 GHz operation in the downstream path as well. These upgrades to the amplifiers typically allow for the housing to remain in place while the active part of the product is swapped out. This saves time and cost and reduces the potential for problems to arise from cutting out and replacing products. Regarding passives, if taps currently deployed are limited to 1 GHz operation, the operator may choose to upgrade these to support 1.2 GHz via a tap faceplate swap while working on the cable plant. When operators implement the upgrade to high split, they will generally need to upgrade the node and subtended amplifiers at the same time or avoid using a portion of the spectrum while making the switch. If an operator is using conditioned taps, then the conditioning in place—whether via attenuation, equalizers (EQs), or cable simulators—may need to be adjusted to handle the new frequencies in use.

There are some considerations for implementing high split when looking at these three main CMTS/CCAP architectures. When embarking on an HFC network evolutionary step like high split, it is helpful to look out a couple potential steps ahead to leverage the work that needs to happen to better prepare the operator for a step beyond the high split. A DOCSIS 4.0 system, whether FDD or FDX, is generally predicated on implementing a DAA. For D4.0 FDD, a DAA is required to be in place because the HFC access technologies vendors are not currently planning on implementing analog / amplitude modulated optics that can support beyond 1,218 MHz. For D4.0 FDX, the spectrum that is shared between downstream and upstream can only really function well if the PHY is located near the edge of the network. Therefore, given that the operator will likely need to move to a DAA as the next evolutionary step to DOCSIS 4.0, it may make sense to leverage the planned node visit for doing the high-split upgrade to also implement a DAA at the same time. However, the great news is that moving to a DAA is definitely not required. Moving to a DAA requires additional coordination and work by the operator, so the operator may choose to implement high split with I-CCAP CAA first to get the benefits for some portions of the network and then subsequently upgrade to a DAA later in time. Products in the market today provide the flexibility to support multiple evolutionary steps that include a migration to high split!

One of the most common locations for RMDs and RPDs is in the optical fiber node. An RMD will contain network interfaces, such as Ethernet, and perform DOCSIS MAC and PHY functions, QAM video PHY functions, and RF functions including upstream analog signal receive and processing, all contained within a single module. As such, operators will want to ensure that legacy HFC node housings

currently deployed can be initially upgraded to a high split configuration and are later upgradeable to FDD-, FDX-, and/or FMA-compliant nodes via installation of RMD or RPD modules.

Production hardware capable of 1.8 GHz D4.0 FDD or 1.2 GHz FDX operation is not yet available as of the writing of this paper. However, many operators have either already deployed or are trialing D3.1 RMD and RPD solutions and planning for eventual production deployments. Therefore, initial high split deployments must be part of larger initiatives that lay the groundwork for higher frequencies and bandwidth in both downstream and upstream directions. This strategy ensures support for future migrations to DAA solutions that will lead to improved RF signal quality and greater efficiencies in speed, reliability, latency and security.

Operators may need to support more symmetrical gigabit upstream speeds on their I-CCAP infrastructure. The initial phase of a transition to a high-split architecture includes the RF amplifier upgrades and may continue to leverage traditional analog optics for downstream signal transport if the lasers are already 1.2 GHz-capable. For the upstream, digital return optics based on sampling and digitization of return analog TDMA and OFDMA carriers at the node transport those signals back to the I-CCAP at the hub or headend facility. An upgrade to 5-204 MHz modules is necessary, both for the node transmitters and the headend digital receivers. Legacy analog return optical links, typically capable of supporting expanded return bandwidths, can continue to be used but care must be taken to ensure their set operating points are adjusted for the expanded high-split bandwidth load to maintain desired signal-to-noise ratio (SNR) and MER performance targets.

As DAA architectures further mature, deployment of DAA (RMD and/or RPD) technologies can start in select areas as the next rollout phase supporting the migration to a high-split HFC network. At that point, new bi-directional digital Ethernet links will replace traditional analog optics and legacy digital optics as nodes are converted to DAA. Legacy nodes upgraded with RMDs or RPDs remain in place supporting DOCSIS 3.1 services over upgraded high-split coaxial networks, enabling operators to benefit from significant improvements in RF signal quality and ready to support a future transition to D4.0 FDD or FDX operation.

3.2. Spectral Considerations

When operators implement high split (204 MHz) in the upstream, operators need to clear out the spectrum from 54 MHz to 258 Mhz that had typically been used in the downstream and will now be repurposed. A simultaneous migration to 1,218 MHz can help by increasing the overall spectrum in use on the cable plant and enabling operators to shift the downstream spectrum up in frequency. However, this may not be enough to free up the desired spectrum. Therefore, the operator may need to implement additional strategies to free up spectrum, some of which include the following:

- Harvesting / removal of video channels that have a low subscriber watch rate
- Implementation of Switched Digital Video (SDV) for MPEG QAM video
- Migration of QAM video from MPEG-2 to MPEG-4 for greater compression
- Evolution from MPEG QAM video to IP video delivery.

When moving to high split, if an operator has legacy MPEG QAM set-top boxes (STBs) deployed, then one of the legacy STB out-of-band (OOB) is typically utilized, either SCTE 55-1 [SCTE 55-1] or SCTE 55-2 [SCTE 55-2]. While these protocols have served cable operators well in providing interactive video services to subscribers for years, the signals that are used in the downstream for these implementations typically fall between 85 MHz and 204 MHz and are thus now in the upstream direction once a cable

plant is migrated to high split. Two popular methods of dealing with this issue when evolving to high split include the following:

1. Migrate to STBs with embedded cable modems (CMs), potentially also compliant with the DOCSIS Set-Top Gateway (DSG) specification [DSG]. Note that some legacy STBs can be field upgraded from supporting legacy STB OOB to supporting DSG.
2. Migrate to all IP video delivery with IP STBs.

When employing one of the two strategies above, operators should take care that any STB upgrades that take place truly remove the need for any legacy STB OOB signaling as some STB implementations still required legacy STB OOB to either boot-up or for specific functions that required subsequent STB software upgrades to disable.

Cable operators may have some additional signals on the plant that need to be either disabled, relocated, or specially handled, especially when moving to a DAA. For example, cable operators in Europe who have previously operated frequency modulation (FM) radio application on the cable plant will likely need to shut this service down in order to support high split. When moving to a DAA, some of the plant alignment tones can be locally generated by the RPD or RMD. For other narrowband signals that may need to be preserved, the operator can implement Narrowband Digital Forward / Narrowband Digital Return (NDF/NDR) [R-OOB].

In summary, the cable operator needs to explore the entire spectrum in use today and ensure that all services are accounted for in some way when migrating to high split and/or a DAA. Products and features are available to help ensure that nearly all of the services can be available after the migration, but the operator may need to make some decisions on specific services to impact in order to get the greater benefit of improved upstream and downstream bandwidth.

3.3. Leakage Detection

Migration to high split and ultra-high split systems will require moving the upstream/downstream split further up into and potentially above the aeronautical band. Figure 8 below illustrates how the migration to a high-split architecture today—and migrations to even higher splits in the future—will incrementally turn legacy downstream spectrum currently within the aeronautical bands into new upstream bandwidth. This will require new approaches from operators to continue to monitor and repair signal leakage in compliance with existing United States Federal Communications Commission (FCC) and other international governing body rules. Some of the approaches being explored include:

1. Leveraging OFDMA Upstream Data Profile (OUDP) test bursts
2. Implementation of exclusion zones
3. Upgrading legacy leakage meters to detect downstream OFDM pilots.

With OUDP, upstream OFDMA signals will be generated by all cable modems that are provisioned for HS mode to allow new test equipment to detect egress from coaxial plant and accurately measure it for enterprise reporting. The concept involves cable modems that are instructed to generate OUDP test bursts in open timeslots and using specific CMTS configurations and OFDMA parameters that are considered optimum for accurately detecting leakage when driving either slowly or quickly past an RF leak. Specific parameters include subcarrier spacing, cyclic-prefix, roll-off-period, symbols-per-frame, data IUC modulation, pilot pattern, transmit burst gap between CMs, transmit duration and the frequency transmit location(s). Each modem will be instructed to repeat transmissions in a round-robin fashion, so RF Leakage detectors are not reliant on customer upstream data traffic. The primary benefit of using signals from cable modems is that their RF level is the same amplitude as the OFDMA signal which allows for a

much higher capture resolution and accuracy when a vehicle is in motion. A further exploration of this strategy can be found in a prior SCTE paper, “Leakage In A High Split World – Detecting and Measuring Upstream Leakage Levels in a One Gbps Symmetrical High Split Hybrid Fiber Coax Network” by John Chrostowski, et. al. [Chrostowski 2020].

Implementation of exclusion zones carved out of downstream OFDM carriers would allow the insertion of tag signals which would allow the continuous use of legacy leakage detection field meters.

Upgraded meters would allow detection of OFDM pilots within a large bandwidth range.

Interoperability testing to refine and evaluate the effectiveness of these proposed approaches, and their variations, is currently under way. Results today are encouraging, and options to support leakage monitoring obligations are within reach.

Figure 8 – DOCSIS 4.0 Frequency Split Roadmap vs. FCC-governed Aeronautical Bands

3.4. Customer Premise Equipment (CPE) Considerations

When operators decide to move to a high-split implementation, one of the first steps they need to take is to start pre-seeding the market with customer premise equipment (CPE) / CMs that have a selectable diplex filter that is remotely switchable to support the current split—low split (42 MHz or 65 MHz) or mid split (85 MHz)—in addition to high split (204 MHz). Having a large set of modems already in the field that are capable of high split will make it easy to take full advantage of the benefits of high split once the rest of the network elements have been evolved to make it a reality. Therefore, it is imperative for cable operators to start deploying cable modems that have the desired high-split diplexer capability early in time so that the market has enough critical mass of modems in use to justify and take advantage of the upgrade to high split.

After the operator has deployed enough high-split-capable CPE and enabled high split in the network, remotely forcing the CPE to use the new US and DS spectral ranges is critical. There are two main methods for this. One method involves configuring the MAC Domain in the I-CCAP, CCAP Core (for R-PHY), or RMD to tell the modems to start using the high split diplexer setting. This is then communicated down to the cable modems through the MAC Domain Descriptor (MDD) as type-length-value (TLV) 21 as defined in the D3.1 MAC and Upper Layer Protocols Interface Specification [DOCSIS 3.1 MULPI]. This implementation is relatively easy since it is down at the MAC domain level and not at the individual CM level. An alternate method is to set the diplexer setting via the CM config file, and this utilizes TLV 84 in the config file as defined in the same specification and which supersedes any TLV 21 setting in the

MDD [DOCSIS 3.1 MULPI]. While more difficult to manage down to the CM level, TLV 84 provides operators with more granular control of CMs that utilize high split and may become useful. With these two methods, operators have the ability to more broadly implement or to specifically pinpoint high split on the installed CPE as required for the given implementation.

When implementing high split, cable operators may need to address the legacy video CPE that are on the network due to the legacy STB OOB signals that would traditionally be in the downstream spectrum that is now utilized in the upstream. This topic has been explored in more detail in Section 3.2 and will also be explored in Section 5.2.2 but is listed in this section for completeness.

3.4.1. *Potential High-Split CPE Interference on Legacy CPE*

When implementing high split on CPEs, it is also possible that the upstream transmissions from the CMs may interfere with other legacy CPE, such as video STBs and legacy D2.0 and D3.0 CMs, that may not be high-split capable. In short, the transmissions in the upstream band from 54 MHz to 204 MHz may overlap with the downstream spectral window for the legacy CPE, and given that the high-split CM and legacy CPE are close to each other on the cable plant, the transmissions will be relatively high power and may cause issues.

There are two typical potential scenarios that have been considered relative to the potential interference of US transmit signals from high-split CPE on legacy video STBs and legacy D2.0 and D3.0 CMs: single home interference and neighbor-to-neighbor interference, as shown in Figure 9. Testing conducted by CableLabs, vendors, and multiple cable operators across a large set of legacy STBs has shown that STBs generally cannot handle an adjacent D3.1 transmit interference level known as the Carrier-to-Adjacent Carrier Interference Ratio (CACIR) where the interfering US transmission signal is 20 dB higher than the downstream video QAM receive level. Above this level of interference leads to MPEG video data corruption and resulting in an impacted video signal, including tiling and other potential artifacts. D2.0 or D3.0 legacy modems may also experience packet loss. The impacts are generally caused because the automatic gain control (AGC) functional blocks in the legacy CPE devices may be overdriven due to the relatively high-power US transmissions coming from the nearby D3.0 high-split CPE.

Figure 9 – Two Potential High-Split CPE Interference Scenarios

Luckily for both cable operators and end subscribers, interference that has a CACIR of 20 dB or higher is generally very uncommonly seen by operators in the field. Studies have shown that the neighbor-to-neighbor interference would require an extremely rare set of conditions for both neighboring premises to have. Typically, the scenarios that have impacts are with single home interference for a small set of

subscribers who have significant RF losses either in the drop to the premise or in the premise. For these scenarios, the DS signal level into the video STBs will already be quite low while the D3.1 modems running with high split enabled will be operating near the top of their RF output power range to overcome the losses within the in-home cable network. These subscribers have typically already been highlighted as needing improvements by typical cable plant monitoring and maintenance efforts. Additionally, operators can use the monitoring of STB receive power levels and D3.1 high-split CPE transmit levels to identify premises that might be at risk of experiencing such interference and then take steps to correct these scenarios.

Cable operators can mitigate cases of potential or actual interference through several potential solutions, including the following:

- Improving the in-premise cable network and/or drop to the premise to decrease the signal attenuation
- Reconfiguration of the in-premise cable network to better isolate the D3.1 high-split CPE by not placing them on the same RF splitter as legacy CPE that may be impacted by interference
- Replacing in-premise RF splitters with RF splitters that have higher isolation
- Installing band-stop RF filters to filter out the 54 MHz to 204 MHz spectral range for the legacy CPEs. Note that this solution should be used sparingly as the band-stop RF filters need to be very strategically placed within the subscriber premise, and the subscriber potentially moving such filters could cause issue with the high-split CPE deployments.

4. Operational Considerations for High Split

4.1. Upstream Level Considerations

4.1.1. Levels Out of Cable Modem (CM)

In DOCSIS 2.0 (D2.0), quadrature phase shift keying (QPSK) modulation remained as one of the constellations for the return path, and was assigned higher maximum power than the max power for the higher-level constellations, such as 16QAM and 64QAM, as shown in Table 2 from the DOCSIS 2.0 Radio Frequency Interface (RFI) specification [DOCSIS 2.0 RFI]. At first glance, this specification may appear as an error because the higher-level constellations do require a higher signal to noise and as such, would benefit from higher power transmission – provided, that the underlying noise is thermal / white Gaussian in nature.

Table 2 – Upstream Cable Modem Levels from D2.0 RFI Specification

Table 6-6 Constellation Gains and Power Limits

Constellation	Constellation Gain G_{const} Relative to 64QAM (dB)	P_{min} (dBmV)	P_{max} (dBmV) TDMA	P_{max} (dBmV) S-CDMA	$P_{min} - G_{const}$ (dBmV)	$P_{max} - G_{const}$ (dBmV) TDMA	$P_{max} - G_{const}$ (dBmV) S-CDMA
QPSK	-1.18	8	58	53	9.18	59.18	54.18
8QAM	-0.21	8	55	53	8.21	55.21	53.21
16QAM	-0.21	8	55	53	8.21	55.21	53.21
32QAM	0.00	8	54	53	8.00	54.00	53.00
64QAM	0.00	8	54	53	8.00	54.00	53.00
128QAM	0.05	8	N/A	53	7.95	N/A	52.95

But there was no error in Table 2, because QPSK, even though not very bit-per-second-per-hertz efficient, remained to deal with the presence of sizable ingress interference. Table 3 gives further clarification – QPSK was needed for those situations when carrier-to-interference plus ingress was in the mid-20 dB range, and as pointed to in Note 2 from the table, those time-varying ingress bursts could be as high as 10 dB below the signal. Therefore, there was a desire and need to keep QPSK as one of the options and to keep its max power high.

Table 3 – Assumed Upstream RF Channel Characteristics from D2.0 RFI

Table 4-2 Assumed Upstream RF Channel Transmission Characteristics (see note 1)

Parameter	Value
Frequency range	5 to 42 MHz edge to edge
Transit delay from the most distant CM to the nearest CM or CMTS	<= 0.800 msec (typically much less)
Carrier-to-interference plus ingress (the sum of noise, distortion, common-path distortion and cross-modulation and the sum of discrete and broadband ingress signals, impulse noise excluded) ratio	Not less than 25 dB (Note 2)
Carrier hum modulation	Not greater than -23 dBc (7.0%)
Burst noise	Not longer than 10 μ sec at a 1 kHz average rate for most cases (Notes 3 and 4)
Amplitude ripple 5-42 MHz:	0.5 dB/MHz
Group delay ripple 5-42 MHz:	200 ns/MHz
Micro-reflections – single echo	-10 dBc @ <= 0.5 μ sec -20 dBc @ <= 1.0 μ sec -30 dBc @ > 1.0 μ sec
Seasonal and diurnal reverse gain (loss) variation	Not greater than 14 dB min to max

2. Ingress avoidance or tolerance techniques may be used to ensure operation in the presence of time-varying discrete ingress signals that could be as high as 10 dBc. The ratios are guaranteed only within the digital carrier channels.

How high? As high as 58 dBmV per single QPSK channel of D2.0 as sourced from a cable modem. Then, the DOCSIS 3.0 Physical Layer Specification [DOCSIS 3.0 PHY] takes it a step higher, as shown in Table 4: a D3.0 cable modem must be able to generate a QPSK channel with a minimum of 61 dBmV if using a single channel and the same total power if distributed across 2 or 4 QPSK channels.

Table 4 – D3.0 per Channel Power Levels Out of Cable Modem, with Highlighted Max Points

Table 6-21 - Electrical Output from CM⁴⁶

Parameter	Value
Level range per channel (Multiple Transmit Channel mode disabled, or only Multiple Transmit Channel mode enabled with one channel in the TCS)	TDMA: P _{min} to +57 dBmV (32-QAM, 64-QAM) P _{min} to +58 dBmV (8-QAM, 16-QAM) P _{min} to +61 dBmV (QPSK) S-CDMA: P _{min} to +56 dBmV (all modulations)
Level range per channel (two channels in the TCS)	TDMA: P _{min} to +54 dBmV (32-QAM, 64-QAM) P _{min} to +55 dBmV (8-QAM, 16-QAM) P _{min} to +58 dBmV (QPSK)
Level range per channel (three or four channels in the TCS)	TDMA: P _{min} to +51 dBmV (32-QAM, 64-QAM) P _{min} to +52 dBmV (8-QAM, 16-QAM) P _{min} to +55 dBmV (QPSK)

With the introduction of D3.1 [DOCSIS 3.1 PHY], no per-channel max power increases take place; however, the total composite power is nudged up, from 58 dBmV for D2.0, and 61 dBmV for D3.0, to 65 dBmV, as shown in Figure 10. D3.1 also increased the maximum US spectrum to 204 MHz. The latest

DOCSIS spec, D4.0, stays with the same 65 dBmV total composite power (TCP) limit, provided the whole D4.0 upstream spectrum, up to 684 MHz, is utilized [DOCSIS 4.0 PHY].

7.4.12.2 Transmit Power Requirements

The transmit power requirements are a function of the number and occupied bandwidth of the OFDMA and legacy channels in the TCS. The minimum highest value of the total power output of the CM P_{\max} is 65 dBmV, although higher values are allowed. The total maximum power is distributed among the channels in the TCS, based on equal power spectral density (PSD) when the OFDMA and legacy channels are fully granted to the CM. Channels can then be reduced in power from their max power that was possible based on equal PSD allocated (with limits on the reduction). This ensures that each channel can be set to a power range (within the DRW) between its maximum power, $P_{1.6\text{hi}}$, and minimum power, $P_{1.6\text{low}}$, and that any possible transmit grant combination can be accommodated without exceeding the transmit power capability of the CM.

Maximum equivalent channel power ($P_{1.6\text{hi}}$) is calculated as $P_{1.6\text{hi}} = P_{\max} \text{ dBmV} - 10\log_{10}(N_{\text{eq}})$.

For a CM operating with a DOCSIS 3.1 CMTS, even on a SC-QAM channel, the CMTS MUST limit the commanded $P_{1.6\text{hi}}$ to no more than 53.2 dBmV+ ($P_{\max} - 65$) if the bandwidth of the modulated spectrum is ≤ 24 MHz. This enforces a maximum power spectral density of P_{\max} dBmV per 24 MHz. This limit on power spectral density does not apply for a CM operating with a DOCSIS 3.0 CMTS, where the fidelity requirements are the DOCSIS 3.0 fidelity requirements and not the DOCSIS 3.1 fidelity requirements.

SC-QAM channels that are 6.4 MHz in BW have a power of $P_{1.6\text{r}_n} + 6$ dB.

Figure 10 – D3.1 PHY Spec Snippets, Requiring TCP of 65 dBmV Out of the CM

Figure 11 shows how the above TCP-focused specs translate to per-channel levels with the upper left-most green line showing D3.1 high-split levels and the other lines/colors showing various levels of D4.0 FDD ultra-high splits. Please note that the vertical y-axis shows power per 1.6 MHz-wide channel, the method used in the PHY specs. For power per 6.4 MHz-wide channel, one should add 6 dB to all the per-channel powers.

Figure 11 – Max HS CM Levels (Green) with Various Ultra-High-Split Options of D4.0 FDD

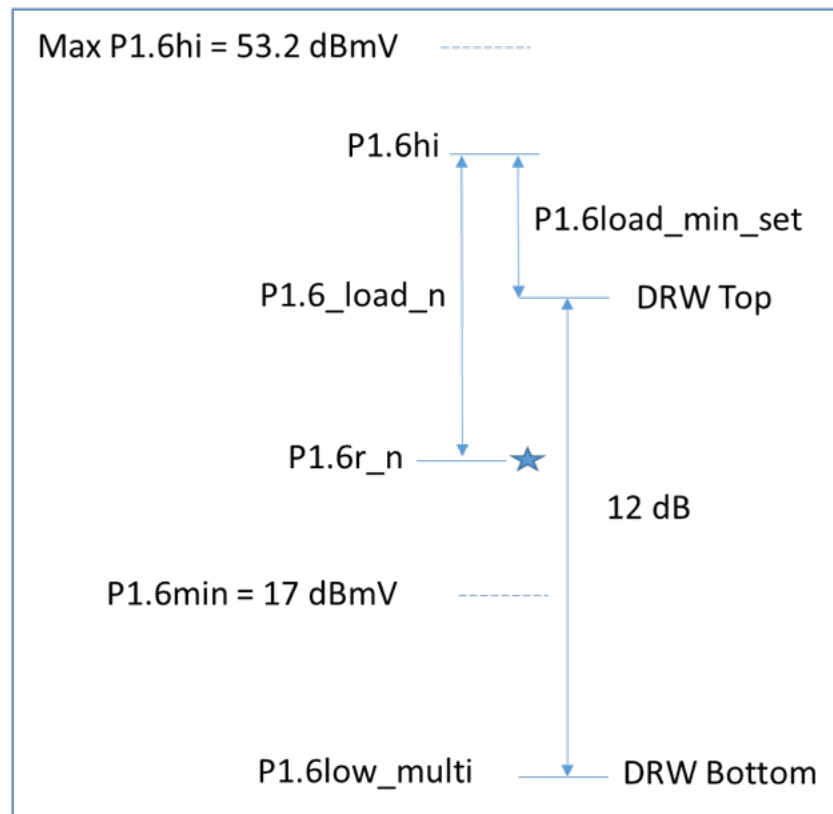

Figure 3.2.7-4. Transmit power at the CM

Figure 12 – Dynamic Range Window (DRW) Considerations from D3.1 PHY

Thus, in comparison to US levels specified in previous DOCIS versions, both TCP and per-channel D3.1 levels are high enough – which gives plenty of room to overcome whatever spurious noises the upstream plant may present. In comparison with the D4.0 levels, the maximum D3.1 high-split levels are also higher—about 6 dB higher and range from ~48 to ~52 dBmV per 6.4 MHz-wide channel, as can be seen in Figure 11. Operators, however, should exhibit caution in approaching the maximum levels, for several reasons as outlined below.

The first reason is that cable modem termination systems (CMTSs) “normally administers dynamic range window (DRW) of 12 dB.” Exact dynamic range window (DRW) details per D3.1 PHY spec are shown in Figure 12. One way to think of this aspect is that HS CM shall not be commanded a TCP higher than 59 dBmV, which corresponds to ~44 dBmV/6.4 MHz channel. If reached, this TCP range is often denoted as a “red zone” by the operators.

The second reason is outlined in Section 4.1.2 below.

4.1.2. Levels into RF Amplifier Upstream Ports

The second reason operators should exhibit caution in approaching the maximum modem transmit levels when operating high split is that the upstream power into the return RF amplifiers should fall into a “Goldilocks” (also known as “just right”) range recommended by the amplifier manufacturers: not too low so as to get affected by thermal noise and the amplifier’s noise figure, and not too high so as to get distorted in the upstream gain stage. Per CommScope’s MB120 amplifier data sheet [MB120 data sheet],

as an example, the high-split configuration upstream distortion specs are shown for 33 upstream channels at 5 dBmV per 6.4 MHz at the amplifier's upstream input port.

Figure 13 shows an in-between RF amplifiers section of HFC plant, as a backdrop for various levels discussed. For completeness, the tap values were selected in order to set the customer-premise downstream levels to fit within -6 to +8 dBmV per 6 MHz-wide downstream channel range, as shown in Figure 14.

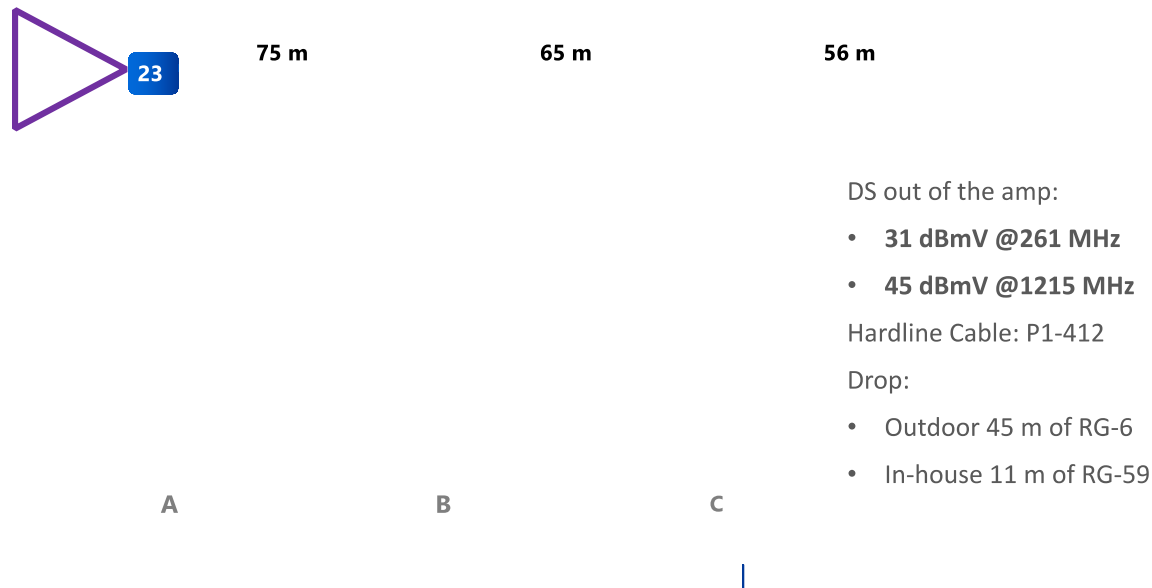

Figure 13 – An Example Section of HFC Plant in Between Two RF Amplifiers

Figure 14 – Actual Per-channel DS Levels, at an RF Amplifier Output and at Customer Premises

Figure 15 – CM Upstream Levels, and the Resulting Input-into-RF Amp Levels

The upstream levels into the RF amplifier, driven by the CM's 31/35, 27/35, and 24/34 dBmV at lowest/highest upstream channel at premises A, B, and C, respectively, are shown in Figure 15. The “smile” shape in the 3 “@Amp” curves is due to the cable loss signature, driven by the selected linearly-up-sloped CM output. The CM TCP comes to 48, 46, and 44 dBmV at premises A, B, and C, respectively.

A more exacting method of DS/US alignment can be carried if “conditioned taps” are used in place of the regular ones. In Figure 16, the first tap, with the original 23 dB value, is replaced by a 17 dB tap with an internal 6 dB cable simulator plugin. Similarly, the third tap with the original 11 dB value, is replaced by a 4 dB tap with an internal 6 dB cable equalizer plugin. As a result, the downstream levels at the conditioned A and C drops will match those of B; and similarly, as shown in Figure 16, the same CM levels out of A, B and C cable modems will produce an identical level into the upstream RF amplifier input port.

Figure 16 – Conditioned Taps Example for an Even Further Optimized Plant Section

The effort required to perform this level of balancing does not appear to produce enough improvement in the high-split plant to pay for itself, and is hereby mentioned as an option, although rarely employed operationally. That may, however, change with introduction of D4.0 and ultra-high splits.

4.2. Field Components Upgrade Considerations – “Rip and Replace” or “Modules Only?”

At minimum, high-split upgrades affect the fiber node and RF amplifiers. In some cases, the RF taps and passives may get a refresh as well. One of the key decisions to consider when upgrading nodes and amps is whether to “rip and replace” the whole housings or to just upgrade the modules inside.

The modules-only approach has several advantages, such as:

- Faster to complete – which leads to less down time
- Crews are more efficient – get more nodes done in a shift
- Fewer opportunities for the things to go wrong (such as broken fiber pigtails, cracked coaxial cable, bent connectors) – thus avoiding “opening a can of worms”
- Lower cost of labor encountered – by eliminating re-connectorization of coaxial cable and/or fiber splicing.

There are, however, several reasons where it makes sense to “rip and replace”:

- If the new device offers future-proof options not available in the old one
- Is the old housing in acceptable shape? If not, replacement is the only option
- Is the old device type an unsupported product? If yes, cut out and use the “standard” product.
- If standardization driven – even if the old device is a supported product, it may get replaced because of standardization.

Standardization does matter as it improves inventory management and thus reduces overall inventory needs. Fewer spares are carried on a technicians’ trucks, and tech training is simplified, which further minimizes opportunities for human error.

Figure 17 and Figure 18 show details of the node replacement process, in support of and as an illustration of how involved it may get, especially if executing the “rip-and-replace” strategy.

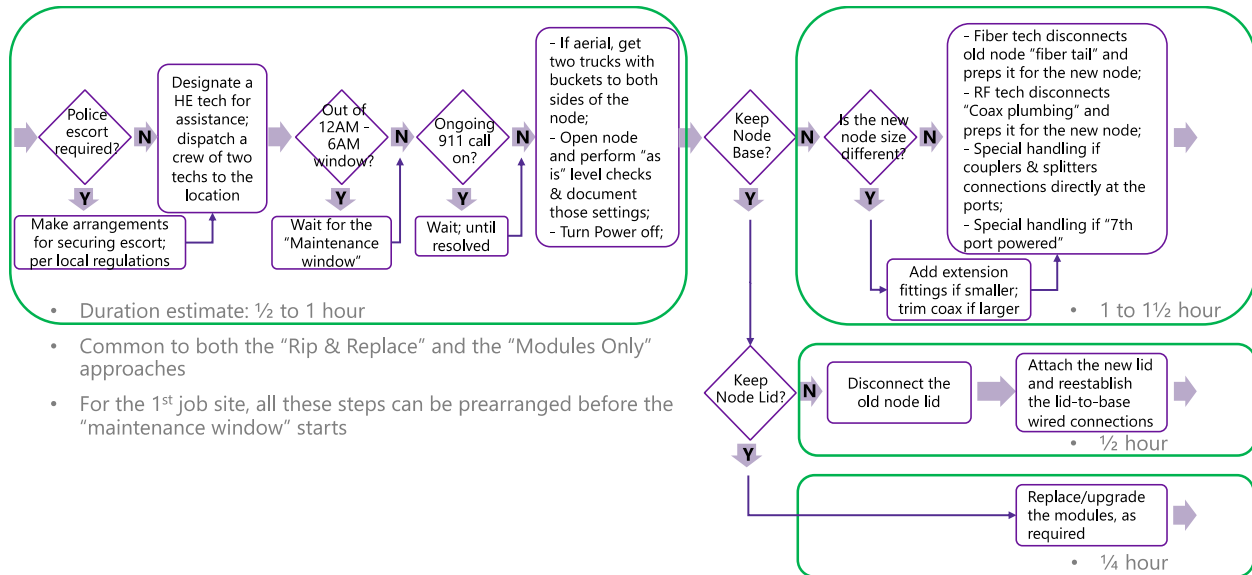

Figure 17 – How to Replace a Node – Initiation and Replumbing Part of the Process

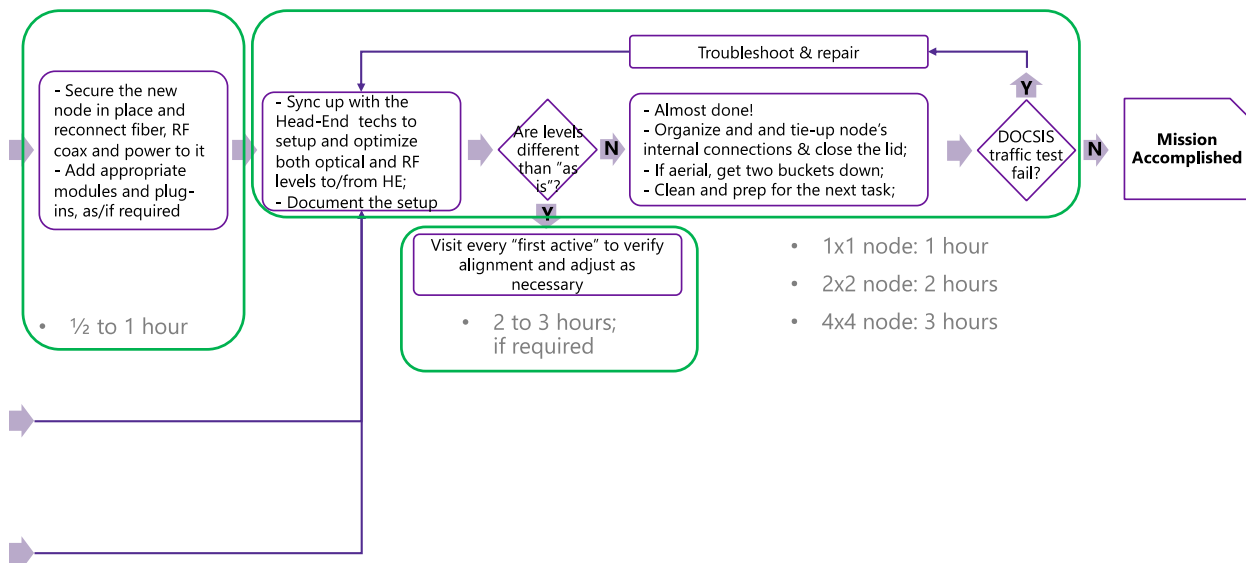

Figure 18 – Setup & Wrap-up Part of the Node Replacement Process

5. Shaw Communications – High-Split Lessons Learned

Shaw Communications has embarked on deploying both mid split (85 MHz) and high split (204 MHz) along with 1,218 MHz downstream in their HFC network. This section describes thoughts behind the upgrade, key considerations, potential future migrations, and lessons learned.

5.1. Why the Need to Modernize the Network Beyond Mid Split?

Mid-split deployments are becoming more and more common for great reasons. With the sudden rise in upstream traffic during the COVID-19 pandemic, mid-split deployment plans for most operators have increased in priority and scale. Mid-split upgrades provide a rapid, cost-effective method for immediate congestion relief. However, for most operators the business case for mid-split upgrades has been primarily focused on congestion mitigation while the benefits of broadband tier enablement are usually discounted. As a result, the broadband speeds offered in the marketplace are typically defined solely by an operator's congestion management strategy. Competitive FTTx deployments will force many operators to shift this thought process.

In many markets around the world, cable operators are facing more competition from well-funded players (typically quadruple-play telco operators) who are aggressively deploying FTTx networks at scale. Even operators with significant mid-split deployments (such as Shaw) face substantial market pressures from the aggressive advertising on the purported advantages of a pure fiber network, along with very aggressive speeds tiers in market. In the Canadian market, Shaw is already seeing competitive 2.5 Gbps symmetrical tiers become broadly available as of the writing of this paper.

While broadband tiers enabled by a mid-split network have been very successful in competing against GPON offerings, these tiers will not be as competitive once FTTx deployments shift to 10 Gbps-capable PON technologies, such as 10G EPON and XGS-PON. As a result, it is paramount that cable operators think beyond mid split and look towards future technologies such as high split and D4.0 to ensure they remain relevant in a very competitive marketplace.

5.2. Key High-Split Readiness Activities (with a Mind Towards DOCSIS 4.0)

Operators who have D4.0 FDD deployment ambitions can utilize high-split deployments as an opportunity to set themselves up for success by dealing with some of the foundational readiness activities early. The following is a summary of key activities an operator can undertake within their high-split programs to assist a future D4.0 transition.

5.2.1. Network Architecture Readiness

As noted, Section 3.1, there are multiple architecture options that can enable high-split deployments. If an operator has D4.0 deployment ambitions, starting down the DAA path is critical. It is recommended that operators include the following architectural considerations when defining their high split upgrade program:

- DAA to implement: R-PHY or R-MACPHY
- Node fiber availability to support analog-to-digital optics conversion
- Proactive cascade reductions
- HFC power supply upgrades
- Elimination of 3x3 and 4x4 (DS-SG x US-SG) node configurations (to ensure compatibility with DAA upgrades given the capabilities of the RPDs and RMDs in the market today).

5.2.2. Set-Top Boxes with Legacy Out-of-Band Signaling

Most operators have set-top boxes deployed in their networks that require SCTE 55-1 or 55-2 out-of-band (OOB) signals to operate. As noted previously in this paper maintaining these signals requires some extra efforts in a high-split network.

Shaw elected to fully reclaim these legacy set top boxes and only support DOCSIS Set-Top Gateway (DSG) or IPTV video set-tops in Shaw's high split network deployments. Note that DSG STBs utilize an embedded cable modem and thus preclude the need for the legacy SCTE 55-1 or 55-2 STB out-of-band signaling. This approach operationally simplifies the deployments while ensuring Shaw is effectively managing the lifecycle of legacy equipment in the network.

It should be noted that should an operator elect to leverage DSG set-top boxes with high split, it is critical that they test this equipment to ensure the capability of operating in a mode where the legacy OOB signals are not present. Some of the DSG STB equipment requires the legacy OOB to come online to function correctly. In this situation, these DSG STBs are not compatible with a high split deployment and will require software updates to eliminate the dependency on the OOB carrier. The potential issue is solvable by working with the STB vendor, but it is good to plan ahead so the operator is not caught off-guard waiting for a vendor STB software update that was unexpected.

5.2.3. On-Premises Architecture

When looking at the on-premises network architecture, operators need to consider the following when defining their go-to-market strategy for implementing high split:

5.2.3.1. On-Premises Interference Risk

Many operators deploy multiple coaxial cable-based customer premises equipment (CPE) in the same premises network to support high-speed data, voice, and video services. There is a risk when high-split and sub/mid-split CPE deployed in the same in-home network that a high transmit level on high split CPE can overload the tuner of the sub/mid split CPE in the same home. If this were to occur services supported by the sub/mid split CPE could be intermittent.

5.2.3.2. Wi-Fi & Ethernet Distribution

With the advancement of next generation Wi-Fi technologies (Wi-Fi 6, 6E) and the proliferation of structured Ethernet wiring (Cat 5E/6), the home IP network is becoming more capable and easier to use than ever. In addition, the market scale of these technologies will drive future capabilities and cost optimizations that are not easily replicated on the coaxial networks in the premise.

5.2.3.3. Future Access Network Considerations

To minimize future re-work, it is important to align HFC install practices with future FTTx, and D4.0 considerations. In these use cases, coaxial cable-based in-home networks are not ideal, and customers are best supported by Wi-Fi and wired Ethernet systems.

Operators should strongly consider moving to a point-of-entry style modem install for their high-split customer activations. This type of installation eliminates the use of on-premises coaxial networking and leverages a converged services gateway (broadband, voice, & video) with Wi-Fi and Ethernet for on-premises signal distribution. This will provide the operator the following benefits:

- Leverages future-proof in-home networking technology (Wi-Fi and Ethernet)
- Simplifies on premises networks and reduces operational support costs
- Improved customer experience
- Supports easy future FTTH and D4.0 upgrades.

5.2.3.4. Spectrum Readiness

The upgrade of existing low-split or mid-split plant to high split does require the reallocation of downstream spectrum to use in the upstream. Shaw had to identify 25 downstream carriers to be reclaimed in its mid-split nodes to enable a seamless transition to high split. This reclaim was enabled primarily through optimizations to the legacy QAM video package. These optimizations included the following:

- MPEG-2 to MPEG-4 conversions (high definition (HD) and standard definition (SD))
- Legacy VOD QAM carrier reclaims
- Improved closed-loop stat multiplexing of linear video services.

To enable the radio frequency (RF) spectrum for high-split deployments, Shaw developed the capability to build a distinct channel lineup that is used for high-split nodes deployments. This distinct channel lineup is delivered by the DAA node via an auxiliary video core. This configuration allows an operator to target any spectrum reclamation activities to the node level and minimize the operational impact of large-scale video STB swaps while eliminating the cost and complexity of managing multiple channel lineups through analog head ends and hub sites.

5.2.3.5. Modem Pre-Seeding

Deployment of modems with capabilities to support future plant configurations is a great way for operators to set themselves up for future success. Shaw was able to leverage a very high penetration of mid-split-capable modems to provide immediate congestion relief and large-scale broadband tier upgrades as nodes were upgraded to mid split.

When looking at high-split upgrades, operators should include the pre-seeding of high split-capable CPE into their overall network upgrade programs. With high-split-capable CPE available today, this is a “no regrets” investment!

High-split modem pre-seeding benefits include the following:

- The full-band capture capability of the modem can be used to validate performance of newly activated downstream spectrum (1-1.2 GHz)
- Investments in high-split CPE are fully leveraged in D4.0 FDD (and also D4.0 FDX) deployments
- Immediate traffic offload to newly activated upstream and downstream spectrum once high-split upgrades have been completed
- Future broadband tier upgrades can be done without a modem swap.

5.2.3.6. Back-office Software Readiness

Back-office software (BSS) updates are often overlooked and undervalued when operators consider network upgrades such as high split. However, the definition of node-level serviceability flags is a key enabler to a successful upgrade. These types of flags tell the billing system what the service capabilities of

the node are and what equipment variants are to be allowed on the node. The following are examples of node service availability flags that an operator could implement in support of high-split investigations:

Table 5 – Node Serviceability Flags for Back-office Software in Support of High Split

Flag	Function
Legacy STB Reclaim Underway (Hybrid)	Informs the customer service representative that a legacy STB reclaim is underway and warns them that activation of new legacy OOB video CPE should not be done on the customers node.
Legacy STB Reclaim Underway (All IP)	Informs the customer service representative that a legacy STB reclaim is underway and warns them that activation of new legacy QAM video CPE should not be done on the customers node.
Legacy STB Reclaim Completed (Hybrid)	Informs the customer service representative that the customer's node has completed all required legacy OOB video CPE reclaims and implements a provisioning rule to deny all activations of non-DSG and non-IPTV hardware.
Legacy STB Reclaim (All IPTV)	Informs the customer service representative that the customer's node has completed all required legacy video CPE reclaims and implements a provisioning rule to deny all activations of non-IPTV hardware.
High Split Completed (Hybrid)	<p>Informs the customer service representative that the customer's node has completed a high-split upgrade and informs them of the new high-split-enabled broadband service catalog.</p> <p>In addition, informs the access network configuration systems of which RF channel lineup to apply to the DAA node (i.e., high split legacy QAM video lineup + high split DOCSIS configuration).</p>
High Split Completed (All IP)	<p>Informs the customer service representative that the customer's node has completed a high-split upgrade and informs them of the new high-split enabled broadband service catalog.</p> <p>In addition, informs the access network configuration systems of which RF channel lineup to apply to the DAA node (i.e., full spectrum high split DOCSIS configuration).</p>

5.3. A Potential Evolution Path to DOCSIS 4.0

For a cable operator to be successful in a market where there is an aggressive FTTP builder, they will need to have the ability to rapidly deploy competitive speeds to 10G PON technologies, while at the same time increasing focus on service reliability, service experience, and customer service. D4.0 FDD technology gives operators the necessary tools to compete in this type of marketplace. D4.0 FDX technology also gives operators the necessary tools to compete and may be preferred by some operators. Focusing in on D4.0 FDD, it provides operators the following benefits:

- Highly economical upgrade
- Fastest path to compete with 10 Gbps-capable PON technologies
- Enough capacity to reduce focus on speed (i.e., take speed "out of the conversation")

- Improved network reliability
- Ability to leverage previous high-split investments.

Shaw has developed their network upgrade strategy with a view on the most efficient path to D4.0 FDD. In this context, high split is an important and logical steppingstone in setting the stage for future D4.0 FDD deployments.

The following is a potential four step process that operators who are currently deploying mid split could implement to enable a seamless transition through high split and to D4.0.

Step 1: D3.1 High Split (204 MHz / 1 GHz)

In this phase as shown in Figure 19, the operator begins deploying high split using an architecture that can evolve gracefully to D4.0 FDD deployments. This configuration will allow operators to compete in highly competitive markets with gigabit symmetric services while setting the stage for future upgrades.

The following elements are included in this initial step:

- Reclaim of all legacy OOB STBs
- Upgrade any taps and passives with less than 1 GHz capabilities to 1.2 GHz while keeping 1 GHz-capable taps in place
- Resolution of any plant architecture issues (e.g., plant powering upgrades, elimination of 3x3 (DS-SG x US-SG) and 4x4 node configurations, proactive cascade reductions)
- DAA node deployment (Remote PHY or Remote MACPHY) coincident with an upgrade to 204 MHz / 1.2 GHz
- Reclaim legacy QAM video channels to support the high split conversion.

Figure 19 – Step 1: D3.1 High Split (204 MHz / 1 GHz)

Step 2: D3.1 High Split with 1.8 GHz Taps

In this phase as shown in Figure 20, the operator will include a full upgrade of taps and passives into the high-split upgrade efforts. In this phase a sweep of the plant will be completed to upgrade all taps and passives housings to be 3 GHz-capable, and 1.8 GHz-capable faceplates.

Adding a full tap and passive swap enables the operator to achieve the following benefits:

- Minimizes future rework to enable full D4.0 FDD capacities
- Allows the operator to gain experience and optimize full scale tap and passive swaps
- Enables additional plant hardening by allowing the inspection and resolution of craft issues that can cause ingress and RF performance issues
- Improves plant stability issues that are caused by seizure screw related issues

- Improves DAA node uptime by ensuring power bypasses are included in all taps and passives
- Enables 1.2 GHz plant operation and allows the deployment of an additional 200 MHz of downstream capacity.

Figure 20 – Step 2: D3.1 High Split with 1.8 GHz Taps (in 3.0 GHz Housings)

Step 3: D3.1 High Split with 1.8 GHz Taps and 1.8 GHz Amplifiers

In this phase as shown in Figure 21, the operator will include a full upgrade of the HFC amplifiers to be 1.8 GHz-capable equipment (compliant with [SCTE 279 2022]).

Adding a full amplifier upgrade enables the operator to achieve the following benefits:

- Gaining experience with 1.8 GHz amplifiers in production environments
- Improved compliance of amplifier level setup by leveraging auto-setup capabilities of 1.8 GHz amplifiers
- Minimizing operational complexity by using soft-selectable pads and EQs
- Minimizes future rework to enable full D4.0 FDD capacities.

Figure 21 – Step 3: D3.1 High Split with 1.8 GHz Taps (in 3.0 GHz Housings) and 1.8 GHz Amplifiers

Step 4: DOCSIS 4.0 High Split

In this final phase as shown in Figure 22, the operator will include the deployment of a D4.0-capable node and shift to a RMD to enable the full D4.0 FDD capacities.

Adding a D4.0 RMD enables the operator to achieve the following key benefits:

- Enables full D4.0 FDD capacities
- Improves network resiliency by fully separating the data and control planes on the DAA node
- Reduction of technical facility power and cooling requirements.

Figure 22 – Step 4: DOCSIS 4.0 High Split

5.4. Summary of Lessons Learned

As part of Shaw’s high-split deployments and Shaw’s overall D4.0 readiness activities, the following are some key lessons learned:

1. The Frequency Modulation (FM) and Very High Frequency (VHF) Bands are unproven for upstream usage

These portions of the spectrum have historically been used for downstream signals; their use for upstream has not been proven out. Over the air broadcasts can significantly impact the quality of these channels. It is important that operators have a plan on how to validate the impacts of ingress and how much DOCSIS capacity this spectrum can provide.

2. The performance of DAA deployments is amazing!

DAA deployment will be required for DOCSIS 4.0; however, there are significant performance benefits that operators can achieve by including DAA deployments in their high-split programs. Shaw has seen an average downstream modulation error ratio (MER) improvement of up to 8.2 dB and an upstream MER improvement of 5.2 dB.

3. Pre-seeding modems is an effective way to prepare for the future

Having modems pre-deployed in the network that are immediately able to utilize the new spectrum created by deploying high split is a key element to the high-split business case. These modems enable immediate congestion mitigation, tier upgrades without modem swaps, as well as enabling the operator to use the full-band capture capability to test and validate the new spectrum before customer use.

4. Avoid “big bang” changes

A successful D4.0 deployment involves many changes that can be highly impactful to operational teams. It is important to layer these changes in over time to allow for effective change management. High split represents an opportunity for operators to begin their D4.0 journey today and prove out and harden technology changes one at a time.

5. Plan for measuring and minimizing customer impact when deploying high-split change events

As has been highlighted by the COVID-19 pandemic, the reliability of the home’s broadband connection has never been so important. Due to the sheer number of changes required to

deploy high split and ultimately D4.0, it is critical that the operator has a plan on how to measure and optimize the deployments to ensure customer impacts are minimized.

6. Conclusion

Subscribers' growing bandwidth demand and increased competitive pressures, especially from internet service providers deploying 10G PON technologies, are driving cable operators to expand upstream (and downstream) capacity. In addition to these market factors, operators may upgrade plant actives (RF amplifiers) due to reaching the end of their typical 10-20-year lifetime—an opportune time to make the change to 1,218/204 MHz actives.

High-split (204 MHz) operation in the upstream—especially when paired with an upgrade to 1,218 MHz in the downstream—can provide quite the improvement in the HFC network service group capacity of up to 8.6 Gbps capacity in the downstream and 1.5 Gbps capacity in the upstream. Some projections show high split and 1,218 MHz providing enough bandwidth for a service group of at least 150 subscribers with 5 Gbps down x 1 Gbps up speed tiers / SLAs for the next 10 years.

Moving to high split is not only a steppingstone on the path to 10G and to DOCSIS 4.0, whether moving to FDD or FDX, but a huge step in terms of benefits to both operators and end subscribers. Luckily for cable operators, technologies and products in the market—deployable today—enable operators to confidently move forward with high split in the three leading CMTS/CCAP architectures: I-CCAP, R-PHY, and/or R-MACPHY. A node visit, required for the high-split upgrade, is also the opportune time to upgrade to a DAA, whether R-PHY or R-MACPHY. However, a simpler and faster high-split upgrade with I-CCAP, is still a strong option to consider, especially when the bandwidth and market drivers demand an earlier move to high split—before the operator can migrate to a DAA. High split on I-CCAP can have even better performance when utilizing digital return in place of analog return on the fiber optics link.

In planning to implement high split, several potential architectural considerations must be taken into account, such as strategies on how to free up the high-split spectrum, like implementing SDV, reducing the video channel line-up, migrating from MPEG-2 to MPEG-4, or moving to IPTV. Tools and solutions exist that support leakage detection, which in the high-split world now must detect signals in the reverse path. Operators must develop a CPE strategy that aligns with high split, including pre-seeding the market with high-split-capable CPE, migrating legacy video STBs to STBs with embedded cable modems (DSG-capable or otherwise), and dealing with potential interference from high-split-capable CPE with other legacy CPE in the home or in close neighbors. Operators need to consider the cable modem RF levels and the inputs to the RF amplifiers when making the move to high split. Operators also need to consider whether to take a “rip-and-replace” or a “module-only” upgrade path for the RF components, with each one having benefits and drawbacks.

Shaw Communications shared some considerations and lessons learned from embarking on a high-split upgrade. Shaw explained the Canadian market dynamics that drove them to deploy mid split and then high split to compete against FTTx service providers. Shaw explored some of the key architectural considerations for moving to high split, including network architecture readiness, strategies for handling legacy STB out-of-band signals, preparing for the spectral shift, pre-seeding high-split-capable modems, and back-office software readiness, among others. Shaw provided a step-by-step potential evolutionary path to high split and then to DOCSIS 4.0 FDD-capable DAA devices in preparation for the next step of enabling D4.0 FDD. Finally, Shaw shared some of their key lessons learned, including the unproven nature of the FM and VHF bands for upstream usage, the amazing performance of DAA (average MER improvements of 8.2 dB down and 5.2 dB up), the importance of pre-seeding modems with high split

support, avoiding making major changes at the same time, and the importance of minimizing subscriber impacts during the upgrade through proper monitoring.

In short, the time for talk is over, and there is no better time like the present to embark on the journey to implement high split as a key step on the path to 10G!

Abbreviations

10G EPON	10 Gbps Ethernet passive optical networking
10G-PON	10 Gbps passive optical networking (also known as XG-PON)
ACK	acknowledgement (typically from Transmission Control Protocol)
AGC	automatic gain control
BSS	business support system
BW	Bandwidth
CAA	centralized access architecture
CACIR	carrier to adjacent carrier interference ratio
CAGR	compounded annual growth rate
CAPEX	capital expense
CCAP	Converged Cable Access Platform
CDF	cumulative distribution function
CES	Consumer Electronics Show
CM	cable modem
CMTS	Cable Modem Termination System
COTS	common off-the-shelf
CPE	customer premises equipment
D2.0	Data Over Cable Service Interface Specification 2.0
D3.0	Data Over Cable Service Interface Specification 3.0
D3.1	Data Over Cable Service Interface Specification 3.1
D4.0	Data Over Cable Service Interface Specification 4.0
DAA	Distributed Access Architecture
dB	Decibel
dBmV	decibel-millivolts (decibels relative to 1 millivolt)
DCA	Distributed Cable Architecture
DOCSIS	Data Over Cable Service Interface Specification
DRW	dynamic range window
DS	Downstream
DSG	DOCSIS Set-top Gateway
DSL	digital subscriber line
DTA	digital terminal adapter
EOL	end of line
EPON	Ethernet Passive Optical Network (aka GE-PON)
EQ	Equalizer
ESD	extended spectrum DOCSIS
FCC	Federal Communications Commission
FDD	frequency division duplex
FDX	full duplex DOCSIS
FM	frequency modulation
FMA	Flexible MAC Architecture
FTTB	fiber to the building
FTTH	fiber to the home
FTTP	fiber to the premise

FTTx	fiber to the 'x' where 'x' can be any of multiple option for subscriber locations, including home, premise, building
FWA	fixed wireless access
Gbps	gigabit per second
GHz	gigaHertz
gNMI	Google Network Management Interface
HD	high definition
HEO	head end optics
HFC	hybrid fiber-coax
HP	homes passed
HS	high split (204 MHz)
HSD	high-speed data
HW	hardware
I-CCAP	Integrated Converged Cable Access Platform
IEEE	Institute of Electrical and Electronics Engineers
IP	internet protocol
ITU	International Telecommunication Union
ITU-T	International Telecommunication Union Telecommunications Specification Sector
kbits	kilobits per second
LDPC	low density parity check (FEC code)
LE	line extender (amplifier)
LS	low split (42 MHz or 65 MHz, depending on region)
MAC	media access control
MB	multi-port bridger (amplifier)
Mbps	megabit per second
MDD	MAC Domain Descriptor
MDU	multiple dwelling unit
MER	modulation error ratio
MHA	Modular Headend Architecture
MHz	megaHertz
MPEG	Moving Picture Experts Group
MPTS	multi-program transport stream
MS	mid split (85 MHz)
MSO	multiple system operator
MULPI	MAC and upper layer protocols interface
N+0	node+0 actives
NCTA	The Internet & Television Association (formerly National Cable & Telecommunications Association)
OFDM	orthogonal frequency-division multiplexing
OFDMA	orthogonal frequency-division multiple access
OPEX	operating expense
OSP	outside plant
OSS	operational support system
PHY	physical interface/layer
PON	passive optical network
PSD	power spectral density
PTP	(IEEE 1588) Precision Timing Protocol

QAM	quadrature amplitude modulation
QoE	quality of experience
QPSK	quadrature phase shift keying
R-MACPHY	remote MACPHY
R-PHY	remote PHY
RF	radio frequency
RFI	radio frequency interface
RMD	remote MACPHY device
RPD	remote PHY device
SCTE	Society of Cable Telecommunications Engineers
SDV	switched digital video
SG	service group
SLA	service-level agreement (also known as speed tier)
SNR	signal-to-noise ratio
SS	sub split (42 MHz or 65 MHz, depending on region)
STB	set top box
Tavg	average bandwidth per subscriber
TCP	total composite power
TCP	Transmission Control Protocol
Tmax	maximum sustained traffic rate – DOCSIS Service Flow parameter
TX	Transmit
UHS	ultra-high splits (300 MHz, 396 MHz, 492 MHz, or 684 MHz)
US	upstream
VOD	video on demand
VoIP	voice over internet protocol
VHF	very high frequency
XG-PON	10 Gbps passive optical networking (also known as 10G-PON)
XGS-PON	10 Gbps symmetrical passive optical networking

Configurable FDD Allocated Spectrum Bandwidths

Optical Architectures and Capabilities

- Analog or digital optics vs.
- R-Phy or MAC-Phy

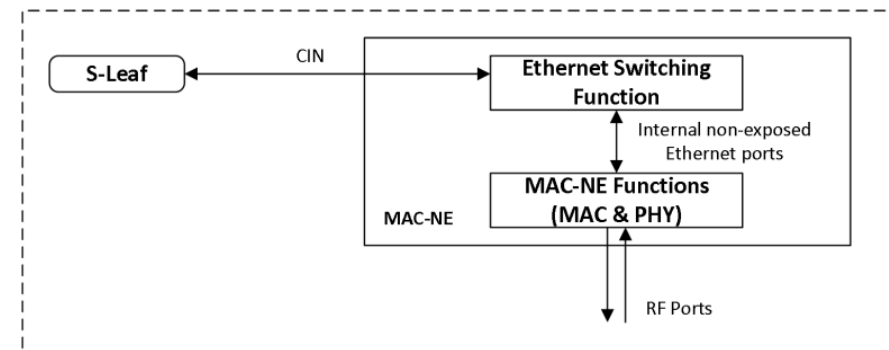

Analog DFB Laser NPR Curve

R-PHY Internal and External Connections

MAC – Network Element Internal and External Connections

RF Architecture Characterization

- Amplifier and BW selection
- Amplifier Characterization
- Legacy Plant Evaluation

Evaluating Legacy Plant

Active and Passive Obstacles

Active Devices

- “Temporary” amplifier placements
 - May not be in design files or maps
- Sub-Split Components in Mid or High Split amplifiers

Passive Devices

- Line Equalizers
- Conditioned Taps
 - Both may contain duplexers for upstream conditioning

Evaluating Legacy Plant

Coaxial Cable and Connectors

- Fused Disc cables with “mold spike” beyond 1 GHz
- Hardline connectors may not be “tuned” to higher frequencies

Craft Sensitivity

- Coaxial Cable Management
- Component Frequency Response
 - Extended Frequency Tuning
 - Fused Disc Cable
- Frequency Specific Testing

PNM Tools

- OFDMA/OFDM analysis
- FBC
- Thresholds

Device Health															
Registration State	6 (Online)														
Down Rx Power	5.2	5.2	5.2	5.4	5.5	5.7	5.8	6	6	6.1	6.2	6.1	6.1	6	6

1. Introduction

Privacy Engineering: The Intersection of Technology, Policy, Standards, and Security

While the term “security” is often used interchangeably with “privacy,” these two disciplines require different skillsets and process. Privacy focusses on access control and data usage. The toolset for the nascent privacy engineering field requires awareness of the development in the technology sector, awareness of risks and threats to protected data, privacy law in relevant jurisdictions, and different privacy standards, as these standards help set the bar as to what constitutes appropriate privacy protections. Security is focused on data access, integrity, and confidentiality. Organizations holding data need to be aware of the business and regulatory risks associated with this data and shape their internal privacy engineering and privacy policy compliance teams to mitigate these risks. This paper addresses the data security and privacy landscape for 2022 to provide some assistance in assessing your organizations’ security and privacy posture.

2. Security and Privacy

Security and privacy get grouped together, it’s easy to think of them as the same thing, they are not. Privacy is about the decisions that surround competing claims for access to, modification of, deletion of, and altering the disposition of information (Bambauer, 2013), as well as the legal right, uses, and potential ownership of data. Security, by the other token, is about the confidentiality, the integrity, and the availability of the data being accessible to only those people or system with appropriate identity and credentials.

In the cable ecosystem, a network operator occupies an interesting position, the operator helps to secure the data in transit through technologies like the CableLabs[®] DOCSIS Security Specification, protecting the confidentiality and integrity of the data through encryption, hashing, and message authentication. At higher levels of the OSI stack, over 92% of US web traffic transiting the internet today uses HTTPS (Google, 2022) and encrypting from endpoint to endpoint.

In many cases, the tools used to deliver security can be used to protect privacy, an example of this is how confidentiality in the above two examples protects from unauthorized users seeing message contents; recall, however, that privacy is about the decisions and competing claims to access information. An encrypted network does not help protect a user from endpoints and services that are going to sell user behavior and identification. The endpoint operator may claim that those observations and data were collected using their hardware, software systems, and algorithms, and how they handle the disposition of those data is their prerogative. The user, on the other hand, may claim that the observations collected about them, and their identification data is personal, and that the expectation was that the interactions made were not reasonably, or lawfully, expected to be shared with others or were used in ways that were not in the interests of the user.

Those differing claims create a new privacy discipline, new technologies and new tools unique to privacy engineering that are not exclusively within the security discipline. This work addresses the current state of how we capture, classify, and protect these aspects and nuance of data.

3. Privacy Enabling Technology

Privacy Engineering, as a discipline, is nascent, as is the supporting ecosystem of products and tooling. Some of the tools in this area begin to show how their application and outcomes drive advancement in data protection and privacy compliance.

3.1. Privacy Compliance

Compliance can depend on the legal jurisdiction, the domain data is held within, and the status of who holds the data (IAPP 2022). A hospital in Tennessee running field trials of new treatments will have different compliance hurdles from a Californian network operator or a direct-to-consumer retailer in Germany, but all of these do have compliance considerations. To address the multitude of combinations of the above, there are new tools being developed and expanded in the privacy sector which are disparate in many ways from the security sector. The Data Privacy Software market size in 2022 is \$US3.26B in 2022 but has a CAGR of 40.8% leading to a projected size of \$US25.85B by 2029 (Fortune Business Insights, 2022). North America alone will grow from \$US682.9M to \$US9.3B by 2029 (See Figure 1).

Figure 1 North America Data Privacy Software Market Size (Fortune Business Insights, 2022)

3.2. Technology Solutions

Several solutions exist in this growing Privacy Enabling Technologies (PET) space, many of these can be grouped together, but custom offerings are appearing in the market and in conferences that cannot always be categorized early.

Traditional data masking techniques include obfuscation (signal-to-noise ratio reductions to hide data), anonymizers (hiding identity or limiting cross-session tracking), pseudonymization (replacing protected data with different identifiers), and data minimization to reduce the overall amount of work performed by remaining PETs.

Self-sovereign identity solutions take blockchains, smart contracts, and an ecosystem approach to exchange of information and verifiable rules for how that data is accessed, used, stored, deleted, and shared. Protected data is stored either off-chain, or encrypted on the chain, and the sharing of that data between participants in the ecosystem is managed through the smart contracts of the chain, recording agreements, limiting use, and setting up the rules for data disposition.

Homomorphic encryption and Zero-Knowledge Proofs (ZKP) are mathematical concepts related to encrypted data whereby an operation such as a query can be performed on the ciphertext without decrypting it. In the hospital example from above, consider a study participant who is being evaluated for treatment of a new concern that arose during the study. While the patient's research status is protected (whether they are in the control group or the treatment group), the treating physician may need to consider a pharmaceutical treatment for the new concern. They query the system to find out the answer to a query that includes the patient's research status, and if they have allergies to the potential medication, and if there are drug-interactions with the research study course of treatment. With zero-knowledge proofs and homomorphic encryption, an authorized inquiry can get an answer for situations like the above without exposing the underlying data, but if the query isn't carefully constructed to be only what's necessary, data can be exfiltrated from multiple queries or overly broad queries.

Differential privacy is another tool based on mathematics. In hospital examples, like the one above, the concern is that medical data will be revealed, but if any given datum or small collection of data were to have a sufficient probability of being false, or untrue, then the release of information would not be damaging to an individual and the aggregate dataset would still be useful for use cases like that of the hospital field trial. For example, modifying data with an acceptable amount of noise to reduce the probability of identifying an individual but still providing a sufficiently reliable result to a query. For example, a query made with an exact age may be used to identify an individual. Adding noise to the data so an age range is created lessens the probability of identifying an individual but still returns clinically relevant information, such as adding sufficient noise to the age data so the query returns results for individuals aged from 34 to 38.

Federated Learning, also Privacy Enhanced Federated Learning (PEFL) is a subset of machine learning and artificial intelligence for using multiple datasets without sharing data (M. Hao, 2020). The data are distributed across independent local hosts and algorithms are trained for each host or dataset and for contributing to aggregate observation. This approach allows for data to be neither centralized, nor homogenous in its structure or distribution. What is shared are the resultant weights and biases for neural networks which can then be used in aggregate without risk of sharing private data used to obtain the trained network.

Secure Multi-Party Computation (SMPC or MPC) is based on the idea of several parties or systems who work together to solve problems using disparate stores of data, not unlike Federated

Learning, but in SMPC the objectives, rules, and model parameters are shared using finite field cryptographic tooling.

3.3. Intersection of Tools Supporting Technology and Compliance

There exist several different hybridized versions of technical solutions and approaches from Technology Solutions, some integrating cryptography in various steps for additional protection from accidental exposure or malicious actors. There also exist several tools for enterprise compliance with privacy regulation, these help to automate the auditing of datastores, databases, files, as well as system interfaces and communication tools for the storage or transit of data that is likely to be protected. The identification of that likelihood can range from simple rules to machine learning based on general training or custom training for specific jurisdictions and industries. The newest entrants into the tooling market are development operations tools (DevOps and PrivOps) where engineers using build tools for custom software development have steps where fields likely to have protected data are identified, in part to help train the privacy engineers as well as identify potential areas inside the software for additional protection.

4. Risks and Threats to Protected Data

Risks resulting in data exposure are different from the risks of exposure. Several risks can result in exposure, these range from accidental, to intentional, and even established markets for this protected information.

4.1. Risks Resulting in Exposure

Risks resulting in exposure include accidental exposure (e.g., misplaced documents), endpoint sale of data, online tracking (e.g., browser fingerprinting, cookies, etc.) intentional aggregators and profile building, linked data sets building identifiable collections (unintentional or otherwise), active fraud (these often have colloquial terms like “social engineering”, “phishing” and “spear-phishing”), real-time markets for data (whether sold or shared), insider threats, data loss or deletion (leading to misidentification or misclassification which can result in as many concerns as incorrect data), intentional exfiltration, technical vectors (insufficient security, unpatched systems, trojans, compromised websites, mobile and personal devices, removable media, poor configuration management, and access to local or cloud servers), as well as several other security compromises from various actors with different intentions (hactivism, cybercriminal networks, disgruntled employees, etc.).

Some of these risks may be more likely than others, and some risks may have smaller or more targeted datasets. The granularity and compartmentalization of the protected assets can limit the scope of a breach and each of the above risks has its own set of potential mitigation steps. This is an area where there is a significant overlap with security, however, some of the risks to exposure, above exist outside that intersectionality.

Risks where the entity or system on the other side of the endpoint has access to protected data (as defined by the laws of the prevailing jurisdiction) don’t necessarily have a security solution;

these include the intentional collection and sharing of data by the operators of that endpoint. Browser fingerprinting, activity monitoring (e.g., how quickly or slowly the user scrolls past different content, or when and where a mouse hovers, or what videos are played and when they are stopped), markers from previous websites, these are all aspects of how even unintentional data is collected. When that data is then shared with larger networks, when linked (or collections of unlinked data) are sold in real-time bidding markets (ICCL, 2022), or when it is retained and associated with future transactional records, individuals and corporations lose control over data that may be sensitive or protected.

Empirical evidence on the public understanding of the scale and scope of what is tracked seems to indicate a significant underestimation of how much data on individuals is collected each day. The Irish Council on Civil Liberties (ICCL) published a breakdown by European and US locality showing this data being sold in the greater than \$US117B Real-Time Bidding (RTB) network market, shown in Figure 2.

Figure 2 Real-Time Bidding Broadcasts Per Day (ICCL, 2022)

4.2. Risks of Data Exposure

Risks of exposure, what happens after the data is in the hands of another party, focuses on two primary aspects, the use of that data by malicious actors, and the regulatory and legal response.

Operational risk is not addressed here, because this paper focuses upon data exposure, not necessarily data obfuscation, modification, or deletion as is common in ransomware attacks.

4.2.1. Malicious Actors

Buyers in the markets described in Risks Resulting in Exposure include sales and marketing organizations, but the buyers also include malicious actors who seek to monetize the data collected. This can be accomplished through resale (there are underground marketplaces specializing in the sale of personal information), through direct ransom for the data (pay to have it returned and presumably not used or resold), and through extortion and the threat of public release of the data.

Ransomware used to be primarily about encryption and extortion payments to return to normal operations, but ransomware attacks that exfiltrated data increased from 22% of cases in Q2 2020 to a massive 81% in Q2 2021 (~270% YOY increase) (Schein 2022). These actors have recognized that threats of exposure can be part of criminal extortion, and some of these actors, when stymied by corporate victims that are reluctant to pay, have turned to threats (and action) of direct engagement with the individual people whose data is the subject of the breach.

4.2.2. Regulatory, Reputational and Legal Response

Those organizations who find that data in their stores has been compromised also find that there may now be both legal responsibilities and regulatory notifications required. Some jurisdictions require notification of real or potential breaches of protected data; this can be based upon the size of the company, the size of the breach, the content of the breach, and the industry within which the company may play. The legal impact may also involve public or private civil responses from those who suffered harm through the breach; depending on several factors, including the jurisdiction, this could involve significant damages.

In addition to the legal requirements on notification, there may be regulatory responses that could involve significant fines. In the European Union, significant violations of the General Data Protection Regulation (GDPR) can result in fines up to 4% of the corporation's gross annual revenue for each offense. Notifications also carry with them the reputational risk to the organization, potentially signaling to the market that they may be ineffective or careless with protecting this sensitive data. Starting with the probability of breach based on controls and tooling; then comparing that to the legal, regulatory, and reputational price organizations may pay in the event of a breach, an organization can balance risk and plan for mitigation investments.

5. Technology Policy and Privacy

The disparate technology policy and regulation across multiple jurisdictions makes this discipline difficult to standardize. These policies have an impact on the technology and are critical to understand for businesses who are engaged in commerce in these jurisdictions. This

paper is not intended as legal advice, please check with your own legal counsel as this may be out of date or incomplete.

5.1. United States

The United States does not have comprehensive national preemptive consumer privacy policy, and although talks on this front continue as of this paper's submission, rapid changes in that status are not anticipated. This said, there are several privacy legislative initiatives, some of which are laws, that cover specific sectors and actors. Examples of areas where laws exist in the US are in health privacy, finance, and protecting children. Other actions have an impact on privacy including cybersecurity, trade, and restrictions on governmental actions. Existing state legislation enacted over the last couple years can make for difficult corporate navigation of privacy rulemaking.

The growth of privacy initiatives around legislative action in the United States does show tremendous interest and inertia; this topic appears to be growing, but the resultant proposals are not consistent, and due to that non-standard deployment, privacy compliance is also growing in expense and potential for errors across jurisdictions. The growth of state privacy legislation can be seen in **Error! Reference source not found.** (IAPP 2022).

Figure 3 Growth of State Privacy Regulation

Currently, five states have enacted laws addressing private data and enterprise responsibilities, California (California Consumer Privacy Act & California Privacy Rights Act), Colorado (Colorado Privacy Act), Virginia (Virginia Consumer Data Protection Act), Utah (Utah Consumer Privacy Act), and Connecticut (Connecticut Data Privacy Act). Additional bills were considered during this 2022 legislative session, visible in Figure 4 (IAPP 2022).

The five states that have laws on the books, have some commonalities, but some dramatic differences. The consumer right to access, rectify, delete, and restrict records exists in all five, as do the business responsibilities for opt-in as the default, transparency, and limits on processing based on purpose of the data. Additionally, enterprises cannot discriminate against consumers who are exercising their rights.

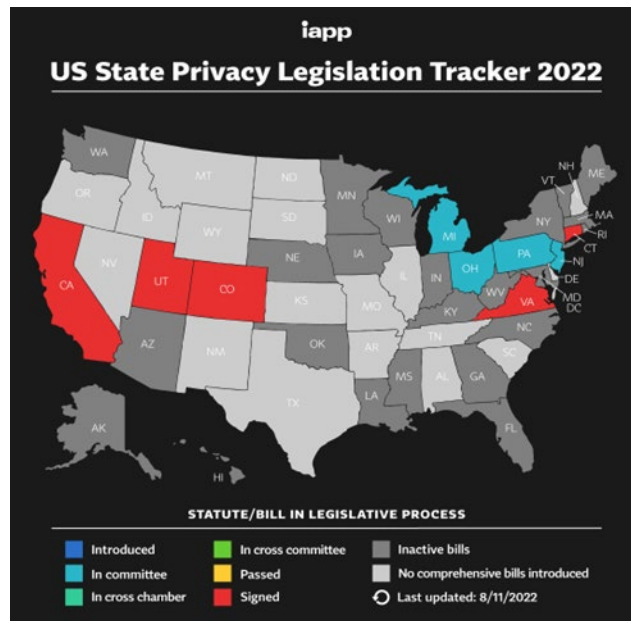

Figure 4 US State Privacy Legislation Tracker 2022

Utah does not have restrictions on automated decision-making based on protected data while the other four states do restrict this (California added this in the CPRA). In Colorado, Connecticut, and Virginia, additional rules are in place for risk assessments and those three states rely upon the Attorney General to prosecute cases. California is currently the only state in the United States with a private right of action for privacy violations. Detailed rulemaking is still taking place in these states, so the fine-grained details of these regulations are still subject to some level of change.

5.2. International

The European Union and eighteen other countries (excluding the United States) have comprehensive consumer privacy legislation and regulation, these include Argentina, Armenia, Australia, Benin Republic, Brazil, Canada's Personal Information Protection and Electronic Documents Act (PIPEDA), China, Colombia, European Union, Hong Kong, Israel, Kenya, New Zealand, Nigeria, Philippines, Singapore, South Africa, South Korea, and Turkey.

As in the United States the consumer right to access, rectify, delete, export, and age-based opt-in options are predominantly consistent across these. The default opt-in or opt-out as well as the consumer right not to be subject to automated decision-making seem to be inconsistently applied or available. Business obligations in these markets often include transparency, purpose limitations for data retention, data minimization, security requirements (somewhat varied), record keeping and breach notification requirements. Requirements for data protection officers, international data transfer restrictions, preemption, and sector-specific regulation are inconsistently across these jurisdictions. The EU, Australia, and a few others require privacy by design raising questions about enforcement interpretation with older systems and processes.

6. Privacy Standards Community

Tool development for inconsistent requirements like those listed in Section 5.2 is difficult due to the lack of economies of scale across ecosystems, in some cases this is made even more difficult by conflicting expectations (e.g., opt-in versus opt-out). The lack of mature, consistent, international standards and due to the variability in technology options, network operators and enterprises are left buying privacy compliance tools that cannot interoperate effectively with other tools in the space, where one tool can't complete all the tasks, and where incumbent vendors and contracting rules inhibit innovation.

For enterprises and operators who are looking for standards that support operations and enable innovation, Table 1 is meant to serve as an incomplete guide:

Table 1 Standard Development Organizations and Initiatives

Organization	Document/Specification/Initiative	Notes
ISO/IEC	Privacy Information Management Systems Scheme (PIMS Scheme) 27701 & 27702 (ISO 2019)	
National Institute of Standards and Technology (NIST)	Privacy Framework	1.0 (Jan 16, 2020) United States Dept. of Commerce

Future Directions Digital Privacy Initiative		
Wireless Broadband Alliance (WBA)	https://wballiance.com/wi-fi-imsi-privacy-protection/	Permanent IMSI privacy protection initiative
Multi-Party Computation Alliance (MPC Alliance)	https://www.mpcalliance.org/	Standards and advocacy group focused on the adoption of MPC technology

7. Conclusion

Privacy technology is advancing on several fronts, technology, policy, standards, and the discipline's overlap with security. Entirely new disciplines like Privacy Engineering are being developed (Carnegie Mellon 2022), nascent tools are being brought to the market, standards are catching up, and legal, compliance and regulatory frameworks are being established and renovated. The objective of this work was to provide the reader the tools necessary to begin their own assessment of the posture of the reader's own organization, to understand the different aspects of the space, better evaluate the nuance and differences between privacy and security and begin to learn to discern where and how privacy technologies should be applied within their influence.

1. Introduction

Cable operators are moving towards wider upstream spectrum for improved speed and bandwidth. Activating new upstream spectrum can come with a number of unforeseen challenges. Fortunately, over a dozen years of Proactive Network Maintenance (PNM) experience can provide an excellent foundation for detecting, characterizing and repairing many of the common obstacles. The result is faster, smoother orthogonal frequency division multiple access (OFDMA) deployments and finding and fixing network problems before our customers are impacted.

In this paper, the authors, Hayakawa, O'Dell, Schauer and Wolcott present the latest results of mid-split and OFDMA from the field. They review a number of unforeseen issues including technical and operational solutions. From frequency response issues caused by long-forgotten network equipment and filters to partial-bonding caused by in-home amplifiers, there are plenty of opportunities to get ahead of. This paper provides valuable insight for cable operators embarking on mid-split and high-split transformations in conjunction with OFDMA technology.

2. Evolution of Pre-Equalization Analysis and Proactive Network Management

CableLabs has evolved three generations of DOCSIS PNM. Starting in DOCSIS 1.1, evolving through DOCSIS 2.0, and reaching wide deployment with the advent of DOCSIS 3.0, cable operators have a rich body of data to identify and correct impairments in the RF plant. While there are numerous data sets available in the DOCSIS and PNM requirements, the pre-equalization coefficients are among the most useful to isolate subtle degradations in RF plant performance.

Processing equalization data involves manipulating complex coefficients in the frequency and time domains utilizing Fourier transformations and related mathematics. The scope of these mathematics is outside of this presentation. They may be summarized as the dynamic manipulation of RF energy across frequency bands to compensate for non-ideal coaxial cable plant parameters.

Collection of pre-equalization data also depends on the cable modem SNMP Set and TFTP file return mechanism described in the DOCSIS 3.0 PNM specification. This process is outside the scope of this presentation as well; operators are encouraged to develop their infrastructure to support these new data sets.

In 1999, the first-generation pre-equalization work in DOCSIS 1.1 codified publishing complex equalization coefficients and dynamic RF management to the cable plant. It also experienced growing pains. The original eight coefficients, the accuracy of the measurements, and the implementation of the specification required significant revision as it moved from the laboratory to full production.

The second-generation pre-equalization work implemented in DOCSIS 2.0 improved the pre-equalization modeling. The number of coefficients expanded from 8 to the now familiar 24 as well as improvements to the algorithms.

Pre-equalization analyses advanced to a current best practice with the third generation of PNM in DOCSIS 3.0. CableLabs released a formal PNM specification and built richer data sets into the base DOCSIS MIBs as well.

With DOCSIS 3.1 OFDMA, CableLabs brings the fourth generation of PNM to cable plants. Changing from classic 6.4 MHz wide Single Carrier QAM channels to OFDMA channels that are up to 96 MHz wide with thousands of 25 or 50 kHz subcarriers brings new capabilities and analytical needs.

The DOCSIS 3.0 PNM capabilities have been covered in depth in previous SCTE papers. They are summarized and compared to the capabilities that DOCSIS 3.1 add to the analyses. These reflect major changes that operators need to embrace and will be detailed later in this paper.

Table 1 – PNM Features compared

US Measurement	DOCSIS 3.0 SC-QAM	DOCSIS 3.1 OFDMA
Channel Ranging Status	Exposed for each SC-QAM US channel on the CM and vital for detecting partial bonding.	Exposed for each OFDMA channel on the CM and include stronger indications of partial service.
Speed test	Coarse reductions in expected speed due to US channel impairments. Losing one out of four bonded US channels will result in up to a 25% reduction in measured US speed.	Subtle reductions in expected speeds due to OFDMA US channel impairments. Partial service capabilities, improved error correction, and larger bandwidth will ameliorate but not eliminate reduction in US speed
Spectrum analysis at CMTS	Collected from CMTS spectrum analysis table with limits on narrow or wide channels	New and expanded CMTS spectrum analysis table. New US triggered spectrum capture PNM file available for all US types
Rx power, MER, FEC at CMTS	Collected from CMTS and analyzed along D1.1, D2.0, and D3.0 evolutionary path.	New channel status table entry with expanded power, MER, and OFDMA performance data. New profile status entry reflecting total, correctable, and uncorrectable codewords per US OFDMA profile. New PNM US OFDMA Rx Power and Rx MER files reflecting OFDMA specific
Spectrum analysis at CM	Available for DS spectrum with limited support for US capture and extended upstream bands.	Expanded to include mid-split and high-split frequencies.
Tx power at CM	Long established 53dBmV (with some extensions)	Higher overall due to OFDMA: must be capable of transmitting a total average output power of 65dBmV
Upstream pre-EQ coefficients at CM	Collected from CM and analyzed along D1.1, D2.0, and D3.0 evolutionary path.	New PNM file. Revised analyses describe in the next sections.

2.1. Differences Between SC-QAM and OFDMA Pre-EQ

There are important changes in Data Over Cable Service Interface Specification (DOCSIS) 3.1 and OFDMA that provide improved troubleshooting capabilities over the DOCSIS 3.0 predecessor, single channel quadrature amplitude modulation (SC-QAM). The first is the larger DOCSIS 3.1 OFDMA channel width of up to 96 MHz, contrasted to the fixed SC-QAM channel widths of either 3.2 MHz or 6.4 MHz. With the wider channels, there is greater time resolution, which provides more precise distance calculations than narrower channels that also contain guard bands and roll off. The time resolution is calculated as the reciprocal of the total equalizer bandwidth.

For example, if an OFDMA channel is configured to operate with 50-kHz subcarrier spacing. In the frequency domain, each equalizer coefficient represents 50 kHz. For SC-QAM using 24-tap equalization coefficients of 6.4 MHz-width, each coefficient represents 233.33 kHz. This is over 4.6 times improvement in the frequency resolution of the equalized channel bandwidth. However, the resolution improvement is even greater when considering the additional inefficiencies inherent with SC-QAM channel shaping and adaptive pre-equalization. First, if the SC-QAM channels have spacing or guard bands, which the unoccupied spectrum will not be subject to the equalizer bandwidth used for troubleshooting. Also, because DOCSIS uses a root raised cosine shaping filter, the SC-QAM channels have a roll off factor of 0.2, leaving only 0.8 of the channel used for the symbol bandwidth. In the case of 6.4 MHz wide channels, only 5.12 Msym/s are visible to the equalizer. Likewise with the 3.2 MHz wide channels, the channel alpha is 2.56 Msym/s.

Figure 1 – Example of SC-QAM equalized spectrum

Figure 1 shows example comparison of 4 SC-QAM channels configured at 6.4 MHz channel bandwidth. While these channels occupy 25.6 MHz of spectrum, only 20.48 MHz of spectrum is available for troubleshooting. Also note that 5.12 MHz of that spectrum is spread across 5 spans of non-contiguous frequency spectrum, creating gaps that cannot be used reliably for troubleshooting.

Figure 2 – Example of OFDMA equalized spectrum

In comparison, Figure 2 shows an equivalent OFDMA channel configured at the same frequency spectrum of 25.6 MHz wide at 50-kHz subcarrier spacing. The entire 25.6 MHz of spectrum is equalized at 50 kHz frequency resolution, providing a total of 512 contiguous sample points, compared to nearly 88 sample points in the previous example (Figure 1).

3. Coefficient Reporting

3.1. Raw Coefficients

When a DOCSIS 3.1 modem has an operational OFDMA channel and its pre-equalizer is enabled, the modem can report the pre-equalizer coefficients. It will upload the coefficients on a specified trivial file transfer protocol (TFTP) server upon a request via simple network management protocol (SNMP) when the coefficients are available. The request typically takes several seconds involving a few SNMP commands and polling, sometimes ending up with a timeout and a failure.

The pre-equalizer covers all the subcarriers between the lowest and highest active subcarriers. Each coefficient is a complex number for a subcarrier and specifies an amplitude and phase adjustment to the subcarrier's transmission. The complex number is encoded with a pair of 16-bit fixed point numbers for the real and imaginary parts. Presenting the coefficients' magnitude values in the log scale gives the familiar amplitude of frequency response. Taking the differentials of coefficients' phase values gives the group delay.

Figure 3 – Example of OFDMA pre-equalizer coefficients and metrics

3.2. Pre-equalizer Metrics

The raw pre-equalizer coefficients are thousands of complex numbers. In order to assess the plant health, we need simpler metrics (Figure 3). The most straightforward is the in-channel frequency response (ICFR) which is the difference between the maximum and minimum of the subcarriers' amplitudes in dB.

Meanwhile, the modem performs the linear fit on the amplitude curve and publishes the following metrics on the SNMP table **docsPnmCmUsPreEqTable**. They are cheaper to retrieve than the coefficients as it takes only a few SNMP queries. The modem does the same calculation on the group delay, too.

- Linear fit
 - Mean (docsPnmCmUsPreEqAmpMean)
 - Slope (docsPnmCmUsPreEqAmpSlope)
- Nonlinear component (ripple)
 - Peak-to-peak (docsPnmCmUsPreEqAmpRipplePkToPk)
 - RMS (docsPnmCmUsPreEqAmpRippleRms)

The modem will have a low in-channel frequency response (ICFR) as well as low amplitude slope and ripple metrics when it is on a clean leg of the hybrid fiber-coaxial (HFC) node. We looked at thousands

of modems on a 44.4 MHz-wide channel among a few hundred nodes and observed the following relationship between the ICFR and the linear fit metrics.

Table 2 – ICFR and coefficient metrics

ICFR Range (dB)	Modem Count		Average Slope (dB/MHz)	Average Ripple Pk-to-pk (dB)	Average Ripple RMS (dB)
0..2	342	7.7%	0.015	1.148	0.204
2..3	1027	23.1%	0.037	1.278	0.235
3..5	1672	37.6%	0.072	1.505	0.289
5..7	798	17.9%	0.111	1.752	0.345
7..10	337	7.6%	0.159	2.353	0.498
10..15	216	4.9%	0.238	3.400	0.703
15..20	24	0.5%	0.204	9.876	2.084
20 or more	33	0.7%	0.158	21.812	3.082

3.3. Coefficient Overflows and Underflows

Each of real and imaginary coefficient parts can take a value between -4 and 4 with a 1/8192 increment. The practical maximum magnitude of a coefficient is 4 in linear (+12 dB) because the magnitudes over 4 will be clipped when the phase is at or near a multiple of 90 degrees.

The magnitude shouldn't go very low either because the coefficient will lose the resolution. In an extreme case where the magnitude is the minimum (1/8192), the phase resolution is 90 degrees. The amplitude resolution is 0.004 dB at the 1/4 magnitude (-12 dB) whereas it is 0.03 dB at the 1/32 magnitude (-30 dB). In most cases the amplitude stays above -15 dB. In very extreme cases we have seen some coefficients collapsed down to zero (0+0j).

Coefficient amplitudes above +12 dB or below -15 dB including the 0+0j value are a good indication of anomaly.

3.4. Monitoring a Large Group of Nodes and Modems

Retrieving the raw coefficients is slow and could fail after all. When monitoring thousands and millions of modems, it is economical to ask for the raw coefficients only when the modem can report them and its HFC condition looks interesting. There are several steps to consider before asking for the coefficients. The step 1-3 can be done by querying just the cable modem termination system (CMTS).

1. Does the HFC node have an OFDMA channel?
2. Is the modem online?
3. Has the modem succeeded in ranging the OFDMA channel?
4. Is the modem's preequalizer enabled?
5. Does the modem have the coefficient metrics at docsPnmCmUsPreEqTable?
6. Are the coefficient metrics interesting or bad enough? Such as the amplitude ripple peak-to-peak is greater than 5 dB or the RMS is greater than 3 dB.

When a modem with bad coefficient metrics is found, it makes sense to retrieve the raw coefficients from it as well as the modems nearby or of the entire node altogether to see whether the modem's impairment

is isolated or prevalent and to narrow down the possible location of impairment cause. If some modems exhibit a similar impairment and they are in the same neighborhood on the HFC topology, it is likely that a single cause is affecting those modems. Overlaying the modems' pre-equalizer amplitude curves gives a good insight.

Figure 4 – Multiple modems' pre-equalizer amplitudes on a node

Figure 4 is an example of overlay plot for a node. The modems on this node and most of the others had relatively low ICFRs. Some of them had many modems sharing the same minor microreflections whose cause would be near the CMTS or remote PHY device (RPD).

Figure 5 – Two modems under impairment with different signatures

On this node, two modems saw a high ICFR with very different curve signatures (Figure 5). The causes of impairment for the two were certainly different and likely between the tap and house. Indeed, they were on very different legs of the node. Several more nodes had multiple modems with isolated impairments.

Figure 6 – Multiple modems under heavy impairment with the same signature (red)

The more interesting situation, where multiple modems reported very similar frequency responses, was found in several other nodes. On one of such nodes, twelve out of 67 OFDMA-enabled modems showed a very similar pair of amplitude spikes whereas others didn't (Figure 6). The spike and dip at 48 MHz were anomalies by themselves as they exceeded the +12 dB ceiling and the -15 dB floor. The twelve were so similar that they were likely to be nearby each other under the same impairment. It turned out that they were all on the same branch of the node and the branch had no unimpaired modem, seen when mapped in Figure 7.

Figure 7 – Impaired modems mapped on the same network branch

It was an easy guess that the impairment came from where the bad branch began. It allowed the field technician to spot an old line equalizer easily. Once the equalizer was removed, the spikes went away in Figure 8.

Figure 8 – Same 12 modems' frequency reponse after repair

4. Learnings From the Field

4.1. Legacy plant

Every bandwidth expansion in the Hybrid Fiber Coaxial network has been met with unforeseen obstacles, both in the downstream and upstream. The flexibility of coaxial cable itself has allowed operators to upgrade electronics and optics and leverage the same coaxial cables successfully for many years. As the designs have evolved, so have the active and passive components deployed in the network.

When we consider the “return” portion of the spectrum, today understood to be 5 MHz – 42 MHz, even this has undergone several iterations. From 30 MHz as the upper band edge, to 40 MHz and ultimately 42 MHz, each of those seemingly minor changes have introduced complexity to the activation and reliable operation of the newly activated portion. Line passives, and return equalizers are a couple of the common passive components that can be disruptive to a bandwidth expansion, or network upgrade.

Line passives like equalizers, and conditioned taps have allowed designers and engineers to build networks that deliver very consistent levels to a large number of subscribers within the service area. Using passive plug-in components (Figure 9) like cable equalizers, cable simulators, return attenuators, or even high pass filters in the taps themselves, it is possible to condition the output signals at every tap port in the network to be within a small target window. They can also allow for the expansion of the feeder or distribution systems to a greater service area, resulting in fewer nodes or amplifiers, and reducing upgrade and operating costs.

However, some of these components do have frequency specific duplexers that would need to be replaced when expanding the bandwidth, and particularly in the upstream portion of the spectrum.

Figure 9 – Example of passive plug-in components

Some line equalizers, in addition to adding equalization to the forward bandpass to account for normal cable losses over long coaxial cable spans, can have a diplexed return path portion to introduce attenuation to the upstream path. These line equalizers would prohibit any expanded bandwidth above the diplex frequency from being enabled at the customer premises southbound of the passive device, examples in Figure 10 and Table 3.

Table 3 – Line equalizer properties showing 5 MHz to 42 MHz operation

Parameter	Frequency (MHz)	Equalization Mode	
		Typical	Maximum
Bandwidth Split (MHz)	---	42/51	
Cable Equalization (dB)	5-42	0	
	51-750	8	

Figure 10 – Conditioned line equalizer

In many cases a walk out is done prior to a system upgrade. This is useful in identifying the location of the previously installed amplifier locations, any traffic or access issues, or verification of passive devices that may need replaced. However, on occasion amplifiers are placed and the locations of these active devices are not updated on the system maps, or design documents. Instances such as: disaster recovery, temporary or special events, or temporary amplifier placements due to coaxial cable deterioration. While these are intended to be temporary, they can be overlooked and left in the system unnoticed. In these instances, they can cause unexplained failures in the recently expanded portions of the spectrum and may require a full physical walk-out of the network to locate.

Figure 11 – Sub-split amplifier installed in a mid-split system

In addition to “old” amplifiers, another potential obstacle to the activation of expanded spectrum is “old” passive plug-in components, example in Figure 9. Several amplifier platforms have remained largely unchanged through several generations, and the form factors for the passive plug-ins in the amplifiers themselves have also remained unchanged. Forward and Return equalizers in particular are a concern. Often, then new nodes and amplifiers are placed, the new portions of spectrum are not immediately activated with signals. The legacy channel line-ups are often retained for a period of time after splicing is complete. In these instances, it is difficult to immediately identify if a legacy plug-in component has been installed in an amplifier using PNM tools. Legacy verification practices such as the use of a signal generator and a spectrum analyzer would be required to ensure that the expanded bandwidth was usable, and there were no legacy components improperly installed in either an active or passive device.

Figure 12 – Sub-split return equalizers installed in mid-split amplifiers

As with the figure above we recognize that it can be difficult to identify the bandpass frequency of the return equalizers, unless you have a key to the letter code which denotes the upper band edge. In the example of Figure 12, the “S” on the return equalizer denotes an upper band edge of 40 MHz. The form factor however is the same as the mid-split return equalizer and can easily be installed in error. If the construction or maintenance teams use legacy sub-split channels for amplifier alignment or device recovery verification, then all indications will be that the system is operating normally and without error.

However, when the additional spectrum is activated, these devices can cause excessive tilt, due to the loss cause by the sub-split passive component, seen in Figure 13.

Figure 13 – Frequency response of OFDMA channel through a sub-split equalizer

4.2. Partial bonding

When the expanded portion of spectrum, like OFDMA is activated, the long loop automatic level control (ALC) function of DOCSIS devices located in the customer premises will attempt to use that portion of spectrum (if capable) and attempt to adjust the transmit power of the device at that frequency to accommodate the CMTS range request. This can result in a significant difference in transmit levels at the device when compared to the traditional sub-split upstream channels. If the transmit delta or tilt are severe enough to violate the dynamic range window of the device, the device will ultimately be forced into a partially bonded state.

There can also be legacy devices left in the network or drop system that can result in failure to activate the expanded portion of the spectrum. In-home amplifiers are commonly used to increase the amplitude of

signals in the home. There have been many different generations of in-home amplifiers deployed, and many, if not most of them, were designed and built for CATV systems that operated sub-split return paths. These sub-split diplexed devices can result in a failure to activate any additional bandwidth above 40 or 42 MHz. Other considerations for the subscriber drop system, are legacy filters and traps. These devices have been used for many years to manage service and channel access, or for frequency specific bandwidth management like, high pass or low pass filters to manage ingress in the premise. The location and placement of these filters may result in some DOCSIS devices to be unable to acquire a clear and unobstructed path back to the node. These instances would result in capable devices being considered as being in a partially bonded state.

4.3. Performance limitations – how to detect?

Depending on the phase of construction, and the business unit involved, there can be different methods to detect obstacles to the activation of “new” spectrum. As discussed in the Section 4.1, there are plenty of legacy devices that can remain in the trunk and distribution system that can affect the signal flow through the expanded spectrum areas. We have also identified several potential obstacles in the premise wiring system. While these effectively result in the same thing, there may be different methodologies to identifying where the obstacle exists.

During the construction phase of the upgrade, once the node, and all the amplifiers have been spliced in and activated, there are several legacy practices that can still be used for spectrum testing and validation. For many years, active sweep transmitters installed in the headend allowed technicians to prove connectivity, frequency response and level validation of a newly constructed network. The introduction of technologies like Remote-PHY and Remote MAC-PHY have rendered this practice obsolete, as the signal generation point is at the node, and no longer in the headend or hub. There are still however, hand-held signal generators and receivers that can successfully be used to insert a carrier at an insertion point, like a terminating tap, and receivers that can detect that inserted signal at an endpoint, like the optical node return input test point. This method is still perfectly valid; however, it requires a lot of time and mobility to validate all the potential end points in a node. Some test equipment can generate QAM signals in the return band to be received on a spectrum analyzer and be evaluated for both amplitude and quality.

The use of intelligence tools is a more efficient way to validate the upstream signal path, however it is also not without challenges. At the earliest stages of the construction and activation process, the downstream and upstream channel plans may not be fully evolved to activate capable devices in the premises. Further, the intelligence tools themselves may not yet be capable of collecting the additional telemetries available from the CMTS or v-CMTS and localizing them to a point in the network which could be causing the failure. It is incumbent on the operators to engage the tooling teams early in the engineering process of an upgrade to begin to develop the application programming interfaces (APIs) and endpoints between systems to be able to integrate newly activated spectrum telemetry into existing tool suites. The use of field strength meters with embedded D3.1 modems can be useful spectrum validation tools as well.

4.4. Customer performance aspects – speed tests

After all the construction, activation and validation steps have been completed, and the capable devices have been configured with the appropriate firmware to successfully use the newly activated spectrum, it is

finally time to see the fruits of all that labor. Just how fast can we go? There are many different methods to evaluating throughput, or speed, and different locations in the network where it can be measured.

Wireless device tests, hardwired computer tests, and field test equipment used by the technical staff can all garner slightly different results. Which one is right? The answer may be that all of them are. As with many aspects of the telecommunications network, the answer may be a nuanced one. Speed tests are a snapshot in time, of the performance of the path between the requesting device and a speed test server located somewhere on the network. There are many factors that affect the results of a speed test, such as: the type of device being used to initiate the test, the methodology it uses to connect to the network (i.e. wired or wireless), the location of the speed test server, relative to the initiating device, the volume of traffic on the network, and whether the test is customer initiated, or a background test executed by the provider.

There have been many studies and publications created on the different types, and the benefits of the various methodologies, but the focus of this paper is not to evaluate speed test methodologies, rather to provide some experiential suggestions on how best to use PNM tools and practices to successfully activate and validate mid or high split networks. To that end, here are a couple of simple suggestions. The first and possibly most gratifying way is to use a capable field strength meter at a point in the network to validate the use of all the available spectrum. The ability to use a field meter with a DOCSIS 3.1 embedded modem and configured to hit a speed test server can quickly confirm that the upstream path is capable of transporting signals in the expanded portion of the spectrum.

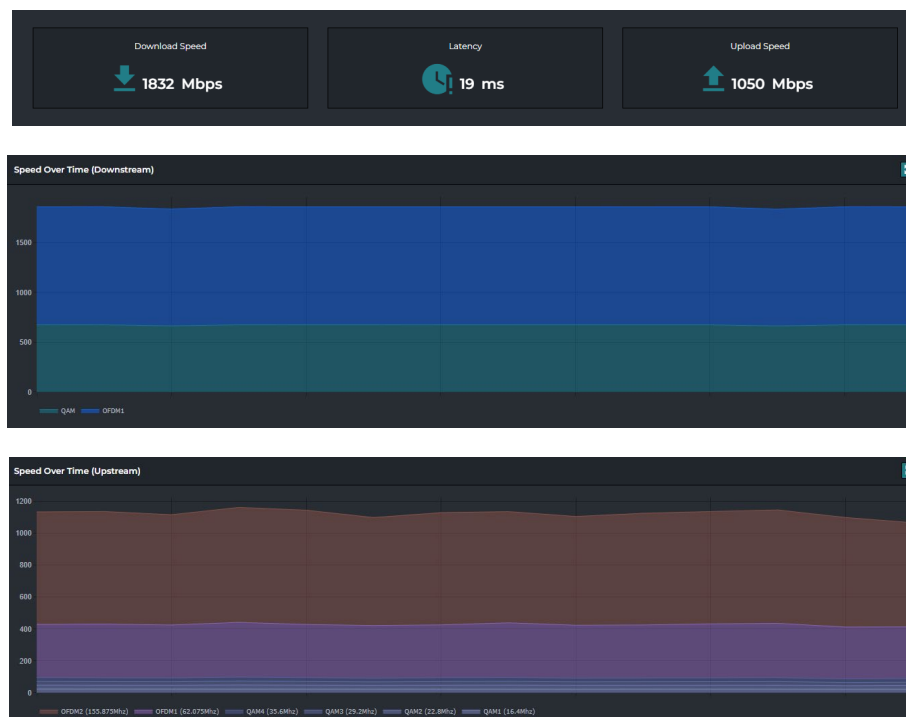

Figure 14 – Field meter speed test results in high-split system

This simple test validates a few things. First that the modem in our test equipment was successfully able to connect and transmit data through the expanded spectrum, and that we were able to achieve a reasonably high data rate through the network. Understanding that this is only one test from a specific

point in the network, and a point in time, we can replicate this at various terminations in the network to validate that there aren't any significant obstacles between the point of the test, and the node location. Devices like the one used for the speed test illustrated in Figure 14 can also provide additional data regarding the quality of the network as it pertains to any impairments that may exist upstream from the test point.

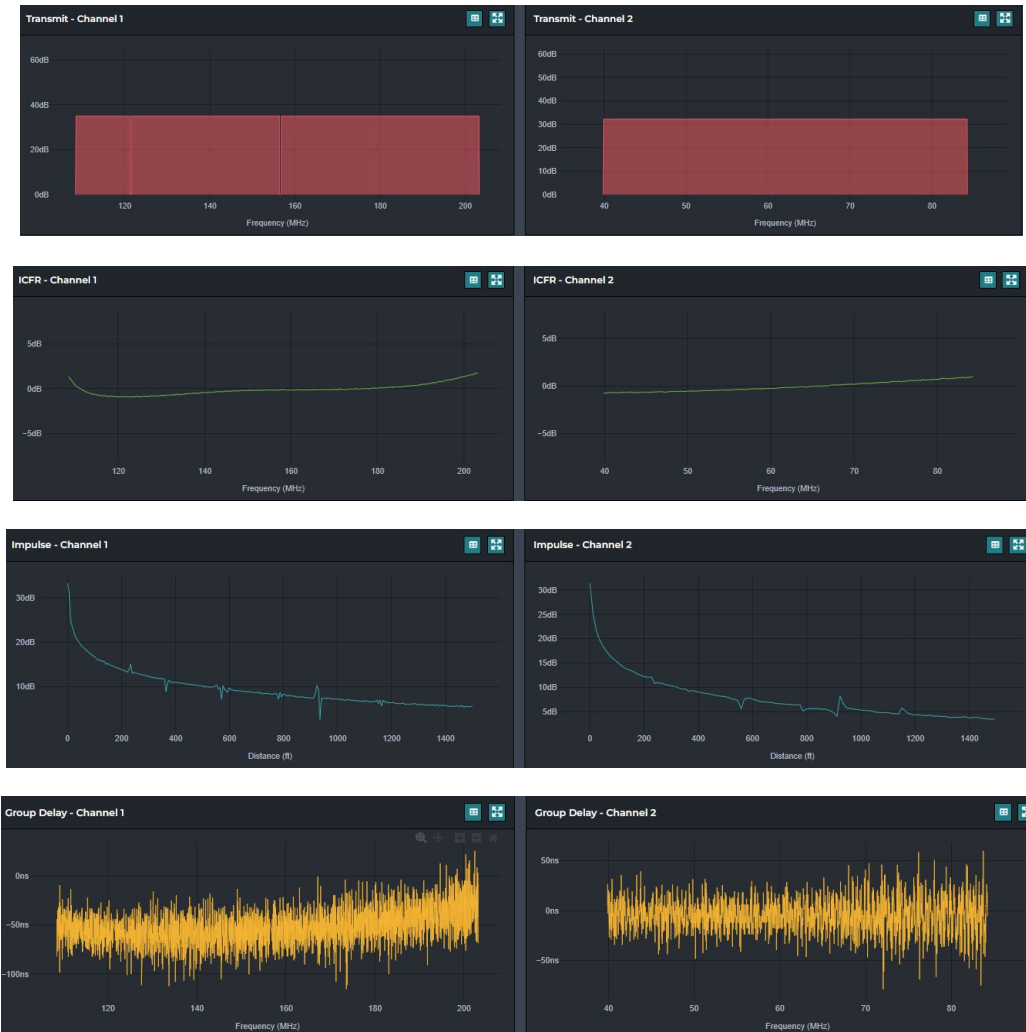

Figure 15 – Upstream signal analysis of expanded upstream using a field meter

Having data points like these are analogous to PNM tool results once the spectrum is activated, and devices are enabled to begin using this spectrum. They can be reliably used to indicate impairments in the transmission medium (coaxial cables), or of passive or active devices that may still be present in the network and have gone unidentified.

There is obvious value in using field test equipment for validation of speeds, and the additional performance data that it can provide. It is, however, time consuming and labor intensive. The other alternative is to do bulk “background” speed testing once devices are activated and online. There are pros and cons to this method also, however. On the plus side, the volume of devices located in different parts of the network can be very useful in localizing potential plant impairments that influence speed. This is also useful in validating those devices are successfully using the expanded spectrums based on their speed

results. While they may not be extremely precise on the actual network speed the way that a subscriber-initiated test could be, they are at least directional with respect to the functional operation of the outside plant portion of the network. The bulk speed tests may not fully stress the network in the way that a subscriber-initiated test does either or transmit as much data to calculate a more precise throughput or speed result, but it can be a good indicator of relative health and functionality of the network. Another potential downside to the bulk testing, is that it doesn't provide any meaningful intelligence on the quality of the coaxial plant or any potential impairments, provided that the subscriber modems are still able to transmit data through the expanded spectrum at some level.

4.5. Implications of PMA

Profile Management Applications (PMA) aren't uniquely associated to the introduction of OFDM or OFDMA signals in expanded spectrums. CMTS's and cable modems have been able to be configured for some level of adaptability to changing plant conditions for many years. These applications are extremely useful in managing data packet loss in the presence of impairments in the network. As the reliability and quality of the customer experience on broadband networks is becoming increasingly valued, their deployments are becoming more commonplace. These applications can adjust the modulation profiles of A-TDMA transmissions as well as OFDMA transmissions. While this is important to the experience of the customers in the degraded service area, it can add complexity to the operational priorities. Prior to the enablement of PMA, an impairment in the network that resulted in measurable packet loss would be identified using packet counters, or other intelligence tools, and would trigger a prioritized repair ticket for a system technician in a relatively short period of time. With the advent of these dynamic management applications, there are some operational considerations that need to be understood. For instance: 1) The poller timing of a monitoring tool(s). 2) The frequency of the PMA analysis and profile change recommendation. 3) Ticket creation and dispatch timing for a packet loss event.

These timing components need to be understood and synchronized to prevent scenarios where a technician is dispatched to an event before the profile management application has had an opportunity to mitigate the impairment. It is understood that the impairment still exists and may need to be identified and mitigated by a network technician, however, the synchronization of the event, mitigation and ticket creation will allow the business to properly prioritize the workforce to address the most impactful events first. The cable plant is a dynamic and ever-changing organism. Many events caused by transient noise in the upstream path, are moderate in severity and can be easily managed by the profile management application without ever sending a technician to affect a repair. There could be instances where the profile management application will intentionally not be engaged to downgrade profiles. Instances where the upstream interface has high utilization, or the profiles downgrade options have already been exhausted, are occasions where it is recommended to dispatch a repair technician to the node as a high priority repair.

5. Conclusion

As cable operators begin to use wider upstream spectrum on OFDMA channels and improve speed and bandwidth, spectrum activation can have challenges. In this first OFDMA PNM attempt, we revisited and applied some of our lessons learned with PNM and SC-QAM adaptive pre-equalization and were able to quickly find several nodes with multiple modems severely impaired and to locate some of the impairment causes. As we deploy mid-split and high-split to more nodes and customers, we will explore more PNM techniques, measurements, and channel configurations, such as wider channels, excluded subcarriers, cataloging ICFR signatures and impairment causes, and analysis along other measurements (Tx power, Rx MER, etc.), to serve us well for troubleshooting and repairing this new service.

Abbreviations

ALC	automatic level control
APIs	application programming interfaces
CM	cable modem
CMTS	cable modem termination system
dB	decibel
DOCSIS	Data Over Cable Service Interface Specification
DS	downstream
HFC	hybrid fiber-coaxial
ICFR	In-channel frequency response
kHz	kilohertz
MHz	megahertz
Msym/s	megasymbols per second
OFDMA	orthogonal frequency division multiple access
PNM	proactive network maintenance
SC-QAM	single channel quadrature amplitude modulation
RF	radio frequency
RPD	remote PHY device
RMS	root mean square
SNMP	simple network management protocol
TFTP	trivial file transfer protocol
US	upstream

1. Introduction

At SCTE in 2012, a group from Comcast presented the Voice Relevance Engine for Xfinity (VREX). Its goal was to understand human utterances for video search and discovery and to take an appropriate action. Since then, Comcast's voice system expanded to cover numerous platforms, won a technical Emmy, and was used for more than 10 billion voice commands last year alone. After running at scale for 10 years, the voice system is being redesigned to suit the new and growing demands for voice control across a range of products.

The original system as described at SCTE in 2012 [1] was divided into three major areas: automated speech recognition (ASR), natural language processing/natural language understanding (NLP/NLU), and action resolution (AR). These services and the division of labor therein include: first determine what the user said, second understand what the user meant, lastly decide what the system should do to resolve the request.

Generic Voice Transaction

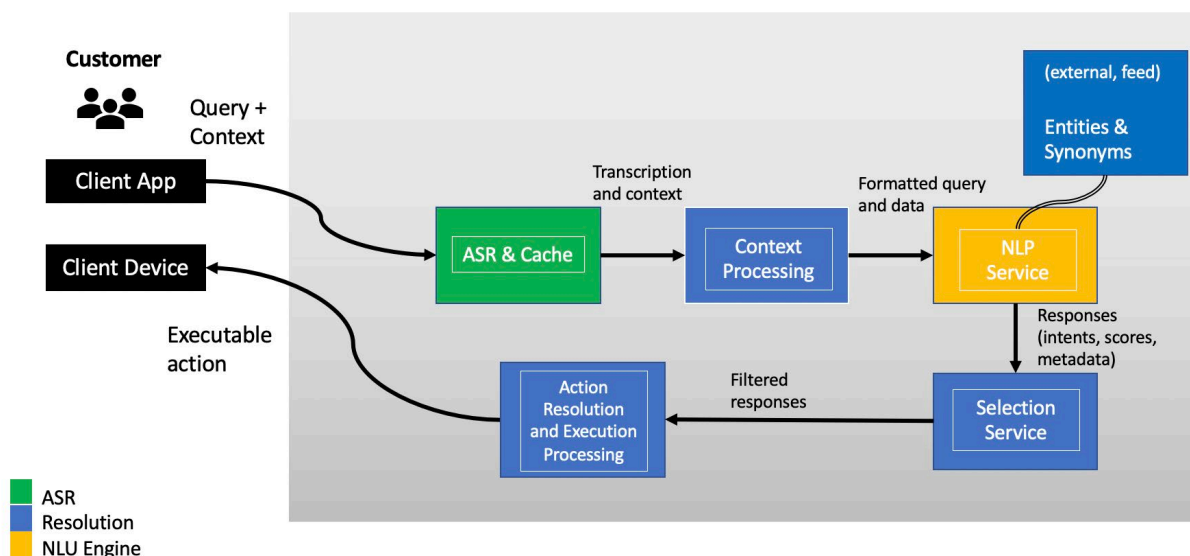

Figure 1 - Basic NLP Process

For the example “show me Adam Sandler movies” the ASR will transcribe the utterance to a text string “show me Adam Sandler movies”. Then, the NLP will attempt to ascribe meaning to the transcription. In this case it will canonically break up the string into <show me> an action, <Adam Sandler> a person, and <movies> a content type. In a simple system, Action Resolution involves the system choosing to provide a list of movies starring actor Adam Sandler. The information is provided in a way that can be displayed on the target device.

The above model is simple and linear. But what happens when there are several domains to cover? (A domain is an area of knowledge like video, customer experience, or home.) More information is needed to determine the appropriate resolution. Is the user interacting with a television? Are they walking in the front door? Are they talking to their car? Context as to when and where the utterance occurred affects

what the domain is for processing the request and what the action resolution will be. There may be several domains that could be applicable, so there can be multiple responses. Selection then must occur based on some quantification of how likely it is that the result is the expected solution. The Action Resolution phase increases in complexity as well because there is more to resolving the action. If the user is in their car speaking to the GPS, the Adam Sandler query should generate an error saying that it cannot find that road. But if the user is speaking to their television, the action resolution should result in a list of movies starring actor Adam Sandler being displayed on the television.

In practice, the VREX system grew organically to support a significant amount of complexity. The redesign assessed the current requirements for the system, those expected in the near future, and the complexity in deployment and support of the voice system. The voice recognition system was redesigned to improve the development, deployment, and servicing of the individual components of the system. These changes will be discussed as they affect each portion of the system.

2. Current Voice Relevancy System

Over time the number of domains, the number of languages, and the breadth of possible uttered commands has increased dramatically. So too, has the relative complexity of the system. The initial design supported speaking into a phone app to choose content to watch on a television set. The use case at design time was that a mobile device was paired to a television and all commands were for tuning content on the television. That model has grown to support not only tuning content but most television controls across smart televisions, voice remotes, hands-free devices, and mobile devices. It now covers many languages in multiple countries. In addition to video, the Voice System processes customer experience, home, sports, and other domain requests. Currently the model looks like this:

Anatomy of a Voice Transaction - Before

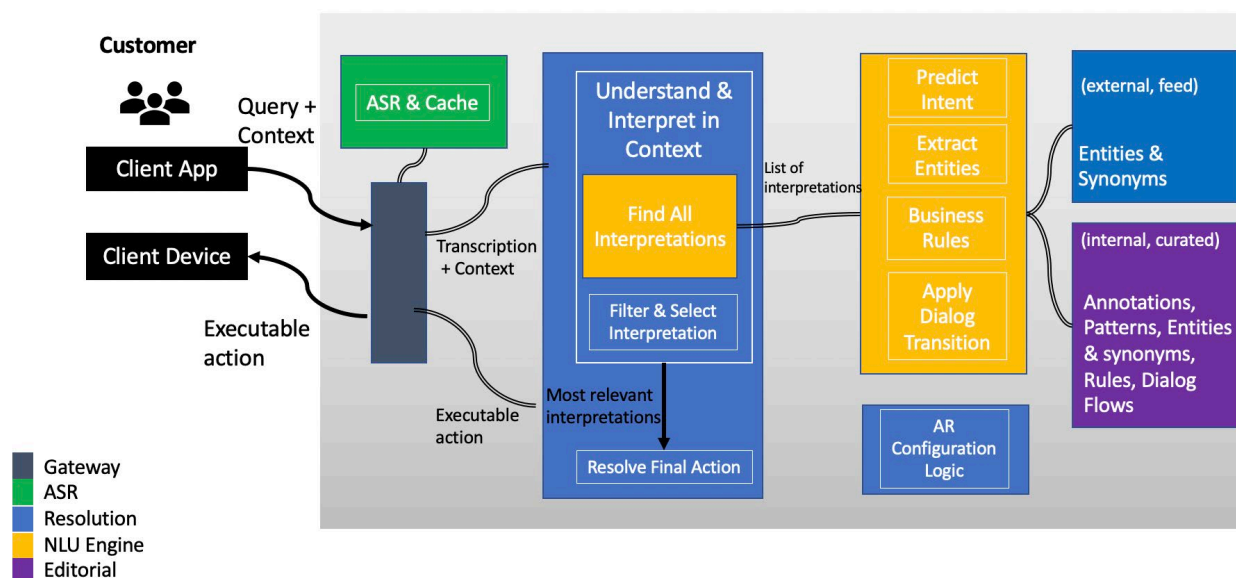

Figure 2 - VREX Voice Transaction (Before)

This drawing is a simplification of the model but includes several parts not included in the earlier simple block diagram. Specifically, it addresses the training of the model including the input of external feeds and the editorial, both of which are a significant piece in managing and training the NLU model. It also includes the configuration necessary to interpret the context of various domains.

Of course, this drawing also excludes several things. There is a significant amount of logic needed for routing, authenticating, and gathering context prior to context processing. While it shows a box for the gateway into the system it does not include the additional external calls to gather context and other needed information. And it does not include any of the testing and observability tools that aid the release and monitoring of the system. But importantly, this drawing adds a level of detail to context processing, NLP, selection, and action resolution. The structure of dealing with a voice command is far from linear. There are loops back to the decision engine with duplication of some common features. This level of interconnectedness, complexity, rigidity, organic system growth, and escalating support costs led to the redesign of the Voice Relevancy System.

3. Redesigning Voice Relevancy System

The goal in redesigning VREX was to improve the development, deployment, and servicing of the components that make up the voice recognition system. This does not mean that the model was simplified, in fact, the drawing below shows there are more components involved. But it allows better separation of work and modularity thus improving flexibility and decoupling and leading to a system that is more reliable and easier to maintain.

3.1. External Interfaces

The gateway for the VREX system had the single purpose of getting queries into the system and returning executable actions, but it grew organically over time and was expanded to cover several disparate cases. The gateway was responsible for directing voice queries to the ASR, gathering metadata from various points in the system (simultaneously to reduce delay), and passing ASR results, context, and metadata to the interpretation and resolution services. It was then responsible for passing the resultant resolution action back to the calling device.

3.1.1. Queries

Anatomy of a Voice Transaction - After

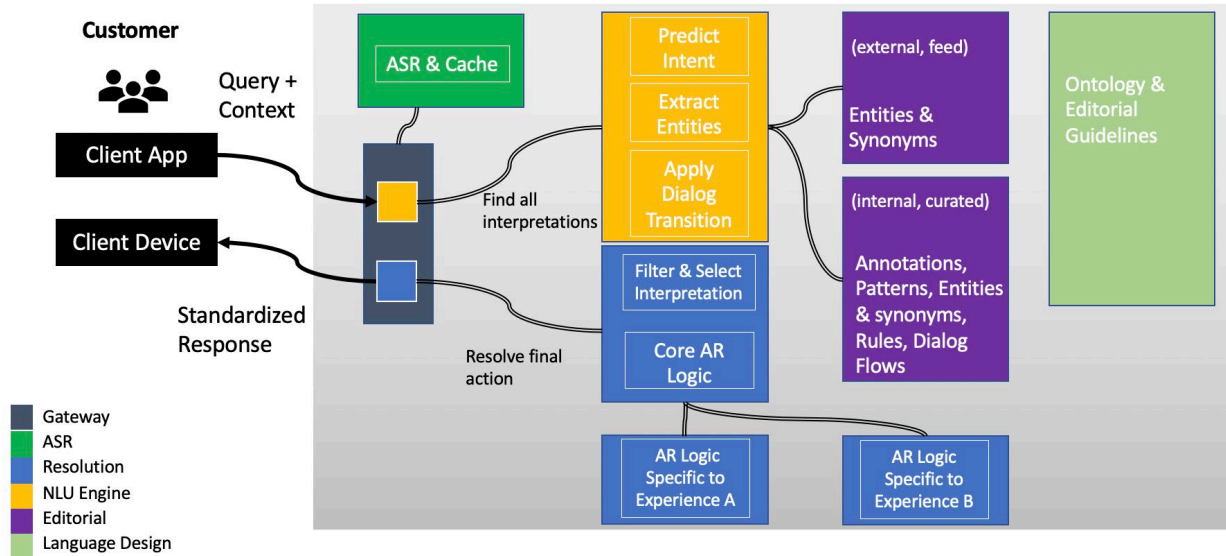

Figure 3 - VREX Voice Transaction (After)

As the client base using VREX expanded, so did the interaction patterns. Rather than just speaking into a mobile device, there was the voice remote push-to-talk, hands-free devices, and text-based chatbots. Some of these clients need ASR, NLU, and AR. But others need only NLU or ASR. The voice system was designed with a single input that gathered all information from multiple sources for every query. It allowed the client to specify the use of ASR, NLU, and AR, but it followed the same pathways regardless. Systems that used the older http requests were on a different, and older, version of the API and the teams had to keep multiple distinct APIs, and the stacks that support them up to date or else allow the older APIs to lag in functionality. It directed transcriptions to a dispatcher that did the domain selection based on the additional context, and answer selection based on the results from the NLU engine. This meant that every query entered the system, gathered all the external information, and traversed the same path through dispatch and interpretation regardless of what the query really required.

This web socket request is still used for voice commands, especially for session-based, multiple message communications. Commands requiring only NLU may prefer to use a lighter weight http call. Most importantly, the gateway can direct the request and so it can be passed where it is needed. If no interpretation is required, then that portion of the system can be skipped entirely.

Being more intentional in what the gateway does, and does not do, allows better use and routing of the services in the system. The client is now responsible for providing whatever additional context is required. The gateway's sole responsibility now is to maintain the contracts for routing information to the right service. It matches the usage of the product with the service and verifies the type of input and output expected. More calls go through the gateway, but it is skinnier and faster. It includes the API to client services, authentication logic, and configurable logic for dispatching messages based on the experience. It

can send audio and context to the speech engine, transcriptions, metadata, and context to the NLU engine, and logical forms to the resolution service.

3.1.2. Responses

A common way of communicating intents back to the client regardless of the experience in question was introduced to decouple the voice system from the experiences they support. The response messages were standardized because prior to the redesign, each client experience could determine what and how they wanted to receive responses from the voice system. This meant that the logical forms created by the NLU had to be translated for each client experience. Many used deeplinks directly to the resultant pages with the result that any resolution often had to be custom designed to support a specific client and changed when the client UI changed. By defining a standard interface, similar, but different from the logical forms created by the NLU system, the entire VREX system has a known language through which it communicates user intents and was separated from client-side changes.

In this case the action resolution provided general intents that include all the information that a client may need to determine the appropriate UI experience to present to the user. It is not prescriptive of the specific page to render, so the same structure can be used by multiple experiences and does not change if there are changes to the UI flow. A result of this is that some of the information is supplied in multiple formats, to allow this flexibility. For example, the rawQuery and the entity could be the same information presented differently for use by different clients. General pseudocode structure of an intent response is below.

```
{
  "type": "xrn:<domain>:<intent>:<receiver>:<action>",
  "intent": {
    "action": "",
    "data": {
      "rawQuery": "",
      "entity": {
        "entityType": "",
        "entityId": "",
        "entityAttributes": []
      }
    },
    "context": {
    }
  }
}
```

Figure 4 - Example Intent Pseudocode

Thin adaptation layers can then be created at the interface where needed. The VREX system is insulated from changes on the client side and the results are more deterministic because the patterns of their resolution and communication are the same.

3.2. NLU and AR

The system was designed for a single client and domain which meant that many of the services were tightly coupled. The speech recognition, NLU, and action resolution are distinct functions and yet, in understanding and interpreting, and doing so within the context of the request, those lines were blurred. This coupling caused cascading changes in the system. For example, when upgrading the ENLP (elastic NLP) which does the pattern matching NLP, the upgrade drove changes into the selection and resolution portion of the system. This was compounded when multiple experiences were supported as the coupling existed for every experience built. Thus, reestablishing the division between the responsibilities of the gateway (as explained above), the NLU, and the filtering and action resolution was needed.

As seen in the ‘Before’ VREX transaction (Figure 2), NLU related functions for finding interpretations was actually part of the resolution services. Everything that was needed to understand, interpret, and resolve actions for the domain was in one place. But this meant there was tight coupling between the interpretation and resolution services, and the NLU engine to find all the interpretations and resolve them. It also meant that everything had to pass through this interpretation even if action resolution was not required

Re-establishing clear boundaries between services within the VREX system meant separating those functions. The NLU logic exists separate from the interpretation and action resolution logic. The gateway contains the per experience information needed to dispatch the queries appropriately. The NLU receives the query text, context, and any metadata it needs from the gateway, and passes back logical forms. The interpretation and resolution services receive logical forms and select answers, determine resolution, and return standardized responses on a per domain basis. The two services, once again, focus on their core responsibilities and communicate only through the defined interfaces in the gateway.

At the same time, the layers of the system were restructured to separate the experience business rules from the core functionality meaning that the individual pieces that need to be built for a specific experience are thinner, allowing for better reuse. Core logic is that which is needed for turning any voice command into an action. Business logic is the configuration and function that is needed to create a meaningful action in each environment.

Before

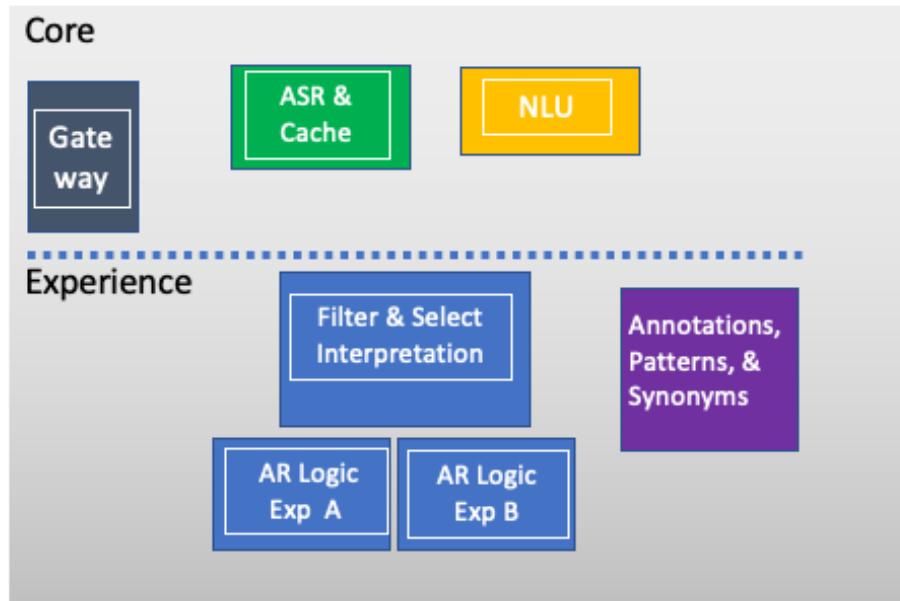

Figure 5 - Core vs Experience Layers (Before)

After

Figure 6 - Core vs Experience Layers (After)

In the above drawings, before the redesign only the ASR and the NLU services were core functionality, and even they had some configuration within the services that required redeployment when changed. Most of the training data input, interpretation, and resolution logic was linked to the specific experience, so each new client or environment involved significant design and deployment resources.

With the redesign, the core filtering interpretation and selection, and the ontology and editorial guidelines, became reusable core functions. This separability of the custom logic from the core logic increases the complexity of the model but greatly reduces the unique work for development and deployment of a specific experience. This then allowed the separation of understanding a query from filtering and selecting the resolution action. This is important because understanding the queries depends on learning processes in the NLU engine and its prediction of the intents based on the appropriate rules. These change only when the model information - the feed, the annotations, or the feedback - change. Filtering and resolution depend on several factors. The first is the fundamental logic for selection and filtering. Understanding what ‘play’ means is near universal. But how to ‘play’ depends very much on the experience in question. The goal here was to, as much as possible, separate that which is universal, the meaning of an utterance, from how to address that user intent in each environment.

Reduced complexity and interdependency resulted. Once most of the specific configuration and logic was pushed as far to the edge of the system as possible, the surface area that needs customization for new experiences was reduced. The entire process of supporting a new function, a new client, or a new experience has a much shorter development time.

3.3. Annotations, Synonyms, Ontology, and Testing

To improve the consistency of the system, a set of ontology and guidelines were specified to simplify the patterns for the editorial work that is used to enrich the dataset. Fallback patterns from optimal behavior to acceptable behavior improve both the flexibility and the resiliency of the system. Finally, each service was shifted to use to a common logging, tracing, and debugging system.

As a system grows it gathers a lot of information. The ontology redesign found several ways of representing similar concepts that were being supported simultaneously. The team took the time to define an ontology and guidelines for the editorial additions that enrich the dataset. This involved combing through the existing rules to define reusable patterns, removing duplication, and designing a process of intro, request, update for creating patterns and entering synonyms. This makes for fewer, more consistent patterns, and makes the job of an editor easier because most additions will fit into a series of well-defined patterns. The ontology changes included using labels that create flexibility for ranking importance of certain structured utterances.

With more commonality in patterns and with the separation of the experience specific logic, and its push to the edge of the system, some behavior can be defined on an experience basis without affecting the core logic.

Additionally, while not expressly mentioned previously, any system is going to have a considerable amount of logging and debugging code. Because of the modular nature of the VREX system a lot of this was done by each individual team in the way that best suited them. But this made it disjointed and harder to debug the voice system end-to-end. The re-architecture was an opportunity to take the best and most useful practices across teams and consolidate them into one structured process including our own testing system and ELK (Elasticsearch and Kibana) cluster for common observability. Note that Comcast collects, stores, and uses all data in accordance with its disclosures to users and applicable laws.

4. Conclusion

VREX was presented exactly 10 years ago at SCTE as a novel way to perform voice resolution for the video space at scale. A large-scale system can be expected to have experienced a lot of organic growth and change over a decade. As systems grow organically to suit changing needs, they often take on unexpected forms.

The Comcast team determined its needs as greater flexibility, faster development time for new features, faster deployment time for new customers, and easier and more consistent support. They then redesigned the system, re-defining the APIs, service boundaries, patterns, and ontology. This fundamentally changed how the services can be called and how they respond. It changed service boundaries to separate core functionality from experience driven code, made configuration handling common, and reduced the scope of the experience layers. Finally, they simplified the patterns and ontology that is used to train the model and make decisions. This redesign, while still in the process of being implemented, has made the development and support of the VREX system faster, and more scalable, by reducing the scope of work needed to support an experience, increasing the reusable code, and isolating the code in the system that needs to be modified closer to the edge of the system.

Abbreviations

API	Application Programming Interface
AR	Action resolution
ASR	Automatic Speech Recognition
BIO	Beginning-inside-outside
ELK	Elasticsearch and Kibana
ENLP	Elastic Natural Language Processor
HTTP	Hypertext Transport Protocol
NLP/NLU	Natural Language Processing/Natural Language Understanding
SCTE	Society of Cable Telecommunications Engineers
UI	User Interface
VREX	Voice Relevance Engine for Xfinity

1. Introduction

Contextual Information (CI) is an asset to every enterprise for its digitization to be achieved end-to-end. The digitization of contextual information and its changes can build a sustainable growth engine for development of new products and services. It can lower cost of software changes and lead to high productivity. To explore how we can achieve digitization of contextual information, in this paper we start with a scenario, explain the personnel involved, the kind of questions that get asked by these personnel, explain the problem that is in exchange of contextual information, and finally provide a possible solution for it. In this paper we also will explore the mechanics of contextual information and how it can benefit small or large use cases for data analysis and machine learning.

We start with a simple question that requires analysis into telemetry data, investigate the journey of how that question gets answered within an enterprise. Let us assume there is a device “X.” This device is part of the internet protocol (IP) network. This device also has a capability to provide consistent telemetry such as its state. State here refers to the overall condition of the device, for example, is the device online/offline, and if the device is offline then reasons for being offline such as error conditions. Given this telemetry data, business owners can ask specific questions that can help them in business impacting decisions. Such as, evaluating device models from various vendors. A sample question might be to find out if a specific device model breaks down more than others. Given the value that can be achieved from answers to such questions using telemetry data, leadership allocates time and resources to capture data from device “X,” ingest its telemetry into a storage layer and then appropriately make that data available for use cases such as alerting, analysis, and machine learning.

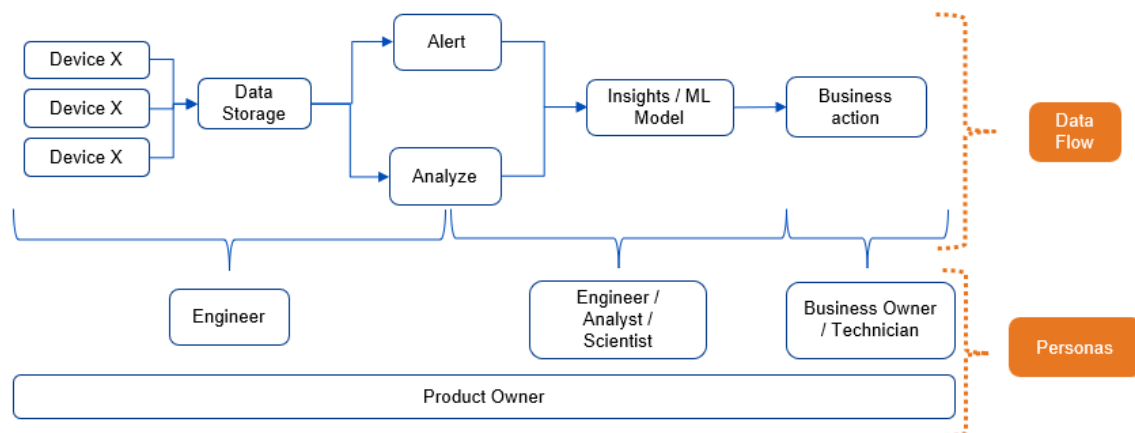

Figure 1- Sample flow of telemetry data and personnel involved

Note: Arrow direction represents data flow.

In the diagram above, which is common flow of data across enterprises, we see five different personnel getting involved in ingesting, storing, alerting, analyzing, and actioning on the insights. In the section below, each of the five personnel are analyzed. Moreover, and some of their motivations behind enabling insights from this data is highlighted.

2. Personnel & Motivation

Business owner(s) are motivated to provide high reliability in the overall service offered to customers. Here device “X” is a critical part of the IP network and should be made reliable and stable. Any disruptions in service due to device outages can negatively impact the customer experience. By choosing the right device models with the highest reliability they look to reduce disruptions. Their eventual goal is to have high customer satisfaction by providing reliable service. Business owners also often have limited budget to achieve the previously mentioned goals. So, they look to strike a fine balance between the highest reliability possible given their allocated budgets.

Product owners are looking to gain value through telemetry data and look for opportunities where the products or features they own, can save cost, or improve productivity. Product owners typically get measured on customer satisfaction, and hence want to see their customers succeed. To ensure customer satisfaction, the speed of deploying features is one of the many criteria’s they focus on, in designing and engineering features. In large enterprises, due to pace of evolution, in many instances this criterion can become the highest priority, while other criteria can take lower priority.

Engineers are specifically interested in maintaining a reliable stream of data to consumption platforms with low latency. Any disruptions in data pipelines are a disruption to data flow where engineers are called upon to fix the issue. Engineers also must optimize data pipelines for low cost of computation while providing maximum data resolution. Given these opposing set of goals, namely cost vs. data resolution, they must make decisions on the resolution of data to fit either compute or storage requirements.

Data consumers on the other hand are keen on getting data that is reliable and of high quality to help them ease their job. Data cleaning is usually a large part of their projects. Given the velocity, variety, and volume of data available within an enterprise, it is safe to assume that data cleaning is a regular routine. However, data consumers are typically/usually demotivated by data cleaning since they view this as time taken away from more exciting tasks, which is to find insights in the telemetry data that provides an accurate representation of the real world.

Finally, network technicians want to see lower repeat issues. They want to ensure lower number of disruptions in the network. They depend on meaningful insights that help reduce avoidable maintenance and repairs. They are usually demotivated with technology and process that is more of a hinderance to their work than assist them, for example: cases where device recalls are made.

Below is a representation of the personnel and exchange of contextual information mentioned above:

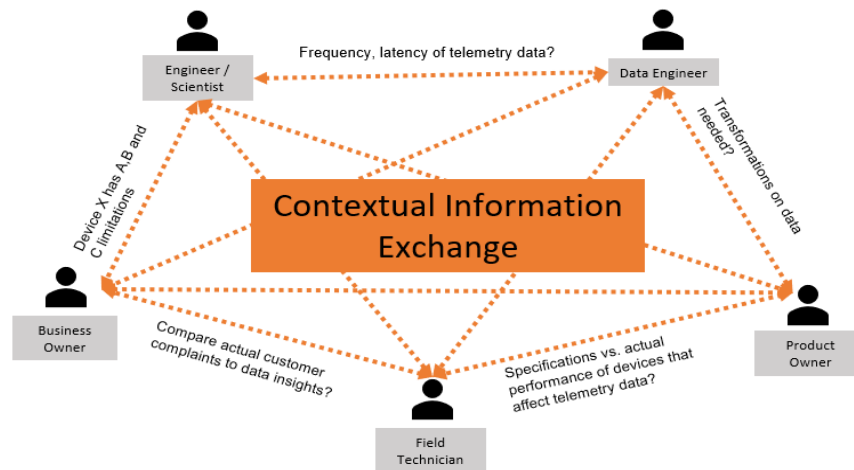

Figure 2- Exchange of contextual information across personnel

Now that we have seen the scenario and personnel involved, let us understand what we mean by contextual information and which of the above personnel might be responsible for such information and possibly where it might be made available in an enterprise.

3. Defining Contextual Information

We start by defining what we mean by contextual information. Contextual information can include but not limited to any metadata that provides context and perspective around telemetry data. For example, application configuration information used to set up the data pipeline, inherent limitations of data, data lineage information such as source and target systems for the entire data pipeline chain, data catalog such as list of data sets available, schemas and their versions, and many more. To better explain this with an analogy, consider contextual information as controls in the control pane of a manufacturing line and the telemetry data as the products being manufactured through the machinery itself.

Continuing with this analogy, in a manufacturing line, the controls (switches and dials) are usually set to certain values to ensure a constant production of the product. To either increase or decrease production that meets demand the demand, these dials in the control pane need to adjust. If the controls are not digitized and automated, then a human intervention is required every time to increase or decrease production. Also, considering the changes in the control values, they are not frequent, but too rare either. If these changes in the control values are not propagated or communicated to the entire manufacturing line, as an example to the packaging department or to the inventory department, the whole manufacturing line fails.

Similarly, consider an application that polls devices in the IP network at every A mins (frequency) to receive B resolution of data. In this case the telemetry data polled by the application is the product, while the polling frequency and the resolution detail polled are the controls in the control pane. If changes to the polling frequency or the resolution of data is not communicated by the application to downstream consumers, the whole data pipeline fails, causing cascading failures.

By nature, Contextual information is usually distributed in multiple systems. These systems may or may not talk to one another. Issues that prevent systems from communicating with one and other can include but are not limited to: mix of legacy and new applications, varying hardware/software platforms, varying cloud environments and varying feature capabilities. Let us consider the first example of telemetry data

from device X discussed in this paper and see how contextual information may be distributed among many systems.

Device vendors publish object identifiers for each device property and define functions, attributes in libraries allowing customers to consume and ingest such information. When telemetry data from the device is ingested, the schema of the data is registered in a schema registry to ensure changes/versions are tracked for field names, descriptions, data type changes. Information such as source, target, transformation logic and resolution of data are stored in application configuration. If data takes few forms such as raw, transformed and aggregated with retention periods increasing with lower resolutions of data then such information might be stored in the configuration of the application as well or in a catalog. Finally, the data catalog could be from well-defined tables or a simple list of storage paths once data is processed and written to a location. The ingestion application is registered in a service catalog that is maintained across the enterprise. Such a service catalog would contain information like, application name, purpose, source, destination, developers, support personnel etc.

Table 1- Sample CI and probable storage systems

Contextual Information	Probable Storage System
Object identifiers, descriptions, limitations, values etc.,	Libraries published by device vendors
Data resolution, polling frequency etc.,	Application configuration
Quality of datasets – raw, enriched, transformed, aggregated etc.,	Wiki pages, word documentation, schemas within DB's, segregation by paths in an object store
Data catalog	Schemas within DB's, segregation by paths in an object store, wiki pages
Application information	Service catalog
Application code and versioning	Version control, code repository
Change information	Tools that support CI/CD such as Concourse

4. Day 1 vs. Day N Scenario

Now that we have outlined the scenario, personnel with their motivations, defined CI, its nature, and the systems/applications where it might be stored, let us have a look at how a data consumer looking to generate alerts on telemetry data from device X discovers CI on day 1 (i.e., when designing the application) and day 2 to day N (when the application is deployed and needs to be maintained).

Initially a “discovery” phase to scrub, understand, document, if necessary, all the above-mentioned contextual information from various systems is required. We will discuss later why it is important to reduce the time involved in this phase. Since the focus initially is on generating alerts atop of telemetry

data from device X, the engineer might take the below attributes into consideration when designing an alerting application:

- Source of device X telemetry data
- Target to provide alerts once processed
- Various conditions within the telemetry data
- Values that signify these conditions
- Any exceptions to the conditions such as occurrences of NULL values or random values
- Applications that provide enrichment information to values within telemetry data (dependency)
- Data types of values
- Frequency of source data & target
- Volume of data at source & target
- Latency of data at source & target
- Modifications/transformations done to values to make them human friendly. For example: consider state information containing '1' for online and '0' for offline or vice versa. To make this more human friendly, one might be converted to "online" and 0 might be converted to "offline" to remove ambiguity for the data consumer
- Source and destination schema of the data

In a perfect world, all the above contextual information and their source systems are digitized and work cohesively (without any linkage breaks) to make the engineers' life easy to consume such information programmatically and design the alerting application in a fully digitized manner. However, it is far from reality since a lot of this information may not be digitized for easy consumption, for example, there might not be easily accessible application programmable interfaces (APIs) that provide information on all the modifications done to data values to make them human readable or a programmable interface that provides the frequency and resolution of the polling application. CI might be available within configuration of applications (as code) or free text documentation or audio/video clips (when recorded as training videos). In such situations, scrubbing through just free form information during discovery phase and then building configuration objects that contain contextual data and using this in alerting applications might be the accepted norm, but is not ideal and does not achieve digitization. This rapid prototyping and is also known as fast go-to-market strategies to justify the acceptance of non-digitization of contextual information. As previously discussed in the section, large enterprises have deadlines, priorities to meet, especially during the development phase since it costs time and money.

Since some of these CI inputs arrive from data discovery for the engineer to use them for building configuration objects manually for the alerting application, we have a breakage in the chain of digitization on day 1 (day 1 here is referring to the application deployed in production) itself. We are interested in showing how using non-digitized CI from day 1 causes a cascading set of problems on day 2 to day N (refer to figure 4). So let us assume that the engineer has configured required CI and successfully deployed the application that generates alerts atop of the telemetry data.

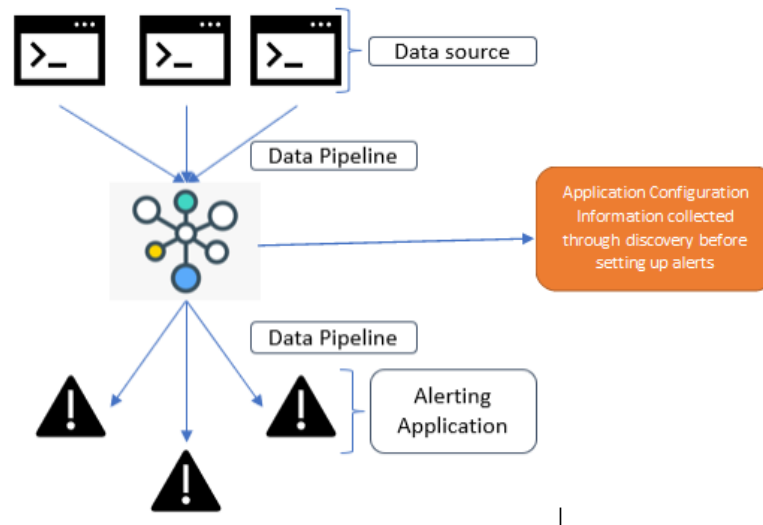

Figure 3- Alerting application deployed with contextual data within configuration

On day two, let us assume there is now a machine learning model set up to consume alerts from the alerting application. Now we have a two-layer dependance on the non-digitized contextual information.

Now let us also assume there is change in multiple attributes of the contextual information such as change in schema (data type changes), source system change, destination system change, data value changes (such as two or more values combined to one or a single value split into multiple), change in frequency of data, change in resolution of data etc. Since CI elements were not fully digitized on day 1, these can be treated as breaking changes for all downstream layers.

Below is a representation of cascading failure can occur on when CI is not fully digitized and transmitted.

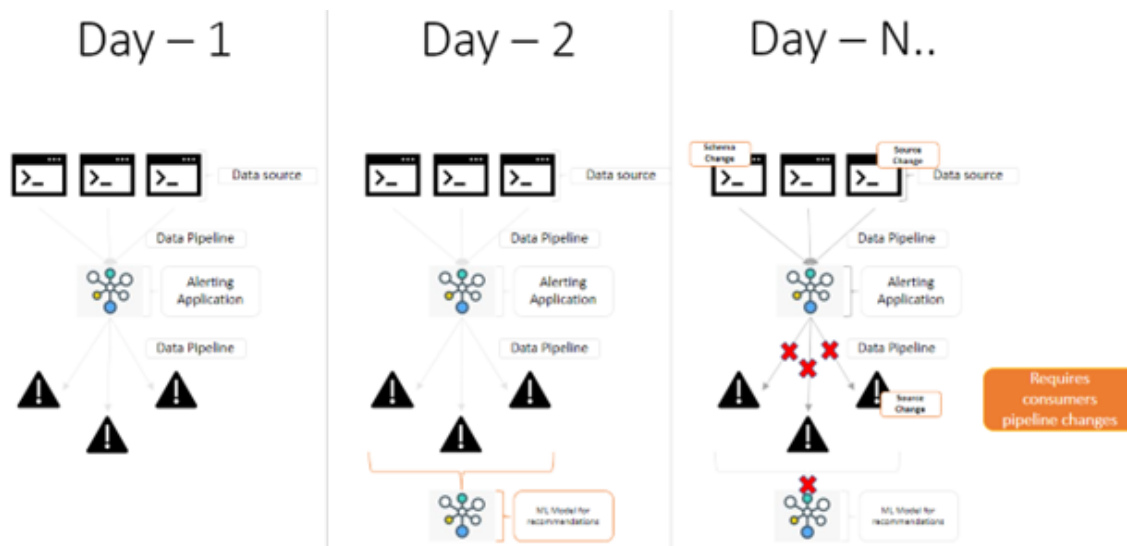

Figure 4- Cascading failure due to non-digitization of CI

If we do not address this problem of non-digitization of CI but kept adding more layers downstream that sends notifications to customers based on recommendations from the machine learning model, this cycle continues until, it collapses due to unmanageable changes in CI.

To give a scale, if there are A number of measurements available from a device going through B number of CI changes and there are C number of dependent data consumers downstream, then we can assume that there would be $A*B*C$ number of changes to manage or intervention due to non-digitization of CI.

This problem only exacerbates if engineering groups are distributed between domains in an enterprise and reporting into various leaders. Groups having many individuals working on a single project with individuals distributed in various geographies. Then there are problems that the enterprise is not in control of such as vendors making devices smarter, software/hardware changes etc., the list goes on. And finally, the growth in volume, variety and veracity of data generation does not help either, where we are having to re-think our traditional well-defined storage formats with well-defined meta data stores to a more loosely bound structure where metadata is distributed all over the place.

If each time CI changes need to be reviewed, handled before re-deploying applications, then it is both very human centric and time consuming. This process is highly error prone and leads to lot of wastage in money and lowers productivity.

5. Proposal/Solution

One of the first things we observe as we review the list of CI elements is that it is diverse, sourced from a lot of systems/applications. Remember CI is meant to provide context and perspective to the telemetry data and its use and hence it includes everything that addresses this requirement.

With the evolution of software, we have an exceptionally good understanding of metadata needed to build applications, microservices and event-driven structures. However, we are lacking a standardized framework of required CI elements, its storage and transmission when cutting across pure software development activities and into more of the realm of data analytics/science activities that prototype and launch machine learning (ML) models that in turn assist software development. The CI elements of interest are varied between these two kinds of activities and hence an encompassing standardized set might be a good one to have to start with. We do not have a standardized list and that is for another day and another research paper. But in the absence of such a list, how should we produce one to address the problem in the short term at least?

One way is to see the kind of questions that get asked to an engineer/analyst/scientist when they present findings:

- What is the source of this data?
- Why did we not use an alternate source to answer the question on hand?
- What does a value mean? For example, in case of state information from a device X, what does online really mean? What does it signify?
- Do we know what is the source of truth between two similar datasets from two different applications?
- What assumptions have been made when generating an alert/analysis/ML model on telemetry data?
- What is the built-in latency into an alert/analysis/ML model? Can we reduce it?
- What thresholds were used to generate this alert?

- Who is the owner of this data?

The personnel asking these questions encountered doubt in the alerting mechanism, or analysis generated or the recommendations from the machine learning model. Based on this, it can be observed that this is just non-digitization of CI manifesting as the problem. The question is not asked to see if answer is known, but it is purely to get more context and perspective on the data. This data could have been transformed from pure raw telemetry to an alert, analysis, or an ML model that is helping drive the insight to help make a business decision.

With that in mind, let us start with a list that solves for these above questions and then build from there. It should be noted that this is not a comprehensive list of CI elements and should not be treated as one. We are merely trying to answer the above questions and providing a means to solve the problem. If these questions are not of high priority within your enterprise, then this list should be reformed to fit your enterprise needs.

Table 2- Sample list of elements in CDO's

Sample CI standardization	Description
Source system	Refers to the device, application etc., providing the telemetry data
Target system	Refers to the storage layer, application etc., where data is persisted after transforming the telemetry data
Data Frequency, Data Resolution etc.,	Explaining how frequently fresh data arrives, how deep can the data go etc.,
Data lineage	The source system/application where the data originated, got transformed, stored etc.,
Data description	Describes the telemetry data and can include field descriptions, value explanations, value limitations etc.,
Data schemas	Structure of the data
Data catalog	If more than one stream in the telemetry data, then list or catalog of those datasets
Exceptions	Exceptions when data might not be transmitted, transmitted with errors etc.,
Transformations applied	Changes to the datasets applied between source to destination

Next, we discuss the approaches we can take to solve for CI list to be transmitted through the entire lifetime of the data within an organization i.e., through various domains:

1. Ensure all contextual information is documented, distributed at regular intervals
 - Time consuming, human intensive and error prone if not for impossible.

2. Ensure all applications transmitting data provides interfaces for not only data, but also contextual information about the data (including metadata)
 - Well defined micro services powering every application within the organization with great programmable interfaces that data consumers can interact with to gain contextual knowledge, we can deem this problem solved.

However, this is not always the case since there will be standalone applications that do not have interfaces but are vital within enterprises. These applications came about as prototypes or as legacy service. Information technology (IT) is no more centralized where one central IT organization sets standards. The distributed nature of modern IT ensures that applications/systems are always built in a diverse way.

Start by bundling everything we determine as necessary contextual information required for the application in question and for downstream applications and build a contextual data object (CDO) and domain contextual data objects (DCDOs). Store and transmit this CDO in a way that it can be easily queried for changes. Also ensure that DCDOs can be enhanced by multiple application owners starting from the data producer, all the way to the last data consumer. Our solution proposal resolves around this third option. This is not necessarily new, since we have various flavors of this solution in usage within enterprises today, but the semantics of how we implement this might need another look.

A typical set of personnel working on making telemetry data smarter through alerts, analysis, or ML models, are distributed in various parts of the organization from functional, hierarchical, and geographical perspectives. Given such a distributed workforce, it would be wise to ensure that we start building the CDOs in bits and pieces throughout the domain and allow each data producer and consumer to decide the kind of CI they would like to add into the CDO. And when the CDO needs to be moved between domains, ensure that domain contextual data objects are used to transmit such information.

We see a way that contextual information can be digitized into an object that gets transformed as it moves along the enterprise systems and applications. First the data producer might produce a CDO as below:

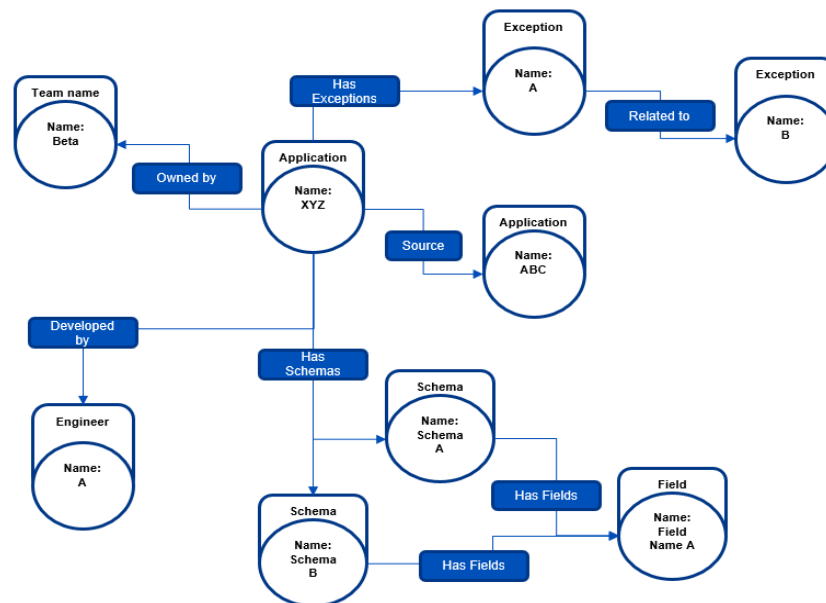

Figure 5- Contextual Data Object

Remember the above CDO is entirely up to the data producer to determine what to populate and what to leave out. In this paper we only define a common set of elements part of the CDO that is available to the producer to add into the CDO as part of the standardization. We want to ensure that this CDO is used internally by the data producer to drive changes to their application. This is an especially crucial factor, since self-use is the best motivator for the data producer to keep the CDO up to date and can help drive automation.

Now as this CDO makes its way through the organization to say, another engineering team that is in a different domain (in this case let us assume the elements in CDO and DCDO are same), that adds alerts atop of the “field name A.” The engineering team enhances the DCDO with alert contextual information.

Observe that each of the DCDO elements connected to one another through a relationship. For example, the source data in application XYZ is FROM the application ABC. This signifies lineage information. The application XYZ was developed by team Beta and the engineer A was responsible for its development. Application XYZ has two exceptions named A and B, while B is related to A. Application XYZ also has two schemas: A and B. Both these schemas have common field A.

Below is a representation of how a DCDO might evolve as it makes its way through the enterprise. All orange nodes and edges are added by a different domain:

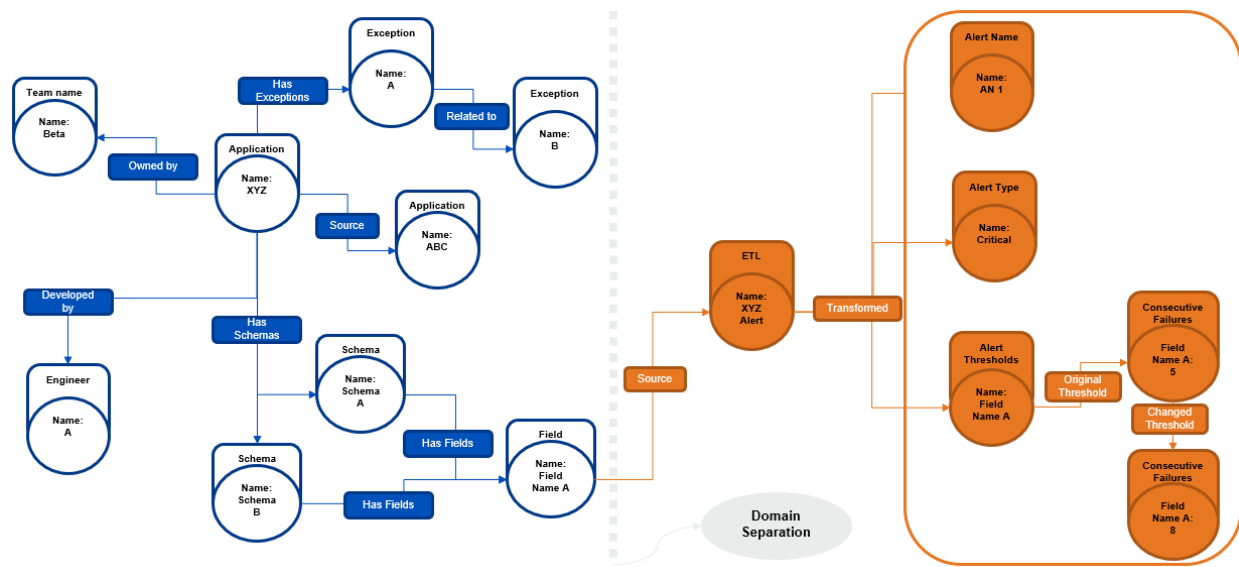

Figure 6- Buildup of domain contextual data object

Input source to an extract, transform and load (ETL) job that performs the function of generating the alert has source XYZ and transforms the data to alert name “AN 1” that has an alert type “critical” with the thresholds set as five consecutive failures originally. The team decided to change the alerting threshold to 8 at some point, which can just be another node signify the date of change.

We can also observe that application that performs the ETL is linked to the source team name and the engineer. This is immensely powerful. This is now helping connect elements that were not intended to be connected in the first place and allows for a lot of questions to be answered. This is the power of having DCDOs.

Expanding on the topic regarding the representation of DCDO and its evolution through the enterprise, an observation can be made that the nature of this data has an entity relationship during its formation. Given this nature of contextual information, two entities (nodes) being linked by a relationship (edge), using a graph storage mechanism for CDOs and DCDOs might be a good idea. As DCDOs evolve we start to build a knowledge graph across the organization giving the consumer access to powerful information that is hidden from many users.

The solution does not stop here. To help data producer teams and the consumer teams to create, interact with CDOs & DCDOs and build on it, we must provide them easy access ways to interact and modify them. Or else, we are just moving the breakage in digitization to a later point in time.

This is only the beginning of the solution. CDOs are built to assist the automation of functions within applications. When this automation controls are needed to be handed over to another domain, we need DCDOs or domain contextual data objects. These DCDOs can be directly used within ML models to ensure that recommendations from the ML models powers the application through automation vs. intervention.

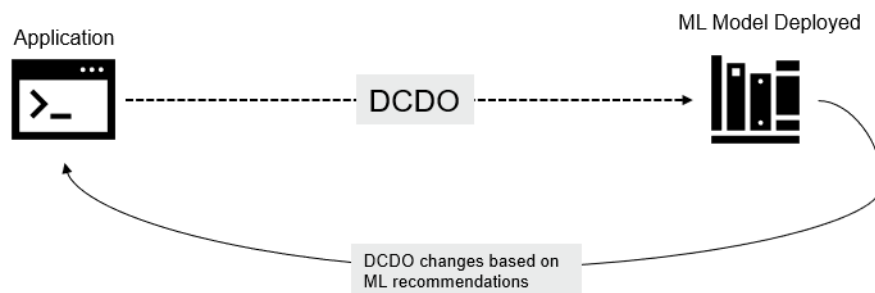

Figure 7- DCDO enabling a full cycle of automation

We should also enforce standardization of CDO/DCDO elements that the enterprise deems necessary and ensure this is adopted from the start for all new applications being developed. This is the hardest part since enforcement of a norm is hard within distributed structures unless it is used by the application.

The way to bring domains to onboard and share their CDOs as DCDOs into a common repository like an open WIKI within the enterprise is to help domains understand the time and cost savings from such an effort. The questions addressed earlier may seem trivial at first, but add in the mix of employee attrition, accidental deletion of information, modifications done for an ad-hoc request, and then having to invest time in discovering all this, the value will speak for itself.

6. Conclusion

Contextual information is vital and should be treated as an asset that needs to handle within an enterprise. Changes in CI is even more vital to enterprises and their propagation through DCDOs is essential for sustainable interaction between domains.

In this paper we first outlined a typical scenario for ingesting, persisting, and acting on telemetry data to derive alerts, insights, and ML recommendations. We also observed personnel and their motivation when interacting with telemetry data and its context. We saw how a cascading failure can occur when CI is not digitized and managed for propagation into downstream systems. Finally, we observed how digitizing CI in the form CDOs and DCDOs not only enables rapid transfer of knowledge between humans but also provides a methodology to handle updates programmatically in fully automated systems.

Digitization of CI also builds resiliency in automation against external factors not under direct control of the organization such as vendor device decommissions and recalls. This is also the case for applications where CI reside needs to evolve at a fast pace. Without effectively tracking changes to CI, models that power ML and automated systems built atop these assumptions can be ineffective. Such ineffectiveness in ML models lead to low return on investment (ROI) and sometimes even negative ROI. Assumptions underlying ML change rapidly with the evolution of network objects, applications, platforms, infrastructure, data pipelines, storage mechanisms and application configuration information. Digitizing CI and storing for easy access, ensures changes can be discovered programmatically by automated systems without intervention. Although we are not entirely solving for end-to-end digitization of all CI in an IP network, we provide means to show how it can be done.

Finally, imagine the amount of time required by engineers, analysts, scientists in discovering contextual information every time a change needs to be made. It is both wasteful and lowers productivity. Digitizing CI as mentioned in this paper by starting to create CDOs for internal use by application owners and DCDOs when transmitting to different domains saves money and time.

Table 2 - Location where services are being offered by current and some future applications	6

1. Executive summary

Customer premises networks have been evolving since the early days of POTS (Plain Old Telephone Service). The introduction of new services like Cable TV, Broadband, and later VoIP, has driven numerous changes in the premises networking requirements. It is therefore no surprise that with the emergence of a vast array of new Internet of Things (IoT) applications and other revenue-generating applications, the premises networking requirements will change yet again. Also, with the advent of these new service offerings such as Telecom for Wellness (T4W) [3], [4], [5] and Smart Cities [12] applications, even the definition of the term “customer premises” itself needs to be realigned.

To better understand these changes in the customer premises networks - as well as plan for them in advance - the SCTE has launched a new initiative under its IoT Working Group called the Wiring Closet Drafting Group (WCDG) [13]. This is a cross-functional team comprising members from the IoT, Smart Cities, Telehealth, and Aging in Place (AIP) working groups. The expectation is to gather and consolidate customer premises networking requirements from all these various classes of IoT applications and make recommendations for future customer premises networks that can be built in a modular fashion using the recommendations from the WCDG.

In this paper, we explore the special needs arising from these recent developments in the customer premises network and outline a framework of requirements that are being compiled by the SCTE WCDG. We highlight key service and business considerations for various application use cases including managed Wi-Fi, home security, home automation, telehealth, aging-in-place, hospital-at-home, smart cities, and their associated security, installation, and support services. We believe this framework can greatly enhance the serviceability and adoption of these new services and can enable significant future revenue opportunities for communications service providers (CSP).

2. Evolution of cable customer premises

Home networks have come a long way over the past few years. They are no longer the domain of technology enthusiasts who cobbled up connectivity between various devices in the home. Today – especially in the wake of the ongoing pandemic – home networks have taken center stage in the life of most people. In addition to the need for ubiquitous Wi-Fi service being the critical driver for these networks – a host of home automation IoT services including sensors, video communications, interactive devices, as well as other next-generation service offerings such as aging-in-place and telehealth are beginning to drive significant complexity in the home network.

From the cable customer perspective, the scope of cable services has also evolved from primarily video services to mainly residential subscribers to now a much broader set of video, voice, and data services to subscribers spanning residential, businesses (offices, retail, hospitality), airports, parks, stadium, hospitals, and even governments (municipal, city infrastructure) etc.

The recent emergence of IoT applications has dramatically expanded the type of services cable networks can deliver. At the same time, the needs of all these disparate services have brought with it significantly increased complexity in the network infrastructure in the customer premises. The future of in-home networking is dependent on the modular deployment of revenue-generating services that not only offer services in a tiered fashion but also are manageable from installation and service assurance points of view. To better understand the needs of the emerging IoT applications and services, and to better prepare for them, the SCTE IoT working group has launched the Wiring Closet Drafting Group (WCDG). This group is a cross-functional team from the IoT, Smart Cities, Telehealth, and Aging in Place (AIP) working groups. The fundamental Premises of WCDG is that by deploying relevant solutions where the

services are deployed a priori, the cable operator can (1) turn up the service faster, (2) customize services to the needs, and (3) can have a competitive advantage in delivering end-to-end services. In this work, we evaluate different needs that arise from such enhancements to the in-home (SFU, MDU), common area (MDUs and planned communities), and smart cities network. We propose a step-by-step upgrade to the Telecom closet, a general-purpose term used for an aggregating unit of the Telecom services offered by the operators. These factors are further explored in this paper.

3. Emerging IoT applications

No new technology in recent history has had the dramatic scope of impact as IoT. This is a technology that touches just about everything we deal with and has the potential to revolutionize life in unforeseen ways. Many ecosystems (such as Telehealth, AIP, smart cities, etc.) are being developed using these IoT devices. Let's take a quick look at some of the more popular IoT applications and services being deployed today.

Home Automation and Security Applications: Some of the most popular IoT applications deployed in homes today are for home automation and security. Home automation enables homeowners to control various elements in their home remotely. These include lights, door locks, thermostats, sprinkler systems etc. While home security has been deployed for many years, most applications in the past involve professionally installed and monitored systems using proprietary technologies. IoT has opened the door to self-installed security systems and devices including sensors and cameras for monitoring the home remotely. These have brought not only significant convenience to homeowners, but they can literally be lifesaving at times.

	 Aging in Place	 Telehealth
Users	Older adults (65+), caregivers	Individuals, providers
Stakeholders	Family members, caregivers, doctors, service personnel etc.	All family members, providers, (payors)
Needs	Communicating, monitoring, service, support, integration	Communicating, monitoring, integrating with provider systems
Challenges	Ease of use, provider network integration, problem solving	Ease of use, device and EMR integration, remote monitoring,
Telecom opportunity	End to end solution, managed services, provider integration	End to end solution, managed services, provider integration

Figure 1 - Telecom for Wellness Opportunity and Challenges Summary

Telecom for Wellness (T4W) applications: The wellness industry is going through a major transformation to modernize the infrastructure, reduce the cost and increase the quality of care. In a series of articles, we have suggested how the Telecom industry can assist the wellness industry[5], [6], [7], [8], [9]. We call this inter-industry collaboration Telecom for Wellness (T4W). Even though the T4W

opportunity is not limited to these two major intersection points, we focus on AIP and Telehealth use cases to illustrate our requirements on the WCDG architecture. (Refer to [1] for six different opportunities that a Telecom operator can address through the T4W.) The SCTE Data Standards Subcommittee, of which two of the authors are members, is actively working on T4W solutions for the AIP and Telehealth areas in working groups three [10] and four [11].

Figure 1 provides a quick summary of the T4W opportunity and challenges from AIP and Telehealth points of view. Many of the needs, challenges, and Telecom opportunities of both markets are similar (refer to the SCTE working group analysis at [10], [11]). Some of the high-level use cases that need to be supported for these two markets include:

- Providing basic communication between the users and the providers/caregivers
- Providing seamless communication between the users and the stakeholders
- Monitoring the users for health, mobility, fall detection, etc.
- Analyzing the data collected from the users and properly notifying the stakeholders
- Assisting the T4W service providers with claims by documenting accountability
- Offering managed services to support installations, product support, and other services to improve adoption and retain customers

The goal of this paper is not to elaborate on these use cases, but to use them to motivate the WCDG modular architectures. For additional information refer to the working group documents.

Retail Business Applications: Retailers have been on the forefront of the IoT revolution trying to exploit the troves of valuable information made available by IoT-enabled devices. From managing the store security, environment, lighting, to monitoring customer traffic and store inventory on a real-time basis – IoT is finding uses in almost every facet of their business today.

Factory/Industrial Automation: Factories and the manufacturing industry has been at the forefront of automation for a long time. Most factories deploy purpose-built machines, tools, robots etc. to automate repetitive tasks. IoT has brought a whole new dimension to this automation. Machines do not just automate their workflow – they can even coordinate seamlessly with other machines and systems on the shop floor, and perhaps even with others across the world.

Inventory/Fleet Management: IoT enables convenient and precise tracking of the location of enabled devices. This has found many applications in the shipping and logistics business for managing product inventory as well as for vehicle and material tracking within a building to all the way across continents.

Smart City Applications: IoT is finding many applications in municipal governance from automated utilities monitoring to smart streetlights, traffic and parking management, energy, and waste management to public transportation applications. Cable operators are uniquely positioned to assist in accelerating many of these applications (refer to Smart City working group at [12]).

Some of these applications intersect in terms of service offerings. For example, smart communities can provide wellness applications along with smart city applications on the managed public Wi-Fi infrastructure.

All the above evolving solutions can provide a huge differentiator for cable operators if they are ahead with their infrastructure to monetize them through flexible and managed offerings at the service delivering locations.

4. Special needs of IoT applications

The vast array of new IoT applications – some of which we outlined above - bring with them many special needs. Let's explore some of the key needs of these IoT applications across various dimensions.

4.1. Location needs

The first dimension we will look at is location. The location where a service is delivered has a major impact on many other requirements across many other dimensions as well. The location determines the scope of the service, and hence the prebuilt modular components that can be deployed in that location are determined. Table 1 gives a high-level view of the typical location where certain types of IoT services are delivered.

Table 1 - Location where services are being offered by current and some future applications

Service	In single-family homes	In multi-dwelling homes	In business premises	In common areas	In public places
Traditional quad-play	X	X	X		
Residential IoT	X	X		X	
Business IoT			X		X
Smart city applications			X	X	X
Telehealth applications	X	X	X		
AIP applications	X	X		X	X

4.2. Security needs

The second dimension we look at is security. Security is another dimension that has broad implications across many areas of an IoT application. IoT devices and applications can expose sensitive data and details about subscribers. Modern networks must be architected to protect and isolate these devices. The network should be capable of identifying the devices that run on it, and where possible, implement security controls based on this device's identity. Devices should be explicitly and securely onboarded on to the network using standards such as Wi-Fi Alliance's Easy Connect protocol, which gives devices unique credentials on the network that can be easily updated on a per-device basis and does not require re-credentialing of all the devices on the network.

In addition to device identity, the network architecture should allow devices to be isolated and segmented based on several factors including device type, function, or risk. For example, medical devices may be put on a network that is separate from other smart home devices. This would allow for access controls scoped to the medical device and prevent generic smart home devices from connecting to the medical device.

Finally, future networks should be able to recognize if the behavior of a device is acting outside of established bounds. This could be accomplished deterministically using a device's Manufacturer Usage Description (MUD) which gives explicit ports and protocols that the device is allowed to communicate with over the network, or probabilistically using heuristics or machine learning.

4.3. Reliability needs

As we move from entertainment services to many more mission critical services in the customer premises, the need for system reliability increases significantly. Telehealth services in the home, industrial IoT and connected vehicle support applications will require high availability.

4.4. Timing/Latency needs

Many real-time applications like industrial IoT and connected vehicle support applications that will require stringent network timing and latency control. Since not all applications have the same level of need, it is best to architect the wiring closet based on the needs of the applications being served.

4.5. Power needs

Once again, the applications requiring high reliability will also require reliable power. Backup power will commonly be needed in many cases. The location of the wiring closet will determine the powering options. Battery backup will commonly be needed in many cases. The type of applications being supported by the wiring closet and the location will determine the battery backup options.

Power has many considerations in this infrastructure. There are power sources, power demands and power distribution which must work in concert.

4.5.1. Power sources

Let's look at some of the typical power sources that can be used for these applications.

4.5.1.1. Utility power

Utility power is the most abundant of the power source which is available at all but a few potential deployment sites. The North American power grid is delivered to customer premises using a 120V/240VAC single split phase deployment. The same grid can deliver this 120/240VAC service to businesses, but 3 phase utility power is also delivered to businesses. These 3 phase deliverables can be modified using a transformer to deliver the common 120/240VAC used elsewhere, so this utility power standard will be referenced throughout this document. The frequency of the utility AC waveform is constant throughout North America using a 60Hz standard.

Most electronic devices considered for this IoT infrastructure deployment support utility power using a universal utility AC power supply or power pack which can directly connect to the utility grid for powering. These packs are reliable, cost effective and energy efficient. The packs come in a wide range of capacity to drive both the direct device needs as well as those that may be hosted by these devices.

Though the utility grid is ubiquitous and capable there can be issues with its delivery. A utility or grid outage is a common term for these delivery issues. In most cases these outages are of a short duration and more of a nuisance for the end user, but the electronics and services supported by this IoT infrastructure system could provide "Lifeline" services, so any interruption of their operation can create a bad scenario. The following steps should be taken to improve resiliency and reduce trouble calls:

- Limiting user intervention to the power source of the IoT infrastructure.
- Avoiding a “switched” outlet and have a dedicated power circuit, if possible, with a clearly marked circuit breaker in the panel.

4.5.1.2. HFC plant power

HFC plant powering is one of the oldest methods of proving CPE power in a cable network. eMTAs and ATAs are also commonly powered by the cable HFC plant. HFC plants typically power the copper network and associated actives using 63VAC or 89VAC power supplies. This power can be routed anywhere the hardline plant is deployed and extended to the customer through the use of power passing taps. The older HFC CPE power passing taps could only support about 300mA, but newer power passing taps can support 2+ Amps of HFC power to the CPE devices.

There are some considerations while using HFC plant powering:

- The load on the HFC plant must be considered in larger, high current deployments. The typical HFC power supply has a capability of delivering 15A @ 90VAC routinely; but if the IoT infrastructure demanded 2 Amps for each site this would quickly exhaust the available power.
- HFC plant powering could be used as a primary or backup source of power, but once again, a high demand would exhaust the HFC powering batteries quickly; additional batteries might have to be added to the HFC powering location to address this additional power demand. The HFC plant is very efficient at propagating RF signals, but slightly less efficient at conveying the HFC powering. Losses occur through the hardline, actives, passives and largely in the customer drop. The end of line voltage range would need to accommodate a voltage range from 45 to 90VAC.

4.5.1.3. Hybrid fiber power

The Hybrid Fiber Power solutions have been deployed in cellular tower deployments as well as similar high voltage low current powering of DSLAMs. PON architectures could provide centralized powering sources and hybrid power cable with converters in the IoT infrastructure cabinet to provide the needed power for the supported electronics. The basic designs leverage several 24 AWG to 12 AWG conductors to allow a high voltage low current transmission, some touting distances of up to 10km. The hybrid fiber powering could be delivered as a primary or backup source of power and communications.

4.5.1.4. Local renewable power

Consumers and businesses are deploying renewable energy resources at their sites and these sources can be leveraged to power our IoT infrastructure hardware. Solar, Wind, Micro-Hydro are the main sources of these renewable energy systems and there are several modes of operation of these systems: Grid Direct, Off grid, and Hybrid. Grid direct and Hybrid are most likely what would be used in concert with our IoT infrastructure; but our connection considerations are very different in those two deployments. Grid Direct systems rely on the utility grid for operation, and the loss of the utility grid causes these systems to shut down for safety reasons. The IoT infrastructure would be connected to a panel as it would in a utility deployment, the major difference is that during renewable production the IoT infrastructure would be powered from the renewable energy source. The Hybrid renewable system includes storage and handles grid loss a bit differently by disconnecting itself and its loads from the Grid to assure safety, but a “Backup Loads Panel” would be powered by the Hybrid system and its storage. In this case all the IoT infrastructure should be tied to the backup loads panel to assure operation through utility outage events.

4.5.2. Backup power considerations

The IoT infrastructure will likely support lifeline services and will require resilient powering. There are several ways of providing resilient backup power. We will look at some of the most commonly available options below. The amount of backup time these systems provide can vary, so the right option should be used depending on the application.

4.5.2.1. Interdevice batteries

One of the longest deployed backup powering scenarios in cable is the use of a backup battery in an eMTA. A similar method could be used to maintain the IoT infrastructure powering. The battery could be placed in the device itself or located externally. The device can be used to charge the battery. The size of the battery should be sufficient to meet the needs of the application.

Battery based backup is very efficient from both a cost and round-trip power utilization point of view. However, it can prove to be an extra burden when the batteries reach their end of life and must be replaced. Most of these battery backup solutions include battery monitoring for run time and battery health.

4.5.2.2. External UPS

External UPS devices are probably the second widest deployment of backup power for cable user equipment deployments. These are external units that are plugged into the utility and then the supported cable hardware is plugged into them. These systems are largely not monitored, which can create a “delayed outage” scenario where the system runs for a time during a utility event, but when the battery is exhausted in these external UPS devices the hosted IoT infrastructure system goes dark. There are both consumer and industrial grades of UPS devices, with the industrial scale devices providing longer runtime better monitoring options and survivability.

4.5.2.3. Whole house backup

Behind the meter storage and other large scale backup solutions are similar hybrid renewable system that can leverage renewable sources. The idea is that a large battery bank is hooked to an inverter/charger which can provide a backup power source for many powered devices in the premises. The system will disconnect from the grid during a power outage and through a backup loads panel can provide service during the utility outage. The IoT infrastructure electronics would need to be connected to the backup loads panel for power.

4.6. Interoperability needs

With the evolution of IoT technology, a broad range of devices, applications, and services have been deployed in the customer premises networks today. The IoT framework of the future must provide some means of integrating all these devices and applications in a consistent manner.

5. Opportunities for cable operators

So why should cable operators care about these emerging new services in their customer premises networks – especially given all the complexity they bring with them?

It is precisely the complexity that has stymied the widespread deployment of these IoT services in the market. Numerous technology vendors are vying to capture the market – but, at best, most have only succeeded in delivering point solutions to one specific application they control.

We believe that cable operators are ideally placed to take full advantage of their central role in the customer premises network to pull all the pieces of the puzzle together and thereby unlock a lot of potential value in their customer's IoT environment.

It is also clear that many proprietary solutions currently being deployed will only find limited success in the marketplace. For any widespread deployment, a standards-based approach will be needed.

6. Wiring closet concept

The traditional infrastructure cable operators placed in the customer premises was simple and compact. All that was needed was a small enclosure or a closet to house it all. This was commonly known as the Wiring Closet or Telecom Closet. As we outlined above, the needs of the customer premises – and even the customers themselves – have evolved significantly. So, what is the new “Wiring Closet” of the future?

It is clear the needs of customers will vary a lot from a single-family home subscribing to basic cable to a municipality supporting various smart-city applications. Obviously, we cannot have a one-size-fits-all solution for all these applications. It is also clear the customer premises infrastructure of the future will not necessarily even be a closet. The idea is to develop a customer premises framework that provides a standard and modular way of scaling from a simple wiring enclosure to a distributed set of resources where necessary.

The following are the three basic characteristics of a Wiring Closet:

- Expandable to current and future IoT applications
- Address the spectrum of needs from in-home to public areas
- Serviceable unit for the cable operators

7. Wiring closet requirements

What are the requirements for such a broad framework to support IoT services in the customer premises network? That is one of the main questions the WCDG group is trying to address at the SCTE. While this is still a work in progress, we highlight a few key requirements in this section that the group feels are necessary for any such framework.

7.1. Customer premises location requirements

As we noted above, various IoT applications need to be supported in different locations in a customer premises. Following locations must be supported by the customer premises framework.

- Single Family Units: Support in indoor and outdoor locations.
- Multi-Dwelling Units: Support in unit indoor and outdoor locations as well as common area indoor and outdoor locations.
- Commercial Units: Support in indoor as well as common area indoor and outdoor locations.
- Public Spaces: Support in a cabinet as well as pole mounted locations.

7.2. Networking requirements

Customer premises framework needs to support both wired and wireless networking infrastructure.

- Wired infrastructure should preferably be supported for premises distribution where wireless distribution is challenging and for fixed devices.
- Wireless infrastructure should be supported for mobile devices. Adequate signal coverage throughout the customer premises should be ensured.

7.3. Security requirements

As noted above, security is critical for many IoT applications. As such, the customer premises framework shall support comprehensive security capabilities including following:

- All communication links shall support authentication, authorization, and encryption capabilities.
- Wireless Access Points shall support authentication and encryption capabilities.
- Gateway devices shall support secure boot and secure upgrade capabilities.
- No default login credentials should be supported. In addition, security infrastructure should be upgraded to the latest available standards.
- Any test/diagnostic access ports shall be disabled by default or require secure login.

7.4. Powering requirements

Many IoT applications have special powering needs. As such, the premises infrastructure should support following powering requirements.

- The premises infrastructure shall support following options as power sources:
 - AC utility mains
 - HFC 60V/90V
 - Power over Coax
 - Power over Ethernet (PoE)

7.5. Environmental requirements

Since the premises infrastructure will have to support a wide range of premises locations, it needs to meet a broad range of environmental needs. Following are some of the key environmental requirements the premises infrastructure will need to support.

- The premises equipment shall support installation in indoor enclosure, outdoor enclosure, outdoor cabinet installation, and outdoor pole mount enclosure.
- The equipment shall meet all necessary environmental and safety requirements per ETL, UL, and NEMA.
- The equipment shall meet all local building and environmental codes.

7.6. Installation and support requirements

Due to the broad range of potential IoT applications that could be installed in the customer premises and the resulting complexity, the premises framework will need to meet numerous installation and support requirements.

- All serviceable equipment must be located in an area offering easy access for service personnel

- Basic infrastructure should be pre-installed in any new building construction
- Auto-configuration processes should be used where possible to minimize user intervention
- Installer should ensure adequate signal coverage throughout the premise (e.g., Wi-Fi signal coverage)
- All installed equipment and infrastructure should be well labeled and documented
- Support responsibilities should be clearly outlined along with contact information for responsible party
- Maintenance responsibility for any backup batteries should be clearly specified along with necessary maintenance schedule
- Installation should support notification of low/failed/missing backup battery condition to service personnel
- Equipment installations should support easy hardware upgrade.
- Devices deploying software should preferably support automatic online software upgrades.

7.7. Reliability requirements

Many IoT applications will potentially support critical healthcare or business support services that will have high reliability expectations. Following are some of the reliability requirements the premises infrastructure needs to meet:

- **Power Reliability:** Backup power should be made available depending on the type of application and location needs.
- **Communication Reliability:** A backup communication link may be necessary in case of failure of primary communication link.
- **Device Reliability:** Devices providing critical services such as healthcare support should have built-in redundancy or a spare available.
- **Service Reliability:** Critical services must be supported by a highly reliable support infrastructure including a 24x7 support team.

7.8. Interoperability requirements

It is not enough for IoT applications to function by themselves. To minimize complexity for the user as well as to make applications easier to use, the customer premises framework should provide a common infrastructure for applications to interface with each other. Following are some of the interoperability requirements the premises infrastructure needs to meet:

- The customer premises framework should support a common infrastructure for applications to interface with each other.
- The framework should support a consistent way of managing all the applications and devices in the customer premises.

8. Conclusions and next steps

In this paper we have clearly outlined the need for developing a comprehensive framework for supporting the vast array of IoT applications and services in customer premises networks from simple single-family homes to large city-wide smart-city networks. Such a framework will enable widespread deployment of a multitude of value-added services in the near future and place the cable operator in a pivotal role in this vast ecosystem.

The first step in getting to such a framework is to develop a comprehensive set of requirements to be supported by this framework. We have highlighted a number of key requirements in this paper, but much more work must be done. The WCDG group is looking for subject matter experts from a broad range of areas to come and contribute to this work.

Abbreviations

AIP	aging in place

1. Introduction

Service assurance (SA), as a subset of the operational support system (OSS), plays an important role in the internet service provider (ISP) ecosystem. However, the rapidly evolving internet service provider (ISP) technologies, enterprise services offerings, and customer expectations bring great challenges to the modern service assurance system design. This paper discusses several general design principles and best practices that are essential to building a robust and resilient service assurance system with observability and awareness that could stay ahead of these fast-paced industry transformations.

First, collecting telemetry from multiple sources helps to avoid single point of failure (SPOF) and improve confidence and accuracy of alerting customers of network/service issues. Second, introducing a unified mediation layer provides flexibility to isolate vendor-specific implementations and prevent bugs from negatively impacting customer experience. Third, making use of cross product correlation and leveraging machine learning (ML) for data analytics, trending and anomaly detections to prevent service interruptions and guarantee accurate customer alerting.

This paper reflects years of SDN-based centralized service assurance system integration design, development, and customer support experience. In this paper, the authors will share ways in which these principles and techniques are applied in our enterprise service product to support business values and keep our customers happy.

2. High-level Service Assurance System Design and Challenges

This section describes the initial service assurance system design and challenges and next section will describe how we resolved these challenges using the advanced service assurance architecture design. Figure 1 below shows the different layers and functional blocks of the initial service assurance architecture design with the key functional roles played by each layer. Figure 2 below shows the different challenges faced at the different layers in the service assurance architecture.

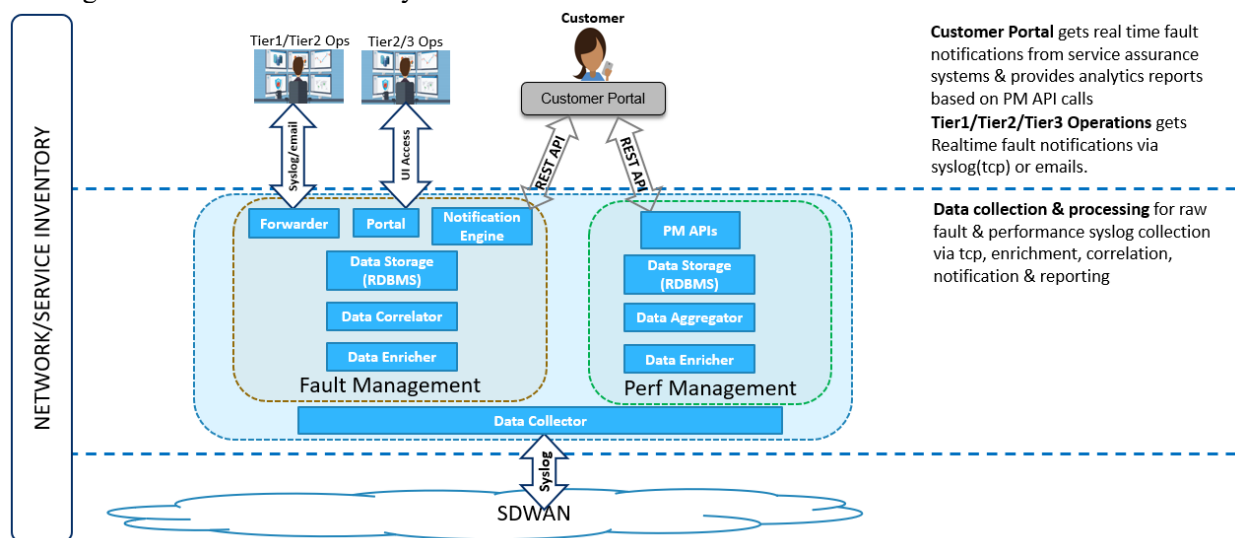

Figure 1 – Initial Service Assurance Architecture

As illustrated in Figure 2, the key challenges faced in the initial service assurance architecture design are:

- Out of sync device or port status between systems;

- ❑ High response time and timeouts for data presentations;
- ❑ Lack of mediation layer to standardize the multi-vendor log/event formats;
- ❑ Least scalable with fewer integration options;
- ❑ Lack of advanced correlation between faults and performance metrics to provide meaningful insights;
- ❑ Lack of visibility to different layers of network service; and
- ❑ Lack of advanced troubleshooting capabilities.

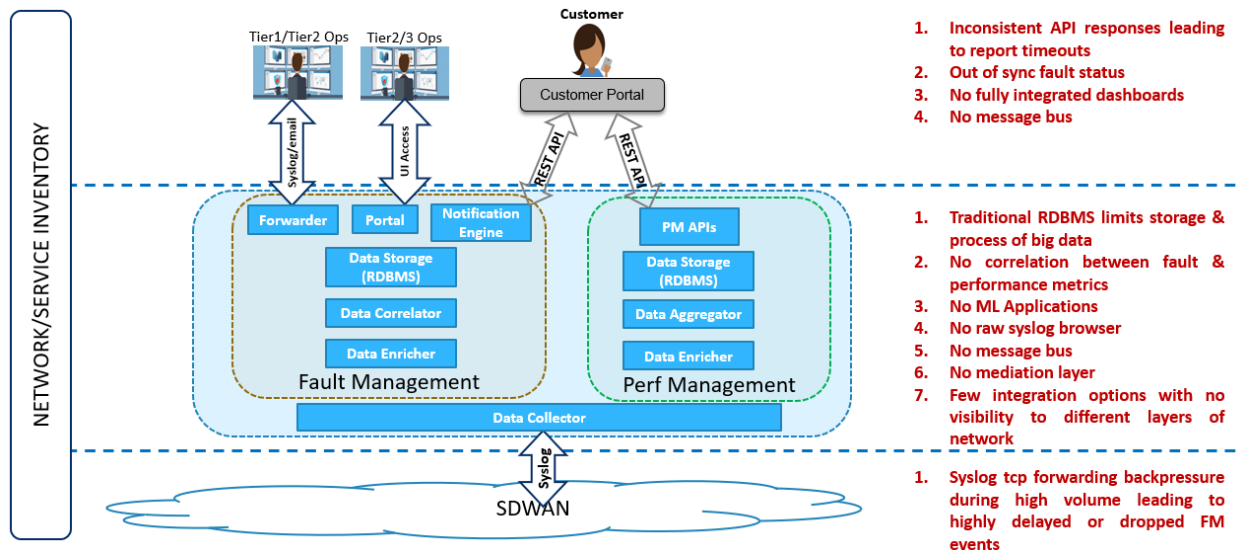

Figure 2 – Initial Service Assurance Architecture Challenges

2.1. Out of Sync Device or Port Status between Systems

With the initial service assurance system, there were some cases of device or port statuses going out of sync between systems. Customer experience may have been impacted by these out-of-sync issues.

Below listed some of the reasons for statuses to go out of sync:

1. When vendor element managers fail to send set or clear event due to bugs.
2. When set and clear events/messages come at the same time.
3. When there is no dedicated path for faults, fault event may be delayed or dropped due to congestion in the analytics data pipeline to service assurance systems.
4. When the vendor does not provide single fault event for a problem and the service assurance system does not have the capability to cross-validate against performance metrics.
5. When producing or consuming systems fail to process the fault events.

2.2. High Response Time and Timeouts for Data Presentations

The initial service assurance architecture design had the potential to cause delays and timeouts in loading data reports for customers.

Below are listed some of the reasons for such high response time or timeouts for the reports:

1. The granular customer data for the top reports were pulled for the selected time and aggregations were run on the fly at the portal reporting platform.

2. Every user click for a similar report triggers corresponding database pulls for the granular customer data. This causes a lot of unnecessary database transactions which is not a normalized approach.
3. The granular customer data was being pulled from non-big data storage systems which caused delays when the customer data were high.
4. The report data were tied with inventory cache where the inventory cache was not up to date all the time, leading to missing or inconsistent data.

2.3. Lack of Mediation Layer to Standardize the Multi-Vendor Log/Event Formats

In the initial service assurance architecture, there was no mediation layer to standardize, filter out, modify, or convert log/event formats to meet the customer needs. This led to higher time to roll out changes because of the need to accommodate log/event format changes.

Below listed some of the reasons for requiring a proper mediation layer in service assurance architecture:

1. Log/event format changes due to vendor upgrades or bug fixes.
2. Filter out log/event due to bugs in existing vendor versions
3. Standardize multiple logs/events into same format for better processing and reporting
4. Define higher priority pipelines for fault events compared to performance metrics
5. Enable tagging and distribution of logs/events

2.4. Least Scalable with Fewer Integration Options

Initial service assurance architecture had scalability limitations at all functional layers, including but not limited to data collection, data storage, data integration with external systems etc. This would become a bottleneck as the network grew and caused delays in processing incoming or outgoing messages leading to bad customer experiences.

Below are listed some of the reasons for requiring a more scalable and highly interfacing architecture:

1. Number of logs/events per customer device is not static but rather dynamic based on customer traffic. The service assurance systems should be scalable enough to accommodate changing volumes of customer device traffic and usage.
2. To achieve a better predictive and reliable service assurance system, there is always the need to integrate multiple datasets from different platforms. This requires multiple integrations / interfacing points.
3. For faster rollout of features, service assurance architecture should be able to consume / collect multiple data types using different protocols, and be able to produce / export data to different interfacing systems.

2.5. Lack of Advanced Correlation between Faults and Performance Metrics to Provide Meaningful Insights

Initial service assurance systems did not have the capability to correlate across fault and performance metrics. Correlating across fault gives meaningful insights into the data along with accuracy and better ML predictions. Alternate options within initial service assurance systems limited the full capabilities one gets from marrying the fault and performance metrics.

Below listed some of the benefits for correlating between faults and performance metrics:

1. For meaningful insights into customer data.

2. Good ML predictions.
3. Better accuracy of fault events.

2.6. Less Visibility to Different Layers of Network Service

The initial service assurance systems were not flexible enough to provide visibility to different layers of network service since there were minimum integration options and no correlation between fault and performance metrics. Visibility to different layers of network service can help in identifying the root cause of any issue, provide better representation of the service to operations or customer, and create a better fit for proactive monitoring of the network service.

Below listed some of the reasons for having better visibility to different layers of network service:

1. Better root cause analysis (RCA).
2. Better visualization of the service.
3. Better proactive monitoring of the service.

2.7. Lack of Advanced Troubleshooting Capabilities

The initial service assurance systems did not have good visualization capabilities to create on-the-fly dashboards on fault, performance metrics or both fault and performance metrics.

Below are listed some of the factors that impaired the troubleshooting capabilities:

1. Lack of visibility to different layers of network services.
2. Lack of correlation between fault and performance metrics.
3. Separate clients for viewing faults and performance metrics, rather than a single pane of glass view.

3. Advanced Service Assurance System Design with Observability and Awareness

This section describes the key enhancements / features of the advanced service assurance architecture that can overcome each of the challenges explained in Section 2 by implementing Architectural design changes or methodology changes.

Figure 3 and Figure 4 describe the high-level service assurance architecture providing observability and awareness.

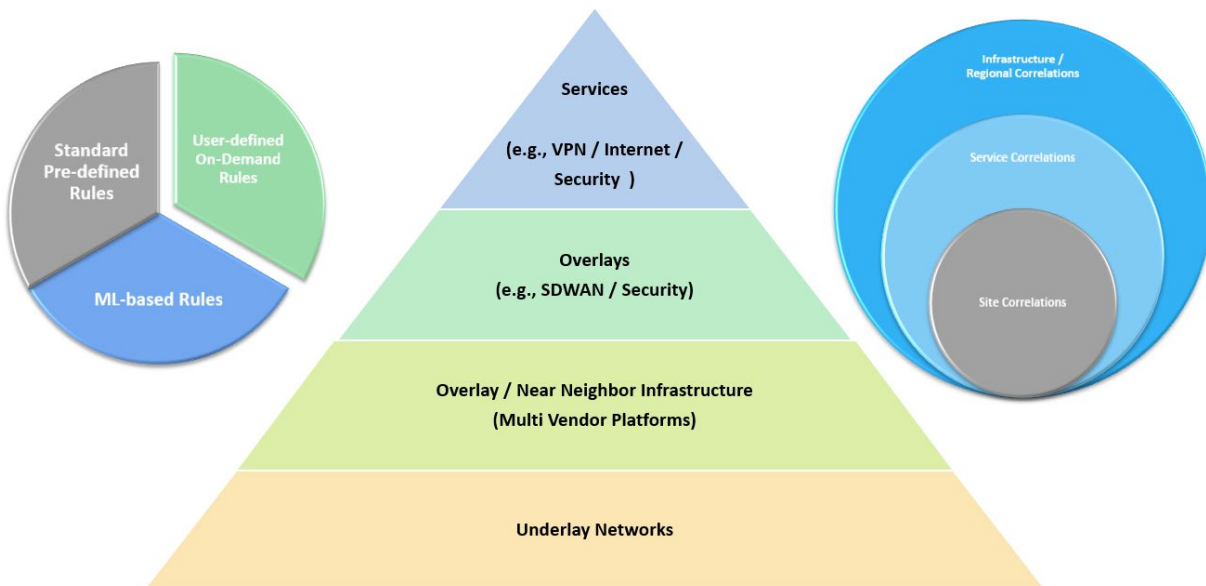

Figure 3 – Advanced Service Assurance Functional Blocks

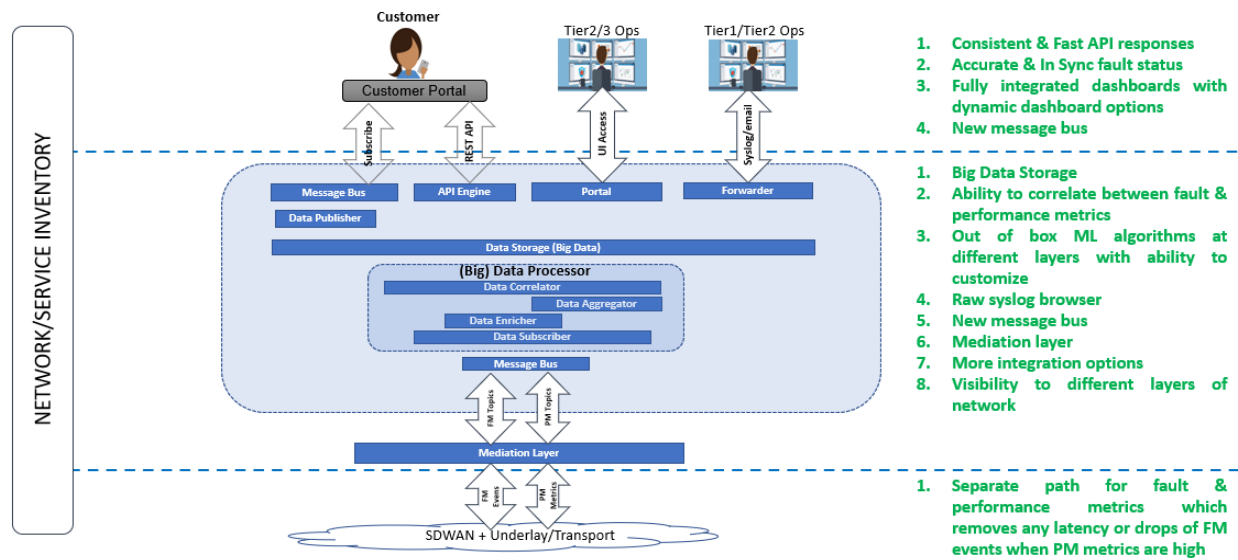

Figure 4 – Advanced Service Assurance Architecture

3.1. New Mediation Layer Added

A new mediation layer added between the network source and the service assurance collection layer as shown in Figure 4. This layer adds the functionalities below to help in creating a more robust service assurance architecture by eliminating some of the challenges listed in section 2. For example:

1. Filtering out messages.
2. Format changes of messages.
3. Supports multiple input and output format for message transfers between systems.
4. Message tagging.
5. Distribution of messages to multiple destinations.

3.2. Separate Dedicated Path for Fault and Performance Events

As part of the advanced service assurance architecture, separate dedicated paths were added for fault and performance events from the source to mediation layer to data collectors in assurance systems. This avoids any latencies on fault events whenever the volume of performance events becomes too high and causes backpressure on those paths.

3.3. Additional Sources for Alarm Validations

As part of the advanced service assurance architecture, more sources were added to fault management to increase the confidence level of the alarm. The below sub-sections explain the 5 major additional sources added to improve the accuracy of device/port/path status. This helped to achieve more consistent and accurate operational statuses.

3.3.1. Polling the Device / NMS

Polling the device/NMS via different supported protocols (e.g., REST API, SNMP, ICMP, etc.) always helps to sync the right operational status within service assurance systems.

3.3.2. *Adding Heartbeat Events from Device / NMS*

Heartbeat events from device / NMS provide a recurring event on the health of the device every 'x' minutes. This helps to keep the service assurance systems in sync on the device health status. This also helps to minimize the dependency on polling since polling device / NMS sometimes can be expensive depending on the device / NMS providers.

3.3.3. *Correlating Events/Alarms against Performance Metrics*

Device / port / path level performance metrics that generated every 'x' mins from device / NMS can be considered as heartbeat messages. The presence of performance metrics can be considered as 'UP' heartbeat while absence of performance metrics from a previously present metric can be considered as 'DOWN' heartbeat. Correlating the events/alarms against these performance metrics will help in improving the confidence level of the corresponding event/alarm. This also helps in minimizing the dependency on polling. Below Figure 5 shows cross-correlation between alarms and performance metrics for finalizing device status.

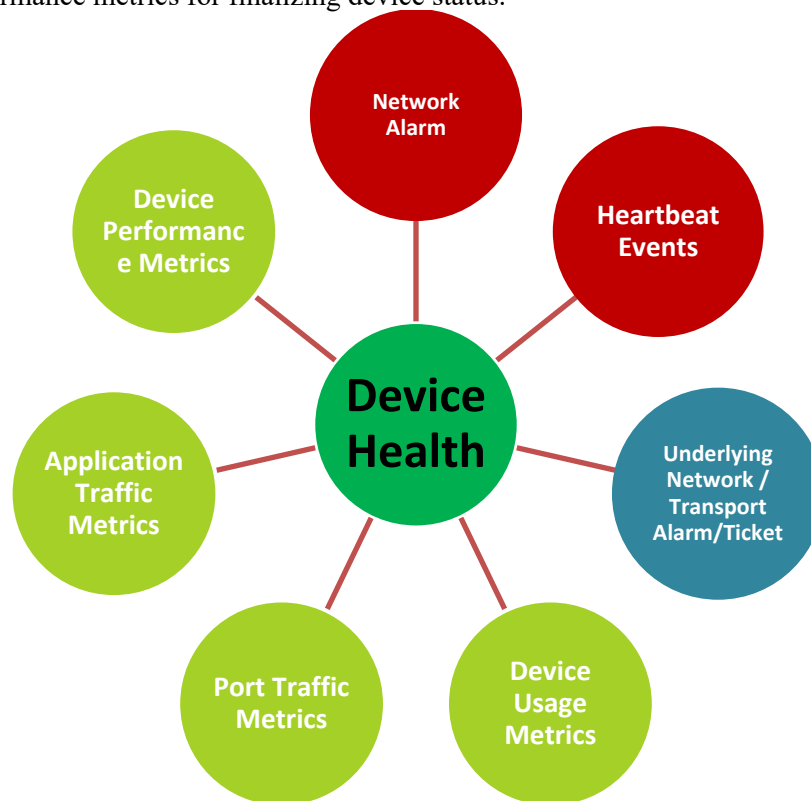

Figure 5 – Cross-Correlation between Alarms and Performance Metrics

3.3.4. *Correlating against Underlying Network/Transport Layer Alarms / Tickets*

Correlating fault events against underlying network / transport layer alarms / tickets always gives better insights into the root cause of the fault/event. This also aids in creating a visual representation of network service and giving the operations team advanced troubleshooting capabilities.

3.4. New Data Delivery Methodology for Faster and Consistent API Responses

In the initial service assurance architecture approach of providing APIs for performance metrics, we have seen multiple challenges leading to delays / timeouts in API responses. In this new advanced service assurance architecture, based on the learnings, we have come up with a new data delivery methodology for performance metrics in reports to customers. The new methodology is much faster and provides consistent API responses.

Below are the key steps for implementing this new data delivery methodology:

1. Identify the different report types to be delivered to customers.
2. Identify the different groupings needed for each of the report, like customer-level, device-level, port-level etc.
3. Identify the pre-defined time buckets with granularity needed.
4. For each type of the above report, pre-stage the data for the report by scheduling these granular data from the database at regular intervals based on the time buckets.
5. Create API request definitions which pick up the latest pre-staged data every time a user clicks a report.

The key benefits of this approach include:

1. No on-the-fly aggregations, leading to faster response times for loading reports.
2. Normalized approach with minimum database calls for reports. No unnecessary database transactions.
3. Removal of the dependency on the inventory cache, thereby resolving any missing or inconsistent data.

3.5. Hybrid Notification Approach

Table 1 - Hybrid Notification Approach (with Underlying Transport Issue Identified)

Category	Status	Realtime / Soaked	Source	Notification Severity	Notification Message
Device / Port / Path Health Notifications	Down	Realtime	Network Set Alarms	Major	Instead of reporting as down, should say something like “there seems to be an issue with the device / port / path. Hold on for further updates”
Underlying Transport Ticket Notifications for the Device / Port / Path Health notifications	Down	Soaked ('X' mins)	PM Metrics / Transport Alarms / Tickets	Critical 	Change severity to Critical and say the device / port / path as down.
Device / Port / Path Health Notifications	Up	Realtime	Network Clear Alarms	Major 	Change severity from Critical to Major, should say something like “issue seems to be resolved. Hold on for further updates”
Underlying Transport Ticket Resolution Notification for the Device / Port / Path Health notifications	Up	Soaked ('X' mins)	Transport Alarms / Tickets	Cleared 	Clear the status of device / port / path

All “Real time” and “Soaked” notifications will go to separate message bus topics. So, consumers can choose to subscribe to specific message topics for each notification type

3.6. New Message Bus Added

Based on the challenges observed in the initial service assurance architecture, message bus is a better fit in the advanced service assurance architecture. Message bus provides a highly reliable, scalable data collector as well as an asynchronous communication platform with decoupling for internal and external data movements. It comes with data persistence and fault tolerance that allows the service assurance system to continue processing data even when different parts of the system fail. Most of the message bus platforms available in market come with a lot of additional features like filtering, enrichment, correlation, and more, providing more intelligence at each layer of the architecture.

3.7. Data Storage Changed from Traditional RDBMS to Big Data system

There are 3 major challenges for traditional RDBMS Storage – data too large, data too complex (multiple data types), and data too fast. As the network grows, the analytics data also grows and as we add more features, there will always be new data types/formats to be processed which makes the analytics data complex with different types/formats. As data grows, data ingestion or retrieval times cannot be compromised as it will negatively affect the customer experience. With these challenges and the added benefits of big data systems, it was an easy decision to move away from the traditional RDBMS to big data.

3.8. New Raw Log/Event/Message Browser

Raw log / event / message browser is a good add-on to any service assurance architecture since it provides the user / operations the ability to skim through historical / real-time alarms / events / performance metrics for troubleshooting purposes / generating on the fly reports / statistics.

4. Improvements for Customers and Operation Teams Experiences

4.1. Out-of-Sync Device or Port Status between Systems Improvement

Figure 6 shows the percentage of occurrences of out of sync device / port alarm status before and after moving to advanced service assurance with the key enhancements or features described in Section 3.

Figure 6 – Out of Sync Issue Before and After

Figure 6 clearly shows the improvements in out of sync issues before (using initial service assurance systems) and after (using the advanced service assurance systems). Before the percentage of out-of-sync statuses varied from 2% - 17% while after there were no such out-of-sync occurrences observed based on 30-day data between April and May 2022

4.2. Data Presentations Response Time Improvement

Below graphs show the API response times at customer / single site / multiple site levels for analytics data consumed by systems external to service assurance systems before and after moving to Advanced Service Assurance with the key enhancements or features described in Section 3.

4.2.1. Customer Level:

Response Times (BEFORE):

Response Times (AFTER):

Figure 7 – API Response Times for Customer Level Before and After

4.2.2. Site Level:

Response Times (BEFORE):

Response Times (AFTER):

Figure 8 – API Response Times for Site Level Before and After

4.2.3. Multiple Sites Level:

Response Times (BEFORE):

Response Times (AFTER):

Figure 9 – API Response Times for Multiple Sites Level Before and After

Figure 7, Figure 8, and Figure 9 clearly show the improvements in API response times at customer / single site / multiple site level for analytics data consumed by systems external to service assurance systems. Below are the key highlights:

- API response times are consistent and lower.
- More aggregation types are supported.
- More flexible filtering with ease-of-use APIs

4.3. Mediation Layer Improvements

The below graph shows the percentage of occurrences of alarms with missing device names for fault events before and after moving to advanced service assurance with the key enhancements or features described in the previous section.

Figure 10 – Null Device Name Issues Before and After

Figure 10 clearly shows the improvements in occurrences of alarms with missing device names for fault events before (using initial service assurance systems) and after (using the advanced service assurance systems). Before the percentage of such missing device names in fault events was very low, varying from 0.01% - 0.09%, while after there were no such fault events with missing device name occurrences based on data collected between Dec 2021 and Feb 2022.

5. Conclusion and Future Work

The initial service assurance architecture design, which faced multiple technical challenges, was changed to include a mediation layer, separate dedicated FM and PM paths, and additional sources of alarm validations, along with a new data delivery methodology for faster and consistent API responses, etc.

This re-architecture has shown a lot of improvements. For example:

- Minimum out of sync issues (reduced from around 15% errors to 0% based on 30-day data between April and May 2022).
- Faster API response times and no time outs for API responses (80% reduction).
- Better integration capabilities.

This new robust and resilient service assurance architecture with observability and awareness has enabled to add more advanced correlations with capability to use ML algorithms to build data models for better prediction, trending, and forecasting.

1. Introduction

Fixed Wireless Access (FWA) is an alternative to wired broadband services using radio links between two fixed points. With the introduction of 5G, advancements in spectral efficiency and antenna technologies using massive MIMO (Multiple-Input Multiple-Output) and beamforming have become key enablers. The technology and costs have evolved and FWA services are now available from many service providers ranging from niche wireless Internet service providers (WISPs) to the largest mobile carriers. Today's FWA services compete directly with other wired broadband options from telcos (DSL and FTTH) and cable operators (HFC).

While our companion paper, "5G FWA Technical Performance Analysis for Mid-Band Rural Networks", investigates the technical performance characteristics of Rural FWA, this paper seeks to provide a framework to assess the economic considerations for FWA. The methodology involves:

- Defining Rural FWA service assumptions
- Determining spectrum and infrastructure
- Characterizing propagation and available capacity
- Projecting household level broadband demand
- Solving for supportable subscribers
- Pro Forma Economic considerations

FWA can be a strategic opportunity to deliver broadband in unserved and underserved rural areas. The analysis focuses on FWA using mid-band spectrum delivered from macro towers in rural geographies as defined by household density. Broadband usage is expected to continue to grow for the foreseeable future and a FWA service must account for projected demand. Therefore, we forecast average fixed broadband usage at the household level in 2027 and determine how many households can be supported in a typical macro cell at that point in time.

We explore the revenue drivers, variable and fixed cost components and discuss how a provider may consider cost allocations for spectrum and internally across business units. Finally, we develop an Excel model to help analyze projected cash flows and returns on investment based on variable assumptions.

For questions about this paper and/or to obtain a copy of the Excel model with a sample pro-forma, please contact the author at s.patel@cablelabs.com.

2. Service Assumptions

This paper will primarily focus on a target 100 Mbps download/ 10 Mbps upload (headline rate) 5G NR FWA service. The FWA service is assumed to have a 95% availability at the headline speed. Subscribers would still experience a connection at other times, but at lower than headline rate. The analysis assumes indoor customer premise equipment (CPE) requiring a simple self-installation, outdoor-to-indoor (O2I) downstream and indoor-to-outdoor (I2O) upstream signal propagation. Subscribers are assumed to be households with average broadband consumption on a GB/month basis. We model growth in household level broadband consumption at 25% per year and determine how many subscribers can be supported 5-years-out in 2027.

3. Spectrum and Infrastructure Considerations

FWA can be delivered using licensed or unlicensed spectrum ranging from sub-GHz to mmWave. Lower bands such as 600/700 MHz offer much better propagation but lower capacity. Higher bands offer better capacity but with lower propagation. While carriers can leverage their active spectrum and carrier aggregation for FWA, for simplicity, this analysis assumes dedicated spectrum.

We model the use of 100 MHz of 2.6 GHz spectrum on existing macro towers in suburban (30m towers) and rural (60m towers) areas. The main advantage is the ability to use the same infrastructure that is used for mobile service with an added layer of radios for the FWA service. These sites have existing power and backhaul infrastructure and would require incremental capacity to serve FWA needs. The typical clutter in these environments is 1-4 story residential and commercial buildings and representative foliage ranging from shrubbery to mature tree canopies. The 3GPP model values we use incorporate large-scale assumptions for clutter using probability projections for line of site (LOS) and non-line-of-site (NLOS) between transmitting and receive antennas. The end result is a composite propagation value incorporating LOS and NLOS probabilities for the target region.

Figure 1 - Suburban Macro Tower

Figure 2 - 5G In-Home CPE

We model the use of indoor Customer Premise Equipment (CPE). The CPE is assumed to be placed within 1 meter of the closest outside wall to the transmitting tower and at a height of 2 meters in the subscriber home. An alternative scenario, not considered in this analysis, involves the use of an outdoor mounted antenna at or above the subscriber home roofline. The use of outdoor receive antenna can add up to ~40% incremental propagation for a 100 Mbps service in suburban areas and up to 50% in rural. This typically requires a professional install, adds significant cost to the service and can extend the payback period depending on whether the subscriber bears the cost of installation.

4. Propagation and Capacity

CableLabs has been investigating FWA performance since 2018 and has developed a proprietary MATLAB¹ based simulations engine to characterize the performance of different spectrum bands using multiple assumptions. The simulations engine is backed by two technical modeling tools working in tandem; 1) a system level simulator (SLS) based on a 19-cell site topology, which statistically calculates aggregated system interference and 2) a link level simulator (LLS) modeling 5G New Radio (NR) waveforms and multiple-input multiple-output (MIMO) antenna patterns. The LLS uses the results from the (SLS) to evaluate the signal-to-noise ratio (SINR) and throughput versus link distance. The output from these models provides aggregate performance and propagation data to inform this techno-economic analysis. Technical details of the CableLabs SLS and LLS models can be found in the companion SCTE paper.

Table 1 - Calculated 2.6 GHz O2I Propagation (distance from base station) for Target Service Speed and Tower Height

	50 Mbps	100 Mbps	300 Mbps
30m Tower	1,718	1,418	730
60m Tower	4,625	3,600	1,765

Table 1 shows the calculated propagation at 3 different headline speeds for 2.6 GHz spectrum deployed on a 30 meter macro tower in a suburban environment and a 60 meter macro tower in a rural area. The distances can be considered a service edge where connections can still be made beyond the representative values, but at lower than headline speeds. Capacity and throughput diminish the further the FWA subscriber is located from the base station as depicted in Figure 3 – 30m Macro Tower and Figure 4 – 60m Macro Tower, which show available capacity per user in O2I and outdoor receive antenna scenarios respectively. The CableLabs model assumes 3 sectors per cell

¹ MATLAB is a proprietary multi-paradigm programming language and numeric computing environment developed by MathWorks (www.mathworks.com).

and 8 simultaneously active users per sector. It also assumes that subscriber households are distributed evenly across the cell area.

In addition to propagation, the model calculates available capacity for each sector of the macro cell. Radio frequencies lose signal strength and data carrying capacity in correlation to their distance from the gNB. Figure 3 and Figure 4 show available capacity per user at varying distances from 30m and 60m tall macro towers in the case of O2I CPE and with the use of outdoor receive antenna respectively. In the 30m tower case (Figure 3), we see that a 300 Mbps service can be delivered at a distance of 730m and a 100 Mbps service can reach 1418m. Of note, if 300 Mbps is the desired target FWA service, not all households within the area would be considered serviceable.

Figure 3 – 30m Macro Tower

Figure 4 – 60m Macro Tower

We assume that households are evenly distributed across the respective cell coverage areas based on the average density (households/Km²) in the area of interest. The calculation for mid-cell incorporates the cell edge for a 100 Mbps O2I service, 1419 meters, in the case of 2.6 GHz deployed on a 30m tall macro tower. At roughly 70% of the distance between the gNB and the cell edge ($1419m \times .7 = 1003m$), half of households would be between the base station and mid-cell and half would be between mid-cell and the cell edge. Calculated available capacity at mid-cell is a total of 1,429 Mbps.

Figure 5 - 2.6 GHz Propagation & Capacity (100 Mbps Service, 30m Macro Tower)

5. Subscriber Household Demand

We assume that a mobile FWA household will have similar usage on a GB/month as a fixed broadband household. OpenVault² is a 3rd party firm that collects, tracks and reports average fixed broadband consumption per household. OpenVault's Q4 '21 report shows the average household consumed 504 GB/month downstream and 32 GB/month upstream for a total of 536 GB/month. As we are interested in what consumption will be 5 years in the future, we assume an annual growth rate of 25%³ and calculate that by 2027, the average fixed broadband household will consume 2,045 GB/month of data. This calculates as an average of 6.2 Mbps in 2027 (2,045 GB/ 30.4 days/ 24 hours/ 3600 seconds * 8000 bytes to bits). While the average usage in Mbps is useful, operators design their networks to support peak usage. At CableLabs, we have observed that peak usage has maintained a consistent ratio of 2:1 against average usage for a number of years. This implies peak usage per household of 12.5 Mbps in 2027.

Table 2 - Average Projected Broadband Usage per Household

		2021	2022	2023	2024	2025	2026	2027
Total Usage (GB/month)		536						
Annual Growth	25%		670	838	1,047	1,309	1,636	2,045
Mbps Equivalent		1.6	2.0	2.6	3.2	4.0	5.0	6.2
Peak to Average Ratio	2.0X							
Peak Usage (Mbps)		3.3	4.1	5.1	6.4	8.0	10.0	12.5

6. Serviceable Households

We have shown propagation and available capacity for a given suburban macro cell sector and calculated the projected average household demand five-years out in 2027. A straight-forward exercise of dividing available capacity by household demand would yield the maximum number of subscribers that could be supported in the given sector. The resulting value would exhaust all available capacity. Service providers typically operate with a maximum target fill-rate to allow for some spikes in peak consumption but also to allow a margin of time to either manage existing subscribers and policies or to add incremental capacity. For a FWA network, this could involve activating additional spectrum, improving the efficiency of the existing network with more advanced radios and CPE or densifying the network with additional macro towers or small cells.

² www.openvault.com. OVBI_4Q21_Report.

³ 25% represents a reasonable growth assumption based on recent non-Covid period data and can be adjusted as consumption data is reported over time. The same growth rate for upstream and downstream is used for simplicity.

In our example of a 30m suburban macro tower, we use mid-cell capacity and apply a max fill-rate of 50% as the average available across all households in the footprint (1429 Mbps * 50% = 715 Mbps). We recognize that households nearer the gNB could experience significantly higher throughput, depending on the providers' policies and practices of limiting available speeds to any given subscriber. Households at the service edge would typically experience the headline speed subject to the number of active users in the sector.

715 Mbps would support approximately 57 households per sector or 171 household per cell (715 Mbps ÷ 12.5 Peak Average usage/Household in 2027 = 57 X 3 sectors = 171). Our calculations are based on average household consumption. Service providers may have the ability to segment and target users i.e. lower usage households and to manage how many subscribers are offered the service and supported in a given cell sector.

An alternative view of serviceability for FWA is to understand how many households can be supported in a given area. The 100 Mbps service edge in our 30m suburban tower example above is at a radius of 1,418 meters equating to a coverage area of 6.3 Km². With 171 maximum serviceable households per cell we arrive at a maximum of 27 on a per Km² basis. Table 3 below shows the maximum number of households can be supported (in green) for a 100 Mbps FWA service across a range of household densities and market penetrations. Note that where the number of macro towers in an area of interest does not provide ubiquitous coverage for the given service, an adjustment would need to be made to account for non-addressable households.

Table 3 - Maximum Supportable Households for a 100 Mbps FWA Service

Market Penetration	Household Density/Square Km						
	100	200	300	400	500	750	1,000
2.5%	3	5	8	10	13	19	25
5.0%	5	10	15	20	25	38	50
7.5%	8	15	23	30	38	57	75
10.0%	10	20	30	40	50	75	100
12.5%	13	25	38	50	63	94	125
15.0%	15	30	45	60	75	113	150
17.5%	18	35	53	70	88	132	175
20.0%	20	40	60	80	100	150	200
22.5%	23	45	68	90	113	169	225
25.0%	25	50	75	100	125	188	250

The U.S. Census defines an area with less than ~325 households/Km² as rural⁴. We can see from the results in Table 3 that, in general in suburban areas, available capacity would be exhausted in areas up to 500 households/Km² once 5% of households have signed up for the service. At this point, the provider would either need to manage the demand i.e. halt additional subscriber adds or increase capacity by adding more spectrum, increasing the efficiency of the network or adding more towers in the service area.

⁴ <https://www.ers.usda.gov/topics/rural-economy-population/rural-classifications/what-is-rural.aspx>. We use 2.5 persons/household to arrive at approximately ~325 households/Km².

Demand could be tempered by targeting areas with smaller households size (predominance of single-person households) or segments that have lower overall usage. Over-the-top video is a significant driver of data consumption and providers could target areas or segments with higher traditional linear video subscribership or lower rates of work and/or study from home.

7. Economic Considerations

To understand the business case for FWA, a proforma of discounted cash flows with the following assumptions and factors should be considered. To obtain a sample Excel based pro-forma incorporating the factors below, please contact the author at s.patel@cablelabs.com:

Revenue and Top Line:	
Area of Interest	<ul style="list-style-type: none"> • 3GPP considers different performance models for Urban Macro and Rural Macro scenarios. • Can be defined as a market, defined target service area or macro cell.
Service Offering	<ul style="list-style-type: none"> • ARPUs and incentives may vary depending on whether a subscriber bundles mobile and FWA. • Target speed offerings affect the service edge or how far signals propagate. A 300 Mbps service would offer a smaller serviceable footprint than a 100 Mbps service. • Target availability of headline speeds. There is a direct correlation between propagation and target service availability. • Spectrum to be used for the FWA service including depth.
Household Density	<ul style="list-style-type: none"> • Households/Km² can be translated into addressable subscribers once the service and calculated propagation are defined.
Subscriber Penetration	<ul style="list-style-type: none"> • Drives the calculation for demand. • Consider mobile market share and the type and number of available competing broadband options in the area of interest i.e. FTTH, DSL, HFC, FWA, LEOS. • Some MDUs offer broadband as part of their rent or Home Owners Association (HOA) benefits. • Consider that a certain (small) percentage of households will not subscribe to any broadband service.
Subscriber Ramp	<ul style="list-style-type: none"> • Time it will take in years to reach target penetration rates.
Max Supportable Subscribers	<ul style="list-style-type: none"> • Note in Section 4, we describe how to calculate available capacity in a cell and in Section 6 the maximum number of subscribers that can be supported based on average household demand. This serves as a subscriber ceiling until additional capacity can be created.
CPE Revenue	<ul style="list-style-type: none"> • If the subscriber bears either a partial or full upfront cost or monthly lease cost for CPE.

Variable Costs:	
CPE	<ul style="list-style-type: none"> • Cost per unit for new indoor 5G CPE. • Useful life and/or replacement cycles. • Distribution costs i.e. warehousing, shipping, delivery, returns. • Cost to refurbish and package for churned units. • We model CPE cost as being borne by the operator. Subscribers may bear part or all of the cost and those revenues should be accounted for accordingly.
Customer Acquisition	<ul style="list-style-type: none"> • Retail, channel partners, online acquisition paths and associated costs. • Promotions i.e. X months free service and other tie-ins i.e. bundled OTT video services or other discounts i.e fixed and mobile.
Churn	<ul style="list-style-type: none"> • Rate of monthly disconnects. Given the nature of the service, FWA churn may be higher than typical fixed broadband or mobile subscriber churn rates. • For a model that considers a terminal number of subscribers following a ramp up, a service provider would need to replace disconnecting subscribers on a regular basis to maintain counts and account for CPE and subscriber acquisition costs.
Customer Cost to Serve	<ul style="list-style-type: none"> • Customer support including retail, online channels, call centers, back-office systems, field techs, trucks, consumable tools. • Can be expressed as a percent of revenue for simplicity.
Tower leases	<ul style="list-style-type: none"> • Incremental cost to lease space on existing towers for FWA specific radios, and land for power and backhaul.
Power	<ul style="list-style-type: none"> • Incremental cost for radios, networking equipment.
Backhaul	<ul style="list-style-type: none"> • Incremental cost to add capacity or new links.
Maintenance	<ul style="list-style-type: none"> • For new equipment and incremental infrastructure
Licensing and Support Agreements	<ul style="list-style-type: none"> • As applicable from vendors for hardware and software.

Fixed Costs & Other:	
Spectrum	<ul style="list-style-type: none"> • Acquisition cost or calculated as \$/MHz Pop based on the population for the area of interest. • Population for a given area can be referenced or calculated based on household data. A typical household has ~2.3 residents in the U.S. • Depending on licensing terms, where regulators extend spectrum licenses indefinitely, they could be considered an asset for accounting purposes. In that case, a carrying cost calculated as the provider's cost of capital against the acquisition cost could be applied. For example, in the FCC's recent C-Band auction, the average price paid was \$1.17/MHz Pop. If the area of interest was a market with a population of 1 Mil, and the operator dedicates 100 MHz of spectrum for the service, the spectrum for that market would \$117 Mil. A carrying cost using a cost of capital of 8%/year would equal a monthly spectrum expense of \$780,000 (\$117 Mil * 8% /12). Note that spectrum cost can vary market by market. • Another consideration is whether the operator has indefinite rights to the spectrum. In cases where the spectrum is considered owned, its value could be incorporated into the pro-forma as a future cash flow if the service is being evaluated on a standalone basis i.e. the spectrum could be re-allocated for mobile use or otherwise monetized. We do not make consideration of a future cash flow in our analysis.
FWA Antennas, cabling, power, networking equipment	<ul style="list-style-type: none"> • MIMO characteristics for the antennas. • Hardware and installation. • Useful life or technology replacement considerations. • Distributed units, Central units. • Incremental core networking and management.
Tax Savings	<ul style="list-style-type: none"> • In some countries, spectrum and other capital investments can be amortized and are tax deductible for cash tax purposes. A typical amortization period would be straight line over 15 years. • www.csimarket.com offers data on tax rates for U.S. companies.
Cost of Capital	<ul style="list-style-type: none"> • Also referred to as the Discount Rate used for Net Present Value (NPV) calculations. • See NYU Stern for average cost of capital rates across U.S. industries⁵.

⁵ https://pages.stern.nyu.edu/~adamodar/New_Home_Page/datafile/wacc.html

Financial Metrics	<ul style="list-style-type: none"> • Cash Flow: increase or decrease in cash for a period once revenues, variable and fixed costs are accounted. • Net Present Value: The current dollar value of future cash flows discounted at the cost of capital. • Payback: Number of years for discounted cash flows to become positive. • IRR: Internal Rate of Return.
--------------------------	---

A pro-forma designed with the above assumptions would calculate contribution margin and cash flows from which a FWA service can be assessed on a net present value basis and payback basis. For an Excel-based example, please contact the author directly.

A final key consideration depending on the operator is cost allocation. Many FWA operators are primarily mobile service providers. Where they build excess capacity, it makes economic sense to use that capacity for other revenue generating activities such as FWA as long as they don't degrade the mobile experience. In that case, a consideration can be made as to how much of the spectrum and infrastructure costs should be allocated to the FWA service. Our Excel tool allows for understanding the impacts to ROI with different sensitivities for revenue, cost and allocation assumptions.

8. Conclusion

This paper lays out the economic considerations for a rural FWA based broadband service. It is a companion to our technical paper which is also submitted for Tec-Expo 2022 titled "5G FWA Technical Performance Analysis for Mid-Band Rural Networks". We show how calculations for propagation and capacity based on a number of service assumptions can be applied to understand how much coverage can be created for a given macro cell and market area. We further describe the concept of service edge and show how capacity diminishes with distance from the service antennas. A methodology to calculate peak average demand for a broadband household and forecast usage 5-years out is used to understand how many subscribers can be supported in a given cell and sector. Finally, we present the revenue, variable, fixed and other considerations that drive a financial analysis of the economics for FWA. Should you have any questions or would like to obtain a reference Excel pro-forma model, please reach out to the author directly at s.patel@cablelabs.com,

1. Introduction

Internet linear delivery has introduced the need for out-of-band schedule and entitlements information (SCTE 224) alongside event signaling (SCTE 35). The popularity and adoption of SCTE 224, Event Scheduling and Notification Interface (ESNI) is opening new use cases for which the protocol is a great fit. SCTE 224 has proven itself as an efficient and effective means for machine-to-machine communication of out-of-band linear rights management. This combination of SCTE 224 and SCTE 35 to trigger the in-band signaling allows precision execution of linear rights for content substitution and addressable advertising management. But the data maintained by the system in the SCTE 224 format is also useful for other entitlement use cases. The main use case we look at in this paper is around sports entitlement and using the SCTE 224 objects to determine whether a user has the rights to see a game or not – before even seeing the video – based on their location.

With its increase in popularity, content providers and operators are now delivering internet linear television to millions of subscribers simultaneously. As a result, SCTE 224 decision systems can receive millions of simultaneous decision requests from individual playback devices. Scaling these systems is paramount to effective delivery and subscriber satisfaction. One scaling strategy is the deployment of distributed decision systems as “serverless” functions. However, merely moving the decision logic to serverless functions did not achieve performant scale for loads expected for marquee events like major sports championships. Even though these functions exhibited acceptable elasticity in launch, the decision logic was not performant at runtime, because SCTE 224 objects do not lend themselves to expedient searches for applicable viewing policies. The Comcast Technology Solutions (CTS) team optimized the design by indexing the SCTE 224 objects and took advantage of other cloud features to create an optimal and performant distributed decision engine that scales in a ready state, making it instantly responsive across the video subscriber footprint. Our highly performant infrastructure decision system expands automatically to accommodate peak loads. As a result, this distributed decision system delivers 50 milliseconds responses under a load of nearly 20K requests per second. Furthermore, the system scales back under times of lower viewership, reducing our cloud processing cost.

2. Linear Rights Background

The ESNI protocol is perfectly suited to communicate rules and policies at an audience-based level, thereby providing a substrate to implement linear rights. ESNI is the key mechanism to communicate linear rights around web or over-the-top (OTT) embargoes, regional blackouts, and even dynamic advertising. ESNI also provides policies for specific rules at the precise audience level. ESNI therefore facilitates appropriate rights decisioning at scale from machine-to-machine. The ESNI objects are perfect for determining such things as channels and events a user has the rights to watch in real-time.

ESNI objects are XML (Extensible Markup Language) messages with relevant fields for rights such as ViewingPolicy actions for content switching, blackouts, and playout restrictions. These ESNI messages are managed with a REST (representational state transfer) interface for exchange between the providers and the distributors. The out-of-band ESNI execution components then link these markers with the ESNI instructions. The hierarchy of ESNI Policy to ViewingPolicy and to Audiences allows support of various ways to evaluate linear rights against these audiences.

3. SCTE 224 Context

SCTE 224, Event Scheduling and Notification Interface (ESNI) is an XML based standard that provides a defined protocol for carrying machine-to-machine metadata for video. There are five basic constructs within SCTE 224, as shown in Figure 1. These constructs work together to provide a programmer with a

means to convey video rights for content replacement as well as advertising instructions on the distributor or operator side of the workflow. These five constructs are Media, MediaPoints, Policy, ViewingPolicy, and Audiences. We describe each of these here, and then tie them all together with the various use cases around sports entitlement.

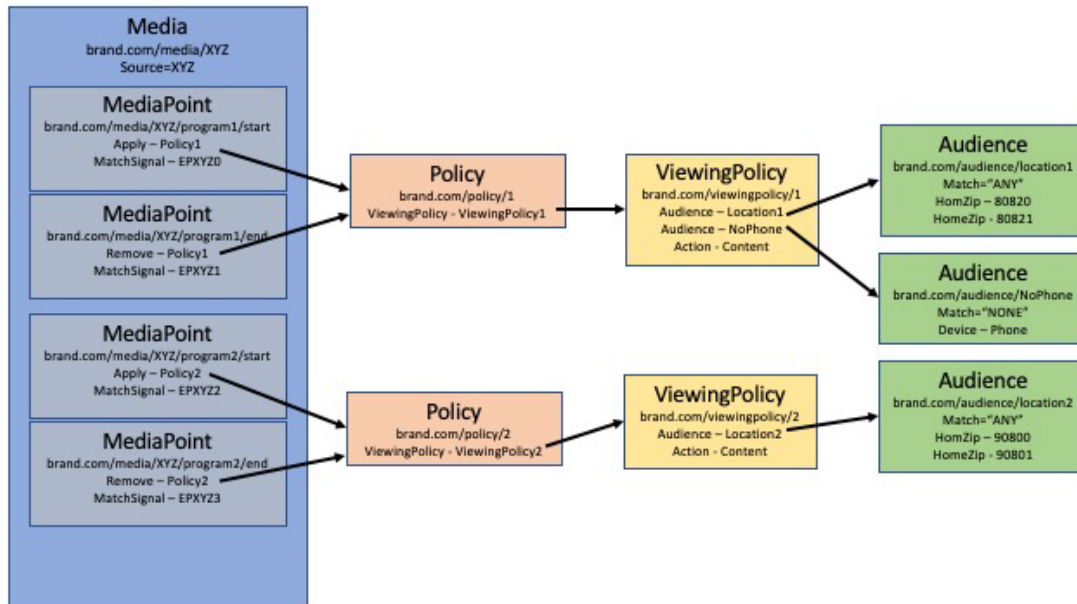

Figure 1 – SCTE 224 Constructs

3.1. SCTE 224 Media

The Media object is a top-level container representing a linear channel whose primary function is carrying all the MediaPoints, so it contains an ordered list of MediaPoint elements as shown in Figure 1. The Media also contains a few key elements like a description and a source for the linear channel it represents.

3.2. SCTE 224 MediaPoint

The MediaPoint object describes a point in the Media when a decision needs to be made or an action needs to be taken. These points can either be time-based (i.e., the presence of a @matchTime attribute in the MediaPoint) or an SCTE 35 in-band signal based for frame accuracy. The signal-based MediaPoints contain a MatchSignal element with XPath matching logic to link the MediaPoint to the presence of the in-band signal. Signals can be reused, because MediaPoints also have an effective/expires window constraining when the MediaPoint can be evaluated.

When a MediaPoint is triggered, based on time or signal, it can either “Apply” or “Remove” one or more Policy objects which affect the state of the linear playback. See the Policy object description below for more details. MediaPoints that “Apply” a Policy do so until another MediaPoint explicitly “Remove” that Policy or they time out based on the duration indicated in the “Apply” statement.

3.3. SCTE 224 Policy

A Policy object is nothing more than a container for defining a set of ViewingPolicy elements that should be acted upon based on this Policy being “Apply” or “Removed” from the Policy stack. The “Apply” or application of a Policy means putting that Policy on that Medias stack via first-in-last-out queue, so multiple Policy objects can be affecting the state at one time. The removal of a Policy then takes it off that stack and out of the state of that Media. SCTE 224 has explicit rules about how to manage the Policy queue in a SCTE 224 execution engine.

3.4. SCTE 224 ViewingPolicy

The ViewingPolicy object is the key SCTE 224 object that associates one or more actions to an audience. These “Actions” can range from telling an audience to go to alternate content, restrict trick mode, or restrict resolution. For advertising specifically, these actions can contain information about the advertising decisioning service (ADS) to use for a particular audience, or various advertisement conflicting rules for a particular audience. The key to a ViewingPolicy is that if the “Audience” criteria is met, then the action must be taken. The SCTE 224 specification maintains a large list of actions allowed within the ViewingPolicy object, many of which are specific to addressable advertising.

3.5. SCTE 224 Audience

The Audience object is a set of characteristics that define a subset of viewers based on criteria such as device-based characteristics (tablet, phone, etc.), general characteristics (local storage, mobile, etc.), or location-based characteristics such as zip codes, postal codes, latitude/longitude, market areas, as well as roles such as distributor or Virtual Integrated Receiver Decoder (vIRD) identifiers that place the audience into groups to dictate specific actions. Audience objects can contain other Audience objects making them a compound Audience. Additionally, logic to associate a client with a viewer or viewers is based on matches of ANY, ALL, or NONE of the characteristics outlined in the Audience, so that characteristics can easily be included or excluded. For example, you can say Match=“ANY” for a list of zip codes to characterize the audience within that area or use Match=“NONE” to characterize an audience outside that area.

4. SCTE 224 Example Logic

So now let’s take those five objects from Figure 1 and run through a scenario of a real-time decision request for the video playout. The trigger is a video signal acquisition system (SAS) seeing an in-band SCTE 35 signal or a user logging into an app. An events triggers the request to a signal decisioning system (SDS) to figure out what it should do. When the SAS calls the SDS it tells the SDS which source it was on, what time it saw the signal, the binary signal, and the client characteristics. Something like “I just saw the signal ‘UhJeafojoihe23edde’ on source XYZ, at 1:00pm and I am encoding for zip code 80820.” Or if it is an app user, they are requesting a determination of entitlement to see if the game they are requesting is or is not on the feed they are requesting it on. The SDS then looks through all the out-of-band SCTE 224 and its Media to find the one for that source (i.e., XYZ). Once it finds the correct Media it looks through its MediaPoints to find the list of MediaPoints that at that time falls within their effectiveness window. Once it has the list of MediaPoints it evaluates each one to see if there is a match with the signal. For the MediaPoint that matches, the decision is either to “Apply” or “Remove” the associated Policy. It then goes from that Policy to the ViewingPolicy where it gets the Audience and sees if the client’s zip code is in or out of that Audience or not based on the Match criteria. If it is in that Audience, the SDS returns the “Action” of the ViewingPolicy to the SAS. In the case of alternate content, it might return to the SAS that it needs to switch over to another source and start encoding the alternate

source. Based on the client information and the construction of the Audience objects, API logic in this use case can give an entitlement answer to a requester.

5. SCTE 224 Indexing

As mentioned in the Introduction, SCTE 224 objects do not lend themselves to expedient searches. To provide a performant service, the SCTE 224 objects need to be transformed into some other form that does support expedient searches. Looking at the types of requests to be processed, there was no single type of transformation sufficient to provide the required performance. Thus, we needed multiple indexing schemes, with each type of request using an indexing scheme that best suits it for the SCTE 224 object.

This is a key concept, because even at the expense of potentially storing the same data in multiple structures, the executional performance outweighed the duplication.

5.1. Scheduling

For linear playout channels, an SCTE 224 Media object typically represents a schedule for that channel, with MediaPoint objects representing individual shows or events. The SCTE 224 specification also allows for metadata about these shows to be contained within the MediaPoint object. Taken together, these two features allow a scheduling interface to determine what is currently playing and to gather metadata on a particular show or event.

The SCTE 224 specification does not make any comments about how MediaPoint objects are stored within a Media object, just how the document order of these MediaPoint objects dictate their precedence. As the MediaPoint objects are stored as a list within the Media object, doing a linear search to determine what is currently playing would take too long on average. For this system under discussion in this paper, the MediaPoints were set up in a true schedule fashion, with earlier events closer to the beginning of the Media object and later events farther down in the document. Additionally, the shows were set up to eliminate any overlap. These restrictions on the MediaPoint objects lead nicely to using a form of self-balancing binary search tree, such as an AVL tree, using time as the search criterion.

Searching for the metadata on a specific show would not lend itself well to using the same binary search tree described above. Therefore, a different form of indexing needs to be applied for this type of request. With the caller supplying the identifier for the show, a hash map object mapping the identifier to a MediaPoint would provide the desired performance.

5.2. Entitlement

Once the information for what is playing and the metadata has been gathered, now it's time to determine if the user is entitled to view the show or event. As with the request for gathering the metadata, the system is provided with the identifier for the show, lending this type of request to rely on an underlying map structure to pinpoint the MediaPoint object. However, unlike the metadata request, these entitlement requests are required to follow the chains of Policy, ViewingPolicy, and Audience objects to make the appropriate decision. Generally, both the Policy and ViewingPolicy objects are succinct, allowing them to be stored as simple data objects. The Audience objects, on the other hand, could contain a list of thousands of zip codes, calling for a more complex structure such as a hash map.

The flow for satisfying an entitlement request would look something like this:

1. Using the show identifier provided in the request, locate the desired MediaPoint object.
2. For each Policy object listed in the Apply elements of the MediaPoint object:

- a. Locate the named Policy object, if it is only supplied as a reference in the MediaPoint object
- b. For any ViewingPolicy associated with this Policy:
 - i. Locate the named ViewingPolicy, if it is only supplied as a reference in the Policy object.
 - ii. For each Audience associated with the ViewingPolicy object, use the zip code provided in the request to look for a match.
 1. If a match is found, use the ViewingPolicy to determine the action for a member of this Audience.
 2. If no match is found, continue searching until all Policy, ViewingPolicy, and Audience objects for the MediaPoint have been examined.
 3. If there is a match in any other Policy, it is handled like step #1 above.
 4. If there are still no matches, then nothing is found, and a default “Not Entitled” response is given.

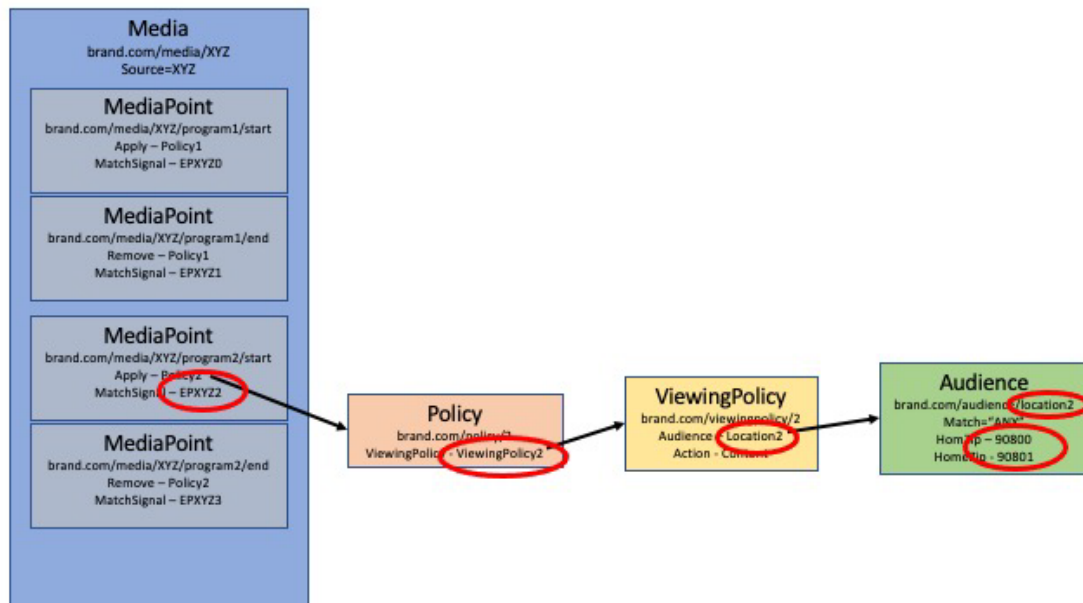

Figure 2 – Entitlement Logical Decision Flow

5.3. Pre-Conversion and Caching

As serverless functions used to supply this functionality are expected to be ephemeral, converting the raw SCTE 224 to structures optimized for SCTE 224, such as AVL or hash maps as described above upon start up excessively impacts the performance of the initial requests. The system was designed to do these conversions externally to the serverless functions providing the searching capabilities. When any update is received by the system, a processor generates the various structures that form the optimized SCTE with the updated data and stores it in a cache that is shared across all instances of the request-handling serverless functions.

6. Concurrency Scaling

Concurrency scaling is what controls the number of concurrent serverless functions that can be set up to handle all of the calls in a scaled event. As the number of connections reaches the limit, throttling of requests can occur during requests that are held until they can be serviced.

6.1. Rate-Limiting

The design choices explained in the indexing section of this paper laid the foundation of this highly performant system and during various load tests that were performed, the system scaled reasonably well until it hit a certain burst load, and requests were being limited.

Most serverless functions are not infinitely scalable and therefore have a configured concurrency limit. There are two types of concurrency limits with serverless functions.

- There is a limit on the number of function containers that can serve requests at a given time. In most cases this value is configurable.
- There is also a burst concurrency limit which is the number of new function containers that can be spun up at a given point in time. This is set at 3,000 in the area these systems were operating in.

In each of the cases above, if either limit is reached during execution, any more requests that need additional serverless functions would not be served. This is reflected during execution as limiting those requests so that available resources can serve the current requests.

The metrics graph below shows, as many as ~16k requests @~11.47AM were throttled, because we hit the burst concurrency limit of 3,000 instances.

Figure 3 – Requests Per Second

6.2. Solution Options

Because the burst levels of requests for these extreme events requests were running up against the limiting, we needed a way to allow the design to work. The goal then was to raise this concurrency limit in some fashion, but there are constraints on the limit, so we looked at two options:

- Increasing the concurrency limit of serverless compute serve. But our functions were being limited because they hit the burst concurrency limit, which is non-configurable.
- Take a closer look at behavior of the functions themselves and identify opportunities for optimization.

It was not enough to just throw more resources at it, because there were cost prohibitions for the majority amount of time when the system is not under load. Since the first option is not configurable, our course of action was to look at the second option around function behavior.

6.3. High Response Time Requests

We decided to take a closer look at:

- What are some of our slowest requests?
- Which part of the code are they spending significant time on?

We already had built some custom instrumentation in our functions, which were basically measuring time taken by different sections of the code and logging them in a structured format to analyze. Querying those logs using analysis tools gave us insights allowing us to answer the two questions above.

#	total_time_ms	db_conn_ms	execution_time_Fin_	execution_time_TreeBySta_

Table 1 Response Times

It allowed us to see a linear correlation between high processing times and:

- i. Time taken to forward logs to a centralized logging system of choice. Yes, we were using two logging systems; one allowed us to correlate log-events from this system with related log-events from other systems that weren't using central logging tools.
- ii. Time taken to establish connections to the database. A burst of requests meant many different serverless function containers were requesting "new" connections at the same time causing congestion on the server side.

We replaced logging synchronously to the second logging system with logging asynchronously. All the events were logged to the central logging tool, then forwarded to the second using another independent

serverless function.

To address (ii), we implemented a connection pooling mechanism and initialized connections to a database in the initial phase of serverless function, rather than on-demand.

6.4. Serverless Function Warm-up

With all those performance advances described above, there was a significant improvement in response times. However, given that the expected scaling for an event like the Super Bowl will be anything but linear (i.e., tens of thousands of users logging in to watch the broadcast just before the game starts), we knew we might still hit the non-configurable *burst limit* leading to requests being throttled. But an advantage is that it's easy to predict when to expect the burst (before game start).

One aspect of the request-processing life cycle that wasn't in our control, but was consuming significant amounts of time, was the server-less function container initialization time. In other words, the time required to perform a cold start of a new serverless function.

To avoid being limited by cold starts so that bursts could be gracefully handled, we leveraged the provisioned concurrency feature of the server-less function. This instructed the server-less function to spin up X number of serverless function containers, ready to handle the burst of requests as they come.

All of the sound design choices, optimizations for less-efficient parts of the code, and enabling provisioned concurrency allowed us to achieve a P95 response times of <50 milliseconds, when the system was under a peak load of 16-18k requests per second.

Figure 4 – Peak Loads

7. Final Architecture

So based on the information and the success of the above optimization, here is a view of an example overall architecture for an optimized solution.

Figure 5 – Architecture View

8. Conclusion

With its increase in popularity, content providers and operators are now delivering linear television over the internet to millions of subscribers simultaneously. As a result, SCTE 224 decision systems can receive millions of simultaneous decision requests from individual playback devices. Scaling these systems is paramount to effective delivery and subscriber satisfaction. One scaling strategy is the deployment of distributed decision systems as “serverless” functions. However, for us, merely moving the decision logic to serverless functions did not achieve performant scale for loads expected for marquee events like the major sports championships. Even though these functions exhibited acceptable elasticity in launch, the decision logic was not performant at runtime, because SCTE 224 objects do not lend themselves to expedient searches for applicable viewing policies. We optimized the design by indexing the SCTE 224 objects in multiple methods and took advantage of other cloud features such as scaling concurrency and warming up serverless functions before use, to create an optimal and performant distributed decision engine that scales in a ready state, making it instantly responsive across the video subscriber footprint. Our highly performant infrastructure decision system expands automatically to accommodate peak loads. As a result, this distributed decision system delivers 50 milliseconds responses under a load of nearly 20K requests per second. Furthermore, the system scales back under times of lower viewership, reducing our cloud processing costs.

1. Introduction

As Comcast progresses through Gen2 of the Distributed Access Architecture (DAA) initiative, “automating everything” is paramount to the continued growth of the footprint. With the exciting milestones achieved in Gen1, which took the first DAA customers online, came a laundry list of operational improvements needed to realistically achieve the desired scale. The common theme among these needed improvements? Automate. So far, Gen2 has made considerable progress in this regard, automating everything from individual virtual cable modem termination system (vCMTS) cluster standups to software and network changes, to incident detection and mitigation (Krishnamurthy & Medders, 2021).

Since virtualization is the name of the game in the world of DAA, the vast majority of vCMTS maintenance and upkeep is achieved with cloud component software updates, specifically component configuration changes. Achieving near total automation involved transitioning software upkeep over to a DevOps approach, with which changes to individual clusters are managed with cluster-specific continuous integration/continuous deployment (CI/CD) pipelines. With this setup, a single Git commit indicating a configuration change to a specific vCMTS component schedules the entire deployment process, which kicks off a cascade of automated events, including but not limited to silencing alarms, microservice performance checks, the actual software deployment, and a network health check to ensure no customer impact. The goal in using this strategy to orchestrate software deployments is to eliminate as much human interaction as possible, as even the slightest human error introduced at a single step can have monumental impacts to the cluster configuration and network performance down the line and can lead to complex outages and delay feature enhancements and releases.

During software updates, preserving or improving the customer experience is of the highest priority. In Gen1, network health was checked manually; an operator would verify no customer impact by checking telemetry dashboards and manually flagging any signs of service degradation. Not only is this practice not scalable but subjecting this critical process to the risk of human error is undesirable as DAA scales and the customer base grows. Therefore, automating and optimizing network health monitoring surrounding software updates is of utmost importance. This paper highlights a data-driven approach to developing and productionizing an automated network health check for use in vCMTS deployment CI/CD pipelines as part of the Gen2 DAA initiative.

1.1. Problem Statement

As the number of software updates needed to maintain and scale the DAA footprint increases from tens to hundreds to sometimes thousands per day, it is necessary to not only have these automated processes in place, but to ensure that they are optimized to near perfection. With millions of customers already converted to DAA, automated network health monitoring is one of these essential processes, given that software updates can sometimes cause unintended side effects on the network, resulting in a degraded customer experience. Software-related service degradation might manifest as anything from interruption of service to poor traffic throughput, to partial utilization of network capabilities, and more. Even though most software updates pose little risk to the customer experience, catching these occurrences when they do happen so that quick mitigative action can be taken is considered to be a critical capability. Therefore, there is a need for an automated and dependable tool for post-deployment network monitoring, which can validate that software updates do not degrade service for the existing customer base *or* flag the occasional software updates that do.

To deliver true value and support the goal of total automation, this tool needs to be compatible with the vCMTS deployment CI/CD pipelines and to deliver highly accurate results, alerting the ops team only

when there is definite service degradation detected following a deployment, while simultaneously maintaining a level of sensitivity as to not let any undetected service degradation slip through the cracks. Additionally, to adhere to target maintenance window timeframes, this tool must determine and deliver a decision on the state of the network back to the CI/CD pipeline within a matter of minutes following the deployment. Last but not least, if service degradation is detected, the tool must provide a meaningful summary detailing the reasons for service degradation so that an operator can take the appropriate action.

1.2. Solution

To address this need, the data sciences team has leveraged the rich network telemetry available within the DAA system to develop a network health decision engine made available as an application programming interface (API). When called, the API queries cluster-specific telemetry metrics live from a time series database and performs a suite of algorithms to assess the health of the network. The API response flags any incidental impact on already-live customers and alerts an operator within a matter of minutes.

The data sciences team has collaborated closely with the DAA engineering and ops teams to identify relevant network key performance indicators (KPIs)—all in accordance with Data Over Cable Service Interface Specification (DOCSIS[®])—to check as part of this process. The application performs *i.* a pre-check to gather a baseline measure of network KPIs prior to a software update and *ii.* a post-check to draw comparisons among KPIs and ensure that the network remains in a healthy state following a software update. The post-check assesses the state of the network instantaneously by comparing instant post-deployment KPI readings to either instant pre-deployment or historical KPI readings. The API is designed specifically to integrate with the vCMTS software deployment CI/CD pipelines and is robust enough to offer a one-size-fits-all solution to all clusters, regardless of configuration differences, number of customers, differences in downstream topology, etc. The API is also compatible with a variety of software deployment types, regardless of the target component and predicted risk level.

The API is currently integrated and running in a production environment. The application is invoked during each software update for a variety of vCMTS components ranging from server builds to configuration updates to operating system upgrades. As measured in recent analytics, the application is invoked, on average, ~400 times per day and triggers alarms on ~2.5% of invocations. This paper will take a deep dive into the methodology used to develop the tool and tune the rule-based algorithms, present performance metrics, discuss lessons learned, and briefly touch on relevant future work.

2. Background

2.1. DAA Topology

While DAA offers a technologically progressive means of providing service to customers, the distributed architectural setup is rather complex. The access network contains a variety of physical and logical components ranging from headend Kubernetes servers to a series of leaf-spine switches to downstream digital nodes all the way down to the customer premises equipment (CPE). When one or more of these vCMTS components undergoes a software update, the deployment CI/CD pipeline performs a series of checks on the entire cluster footprint. These checks can be grouped into two general categories: *microservice performance* and *network health*. Because this paper focuses on the latter, the intricacies of the DAA architecture and the vCMTS cloud environment will be outside the scope of this paper. However, several past papers cover these topics in detail, namely *Distributed Access Architecture Is Now Widely Distributed - And Delivering On It's Promise* (Howald et al., 2021) and *Node Provisioning and Management in DAA* (Gaydos et al., 2018).

To understand how the automated network health check is performed from a customer impact standpoint, three topological entities must be understood: *i.* the physical point of deployment (PPOD), *ii.* the remote PHY device (RPD), and *iii.* the cable modem (CM). Figure 1 portrays a simplified view of relevant DAA topology.

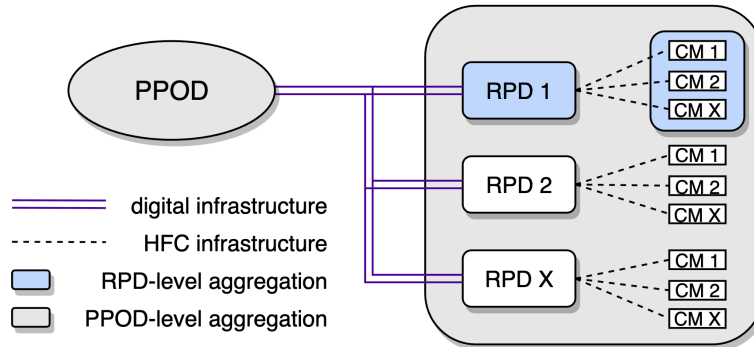

Figure 1: A simplified view of DAA topology

2.1.1. The PPOD

Located at each primary headend, PPODs comprise the actual servers on which DAA software is deployed. PPODs and vCMTS clusters are often referenced interchangeably and, in theory, describe the same technology. However, usage of one term versus the other depends on the context in which the technology is being discussed; a PPOD can be thought of as an abstract deployment unit, whereas “vCMTS” is often used in reference to the physical cluster hardware. Given that this paper discusses DAA from a software standpoint, we will largely use the “PPOD” naming convention going forward.

As Krishnamurthy and Medders discuss, clusters are often spun up with configurational differences, “each with their own slightly different personalities” (2021). Given that any two PPODs might be configured differently, the PPOD is the highest-level architectural component on which it makes sense to perform a series of automated checks and aggregate results. Even when the entire DAA footprint needs to undergo a particular component update, performing PPOD-level checks eliminates any risk of confounding configurational differences into the equation. As such, all DAA deployment CI/CD pipelines are kicked off at a PPOD-level, and subsequent checks are intended to indicate how a particular PPOD “personality” fairs with any given software update. From the network health perspective, this entails checking for any service degradation or incidental impact experienced by customers downstream of the PPOD of interest.

2.1.2. The RPD

Designed to bring digital data transmission as close to the home as possible, RPDs sit on the very edge of the access network and comprise the gateway between the digital system and the hybrid fiber/coax (HFC) network, which eventually reaches the home. RPDs are the most downstream digital component of the access network and can be subject to software updates themselves. Like PPODs, RPDs can have configurational differences and/or come from different vendors, creating variety among them. Therefore, RPD-level data aggregations provide diagnostic value when conducting the network health check. The strategy of grouping together customers downstream of each RPD and analyzing each of these customer subsets separately provides a more thorough network health validation and, if service degradation is noticed, helps the responding operator to determine if the source of the issue lives at a particular RPD.

2.1.3. The CM

The CM, which is often used interchangeably with “CPE”, is the final topological entity involved in the network health check. Individual CM metrics are often the fundamental units used to derive data-based network health algorithms, and all CMs subscribed to the PPOD-of-interest are taken into account during the assessment. However, with millions of CMs already dispersed across the DAA footprint, it would be impractical and disadvantageous to collect, analyze, and report on telemetry data for each and every CM. In analyzing CM metrics, aggregations at both the PPOD- and RPD-levels deliver a more meaningful and statistically robust measure of how the customer experience is fairing across the footprint following a software update. Additionally, if service degradation is detected, this aggregation strategy offers a diagnostic advantage in that it can pinpoint a lowest common ancestor for problematic CMs, allowing for quicker isolation of the issue. For these reasons, almost all algorithms operate at either the PPOD- or RPD-level. The only exception to this aggregation strategy is seen in the analysis of Business Services over DOCSIS (BSOD) customers. This analysis does perform a CM-level evaluation, which will be presented in Section 3.2.2.

2.2. DAA Telemetry

One noteworthy enhancement of the DAA system is the improved real-time telemetry offered across each of the architectural components from the PPOD down to the CM. With the legacy system, telemetry data was only emitted at 5-minute intervals at the very least. With DAA, data is streamed with 15-second resolution. This improvement is key to delivering a speedy assessment of network health, as it eliminates the need to wait for post-deployment telemetry to become available. Additionally, this increased resolution into telemetry data allows the freedom to explore more check algorithms and provide higher quality network diagnostics. In *Solving The Mysteries of the Distributed Access Architecture*, Stehman et al. details the available telemetry across the access network and further expands on relevant topology (2021).

3. Methodology

3.1. Network Health Check Overview and Terminology

3.1.1. Pre-Check, Post-Check, and Metric Snapshots

The automated network health check is meant to detect and alert on any unintended customer impact after a software deployment. This of course entails checking live telemetry metrics directly after the deployment; however, to establish a PPOD-specific baseline on which to compare these post-deployment metrics, data collection and analysis is also needed prior to the deployment. As such, the health check was designed to be a two-part process, consisting of both a pre-check and a post-check. By design, a completed pre-check is required to start a post-check. From the PPOD CI/CD standpoint, this means that the API must be integrated both prior to and after the deployment.

Each of the pre- and post-checks can be further broken down into metric “snapshots”. A metric snapshot can be defined as a collection of related telemetry metrics measured over the same time period and compiled to create a meaningful KPI. Since most of the evaluation algorithms function by comparing a given KPI at two different time points, each time-aligned metric snapshot can be considered a single comparison unit. Pre-check gathers metric snapshots from two different timeframes: *i.* over the course of history for the PPOD and *ii.* in the instant right before the deployment. Respectively, we will refer to these as “historical snapshots” (“historical-snaps” for short) and “pre-deployment snapshots” (“pre-snaps” for short). As historical-snaps often consider a wide timeframe prior to a deployment, typically an aggregation of telemetry data over time serves as the comparative metric value. This could be, for instance, the 10th percentile of a PPOD’s upstream packet rate over the past seven days.

The post-check works by querying and deriving metric snapshots from one timeframe only—in the instant right after the deployment. These snapshots will be referred to as “post-deployment snapshots” (“post-snaps” for short). The post-check also has the capability to load any of the cached historical-snaps or pre-snaps from the pre-check to perform the actual pre-to-post comparisons. Whether or not post-check borrows from the historical-snaps or pre-snaps depends on the KPI being compared. As a general rule of thumb, continuous KPIs, such as traffic flow, tend to be compared post-deployment-to-historical, whereas discrete KPIs, such as number of CMs online, tend to be compared post-deployment-to-pre-deployment. In adherence to DevOps daily maintenance schedules, the target completion time of a post-check, including all queries, data reads, comparison logic, and data writes, is two minutes or less. Figure 2 aims to further clarify the concepts of pre- and post-checks as well as metric snapshots.

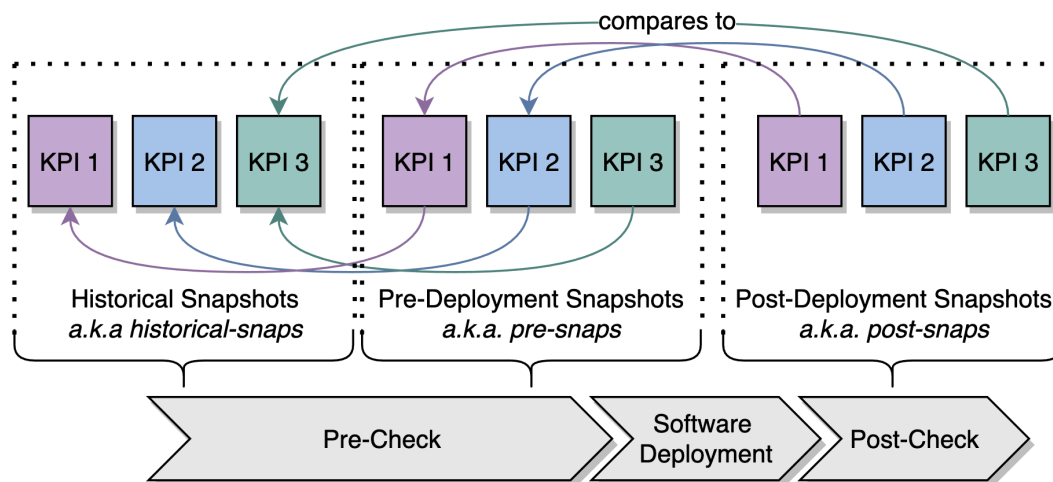

Figure 2: Conceptual relationship among pre-check, post-check, and historical/pre-deployment/post-deployment snapshots

It should be noted that the pre-check currently possesses the capability to compare pre-snaps to historical-snaps and assess network health prior to the deployment. The initial concept of the automated network health check was designed with this capability in mind so that a deployment could be automatically blocked if the network was deemed to be unfit for a software update. As the DAA initiative progressed, this feature was decommissioned, as there are other automated alert systems in place capable of blocking a deployment if the network is not considered healthy enough to undergo an update. Therefore, the main purpose of the pre-check currently is to gather the snapshots needed to perform comparisons in the post-check and to confirm that these snapshots are complete. In other words, the software deployment automation only interacts with network health assessments made in the post-check. Since the data sciences team has primarily focused on developing and optimizing the post-check functionality, this paper will focus on the assessment of KPIs in the post-check.

It should also be noted that the data sciences team’s network health check is not the only post-deployment fail-safe in place within the deployment automation. The DAA engineering team has also incorporated a series of automated checks, more so pertaining to cloud microservice health; however, there can be slight overlap when it comes to the KPIs observed among the various checks. While these microservice checks are deemed to be another essential step within the deployment automation pipeline, they will remain outside the scope of this paper.

3.1.2. Service-Affecting vs. Non-Service-Affecting Updates

All DAA software updates, regardless of the component being updated, can be placed into one of two general categories: service-affecting (SA) or non-service-affecting (NSA). The distinction between the two depends on whether a component update will take customers offline for a brief period. SA updates, which are scheduled during maintenance windows (normally between 01:00 and 04:00 headend local time), typically involve RPD reboots causing all downstream customers to experience a brief expected service interruption. NSA updates, which comprise the vast majority of all DAA software updates, occur on components that often have service-preserving backup units, and will most likely not result in interruptions. In other words, SA updates can be considered high-risk, whereas NSA updates can be considered low-risk. The same automated network health check is performed on both SA and NSA deployments; however, it is important to make this distinction between the two categories when analyzing results, as SA updates tend to trigger more alarms than NSA updates, given that it takes some time for customers to come back online and the network to return to a normal, steady state following SA updates. As SA updates are high-risk and are purposely scheduled on just a handful of PPODs at a time, an operator typically oversees SA updates and interacts with the health check response live. Figure 3 shows examples of typical CM behavior over time during an SA update—specifically the steep drop-off in total number of CMs online during the RPD reboot, followed by a gradual recovery. The expectation for NSA updates is that a service interruption like this should *not* occur.

Figure 3: Example views of CM status vs. time during SA updates at the RPD-level

3.2. Assessment of Key Performance Indicators

The automated network health check, specifically the post-check, works by making rule-based comparisons between two snapshots of the same KPI. Thresholds and comparison algorithms are specific to each KPI and will be detailed in this section. When a particular KPI is evaluated against a threshold and breaks a rule, the KPI is assigned one of two categories: *warning* or *failure*. Whether or not a broken rule indicates a warning or failure depends on the KPI as well as the algorithm being used to assess it, both of which indicate the severity of the anomaly. Warnings can indicate signs of service degradation, but typically to a lesser extent than failures. As will be discussed in the next section, KPIs with warnings are intended to be observed and studied more closely but not quite considered severe enough to automatically alert an operator. The data sciences team has worked closely with DAA subject matter

experts (SMEs) in deciding which KPIs should belong in the failure category versus the warning category.

In addition to warnings and failures, there are a several KPIs which are calculated and presented in the API response for information only, as they are not indicative of service degradation nor are they held to a certain threshold. These KPIs are placed in a category called *info* and are meant to aid in observation and analytics.

3.2.1. Deciding When to Alert

The API response compiles all individual KPI results and provides a list of all KPIs which have failed the check and all KPIs which should deliver warnings. If a single KPI evaluation fails, the result of the entire health check is considered a failure, the PPOD is flagged, and an operator is alerted to take further action. KPIs in the warning category do not automatically fail the entire health check when a rule is broken. Rather, these KPIs are manually observed by DAA operators and SMEs as possible contenders for stricter treatment, further algorithm tuning, or even live operator intervention in the case of SA updates. It is not uncommon for KPIs to start out in the warning category and later be transferred over to the failure category when SMEs confirm the relevancy of the KPI, and an optimal algorithm has been decided. Figure 4 aims to conceptually demonstrate how the overall health check decision is calculated based on KPIs in the failures category *only*, despite KPIs in the warnings category.

Alongside the overall health check decision, a summary of the KPI readings and comparisons is presented to the operator as a diagnostic aid. For PPOD-level evaluations, a summary might include, for instance, CM counts for given states pre- and post- deployment and list any CMs which have changed state following a deployment. If an RPD-level evaluation fails, typically the summary will detail KPI readings and comparisons for the problematic RPD(s).

With this information, an operator can decide on a mitigative course of action in the event that service degradation is detected. For instance, an operator might perform an RPD reboot and retry the post-check to see if detected service degradation has been fixed. If nothing can be done remotely, an operator might decide to send a technician out into the field to intervene with RPD hardware. If a root cause cannot be identified, the operator might ultimately decide it is best to roll back the software update until further troubleshooting can be performed.

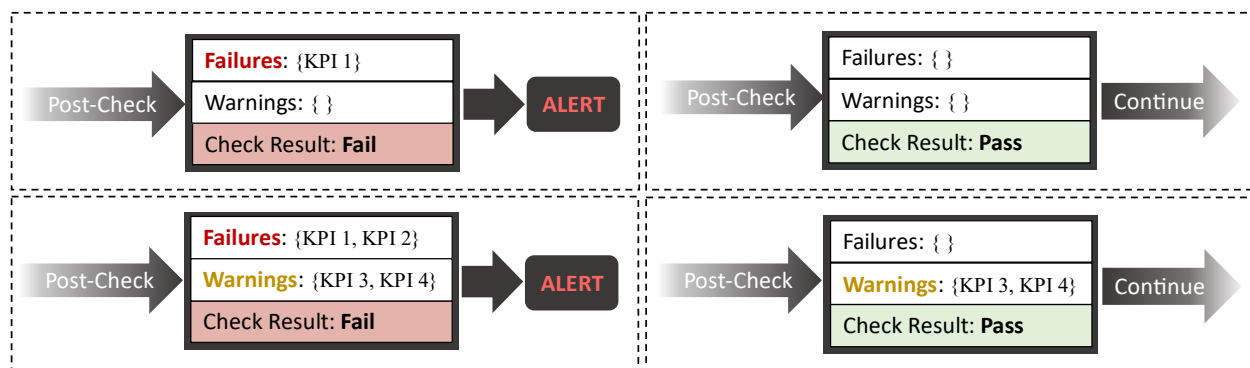

Figure 4: Some conceptual check outcomes

3.2.2. Algorithms and Thresholds

As discussed previously, most algorithms operate at either the PPOD- or RPD-level. This means that more granular CM and traffic metrics will be aggregated to provide a big picture view of the customer experience downstream of the PPOD and each RPD. This might involve, for instance, counting the CMs in a particular state downstream of an RPD, or summing all upstream traffic across all RPDs to calculate a PPOD-level traffic measure.

KPI comparison algorithms can be generally categorized as one of the following: *i.* percent recovery, *ii.* percent increase, *iii.* greater-than-zero, or *iv.* custom. Simply put, algorithms that analyze components in “good states”, such as *online*, *connected*, *synced*, etc., tend to use percent recovery calculations, while algorithms that analyze components in “bad states”, like *partial service*, tend to use percent increase calculations. Some KPIs are analyzed simply by checking if the post-deployment reading is greater-than-zero. This is typically done with continuous traffic KPIs since the algorithm is only limited to an instant sample of data post-deployment, eliminating the possibility of any trend analysis. Custom algorithms, as the name suggests, do not fall into these general categories and are evaluated using customized logic and thresholds. Table 1, Table 2, and Table 3 summarize KPI algorithms, thresholds, and alert categories at the PPOD-, RPD-, and CM-levels respectively. These KPIs are observed in accordance with DOCSIS and are detailed in the latest CableLabs DOCSIS Remote PHY specification and database of DOCSIS Management Information Bases (MIBs). It may be helpful to reference the “Abbreviations” section on page 24 to comprehend the KPIs presented.

As seen in these tables, several KPIs have two evaluation renditions. Typically, this is done when two levels of severity—one that results in a warning and one that results in a failure—are analyzed for the same KPI. Also noteworthy are the several algorithms/thresholds which have scenario-specific exceptions, as highlighted in the “Notes” section in each table. An example of this can be seen when CMs-in-partial-service is analyzed and held to a percent increase threshold ($< X\%$ increase), but the pre-snap count of partial CMs is very low (< 10). In a scenario like this, the addition of just a few more CMs in partial service post-deployment can cause an entire health check to fail, halting the deployment pipeline and alerting an operator. This scenario is likely not indicative of service degradation due to a software update given that it is not atypical to see some random partial service fluctuation. In this scenario, an exception would be programmed which would forgive a few additional CMs in partial service despite technically breaching the percent increase threshold.

Table 1: Summary of PPOD-Level KPI Algorithms and Thresholds

Level	KPI	Algorithm	Threshold	Notes	Category
PPOD	RPDs Online	percent recovery	$> X\%$ RPDs	test/pre-production RPDs omitted from calculation	failure
	CMs Online - Overall	percent recovery	$> X\%$ CMs	uses subset of CMs online in pre-snap	failure
	CMs Online - IP v4/v6	percent recovery	$> X\%$ CMs	IP version breakdown, uses subset of CMs online in pre-snap	warning
	CMs Online - BSOD	percent recovery	$> X\%$ CMs	-	failure
	CMs in Partial Service	percent increase	$< X\%$ increase in partial CMs	custom algorithm for low-CM scenarios	failure
	CPE Types Online	custom	N/A	breakdown by CPE type	info
	CPE Types in Partial Service	custom	N/A	breakdown by CPE type	info
	MD DS/US Traffic	greater-than-zero	packet rate > 0	except when packet rate is historically zero	warning
	Partial Service (Statistical Percentages)	custom	not statistically greater than history ($< 3\sigma$)	calculates historical distributions of percent-CMs-in-partial	warning
	RPDs PTP-Synced	percent recovery	$> X\%$ RPDs	-	failure
	RPD Time Offline	custom	N/A	time each RPD is down during SA event	info
	PCMM Connection 1	greater-than-zero	COPS connected/open > 0	-	failure
	PCMM Connection 2	percent recovery	$> X\%$ COPS connected/open	-	warning
	OFDMA Channels	custom	N/A	breakdown of OFDMA channels	info
	Mid-Split Enabled CMs	percent recovery	$> X\%$ mid-split enabled CMs	includes breakdown of mid-split enablement status pre- and post-deployment	warning
	Mid-Split Utilizing CMs	percent recovery	$> X\%$ mid-split utilizing CMs	includes breakdown of mid-split utilization status pre- and post-deployment	warning
	Mid-Split Enabled RPDs	custom	N/A	breakdown of mid-split enabled RPDs	info

Table 2: Summary of RPD-Level KPI Algorithms and Thresholds

Level	KPI	Algorithm	Threshold	Notes	Category
RPD	CMs Online - Overall 1	percent recovery	> X % CMs per RPD	uses subset of CMs online in pre-snap	warning
	CMs Online - Overall 2	greater-than-zero	> 0 CMs per RPD	except when RPD had zero CMs in pre-snap	failure
	CMs Online - IPv4/v6	percent recovery	> X % CMs per RPD	IP version breakdown, uses subset of CMs online in pre-snap	warning
	CMs Online - BSOD	percent recovery	> X % CMs per RPD	uses subset of CMs online in pre-snap	failure
	CMs in Partial Service	percent increase	< X % increase in partial CMs per RPD	custom algorithm for low-CM scenarios	warning
	CPE Types Online	custom	N/A	breakdown by CPE type	info
	CPE Types in Partial Service	custom	N/A	breakdown by CPE type	info
	MD DS/US Traffic	greater-than-zero	packet rate > 0 per RPD	except when packet rate is historically zero	warning
	DSG Traffic 1	greater-than-zero	packet rate > 0 per tunnel, per channel, per RPD	warns if a single tunnel has zero traffic post-deployment for a single RPD	warning
	DSG Traffic 2	greater-than-zero	packet rate > 0 per tunnel, per channel, per RPD	fails if all tunnels have zero traffic post-deployment for a single RPD	failure
	OFDMA Channels	custom	N/A	breakdown of OFDMA channels	info
	Mid-Split Enabled CMs	percent recovery	> X % mid-split enabled CMs per RPD	includes breakdown of mid-split enablement status pre- and post- deployment	warning
	Mid-Split Utilizing CMs	percent recovery	> X % mid-split utilizing CMs per RPD	includes breakdown of mid-split utilization status pre- and post- deployment	warning

Table 3: Summary of CM-Level KPI Algorithms and Thresholds

Level	KPI	Algorithm	Threshold	Notes	Category
CM	BSOD DS/US Traffic	greater-than-zero	packet rate > 0 per CM	except when CM historical traffic is also zero	warning

One noteworthy feature of our approach is the ease with which custom algorithms and more sophisticated models can be incorporated. Data required to implement a custom algorithm or model is simply gathered and processed, often in-query, to produce the desired data format as an abstract metric snapshot unit. This collection step often takes direction from a configuration file, which might specify the timeframe over which to gather data, for example. The same steps which perform comparisons and evaluate simple algorithms against thresholds can be easily abstracted out to incorporate models instead, all while delivering results and summaries in a format consistent with that of other evaluations. An example of a custom algorithm is discussed in the next section.

3.2.3. Custom Algorithm Example – Partial Service

One particular KPI worth discussing in-depth is partial service. Partial service occurs when a CM is online but unable to operate on one or more downstream (DS) or upstream (US) channels, which may or may not hinder the customer experience. A CM can go into partial service for a variety of reasons, including loss of communication on a channel, inability to acquire a channel, and/or configurational incompatibilities. Despite its negative connotation, partial service is actually a beneficial feature in that it can often allow an impaired CM to have a mostly normal transmit/receive experience on the subset of channels it has available (Volpe, 2011). Nevertheless, partial service is an indicator that a customer is either currently experiencing service degradation or at risk for service degradation in the future; therefore, partial service is an important KPI to monitor during a software update.

As indicated in the algorithm exception example discussed in Section 3.2.2, partial service can be a notoriously difficult metric to analyze pre-to-post deployment. The difficulty lies in the fact that: *i.* the analysis is limited to a brief sample of data instantly after the deployment, as long-term trend analysis is not in compliance with the two-minute check execution window *ii.* partial service can naturally fluctuate due to factors unrelated to DAA software updates, and *iii.* the expected effect of a particular software update on partial service is not always known. As demonstrated in Table 1 and Table 2, there are standard percent increase algorithms in place to analyze partial service. These algorithms vary in efficacy depending on the size of the CM population observed and tend to capture blatant partial service issues but might not adequately flag more subtle post-deployment partial service anomalies. It is not obvious how to define a more sensitive threshold using the percent increase strategy without introducing excessive false positives; therefore, a new-and-improved custom algorithm was developed. This novel partial service algorithm attempts to further capture PPOD-specific partial service anomalies using a statistical approach.

The steps to this approach can be summarized as follows: *i.* perform a historical query in the pre-check to get a sample of partial service snapshots, *ii.* form distributions of percent-CMs-in-partial specific to the PPOD over several time periods, *iii.* assume normality and calculate thresholds for each distribution by considering statistical convention “three standard deviations above the mean” (a.k.a. 3σ) to be the cutoff, *iv.* calculate instant post-deployment percent-CMs-in-partial and compare to the thresholds. Essentially, this algorithm answers the question: “Is partial service outside the normal range following a software update?”. Figure 5 aims to visually depict how these steps are used to evaluate the KPI. An instant pre-snap reference point is also included to indicate the difference pre-to-post deployment in relation to the historical distributions.

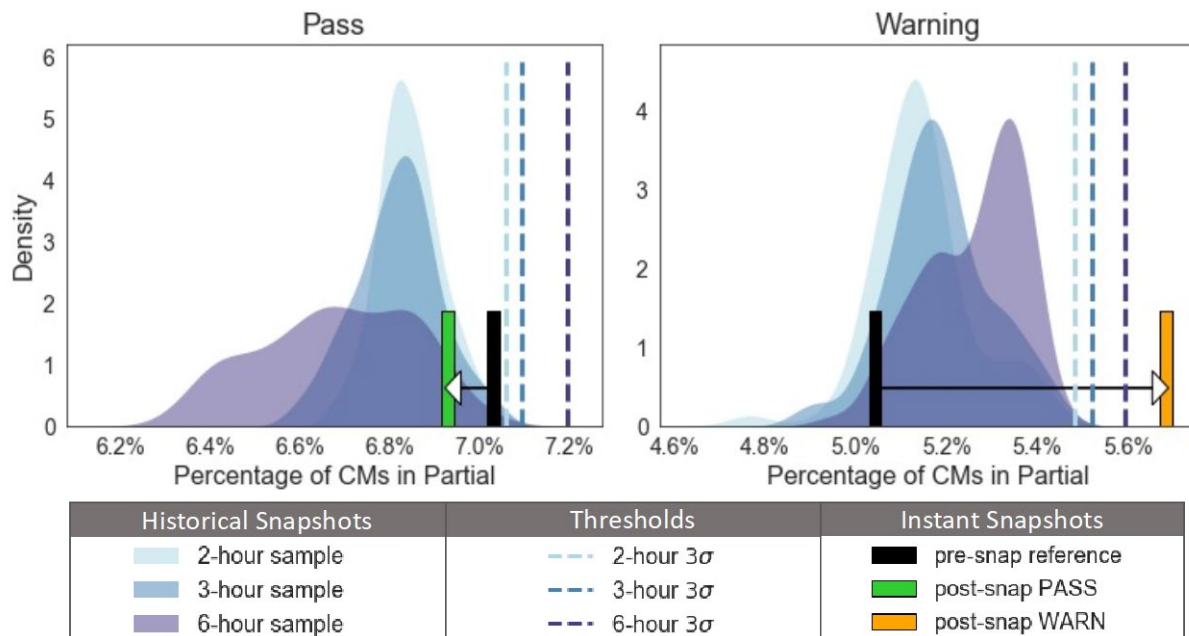

Figure 5: Visuals demonstrating statistical partial service algorithm

3.3. Integration with Software Deployment Automation

As previously mentioned, the network health check integrates with each CI/CD pipeline both prior to and after the software deployment for pre-check and post-check respectively. This setup technically requires four endpoints: *i.* initiation of pre-check, *ii.* polling of pre-check status, *iii.* initiation of post-check, and *iv.* polling of post-check status. The reason for this setup is that each check execution can take up to several minutes, which can exceed the connection time limitations of the cloud resources chosen to implement this application. Check executions are run as asynchronous background processes kicked off by the initiation steps, and the polling steps are intended to deliver a quick indication as to whether the check is complete or still running. Therefore, polling loops are needed within the automation to continue polling a check until the check is complete and delivers results.

When a pre-check is started for a PPOD, a universally unique identifier (UUID) is generated and passed back in the response of the first endpoint call. This UUID is used for reference throughout the remainder of the workflow to ensure each step accesses the correct cached snapshots and process metadata. UUIDs also serve the purpose of representing unique PPOD/software update/timestamp combinations, which is helpful in debugging and analytics.

The application is capable of post-check retries, which take new post-snaps and compare them to the same pre-/historical-snaps when the post-check initiation endpoint is called again. This feature can come in handy particularly during SA updates, when network recovery is gradual and variable from scenario-to-scenario. Typically, a retry is a manual process kicked off after an operator has waited for recovery following an SA update or intervened to correct a detected network issue. Figure 6 demonstrates how the health check features discussed above integrate to form a CI/CD workflow.

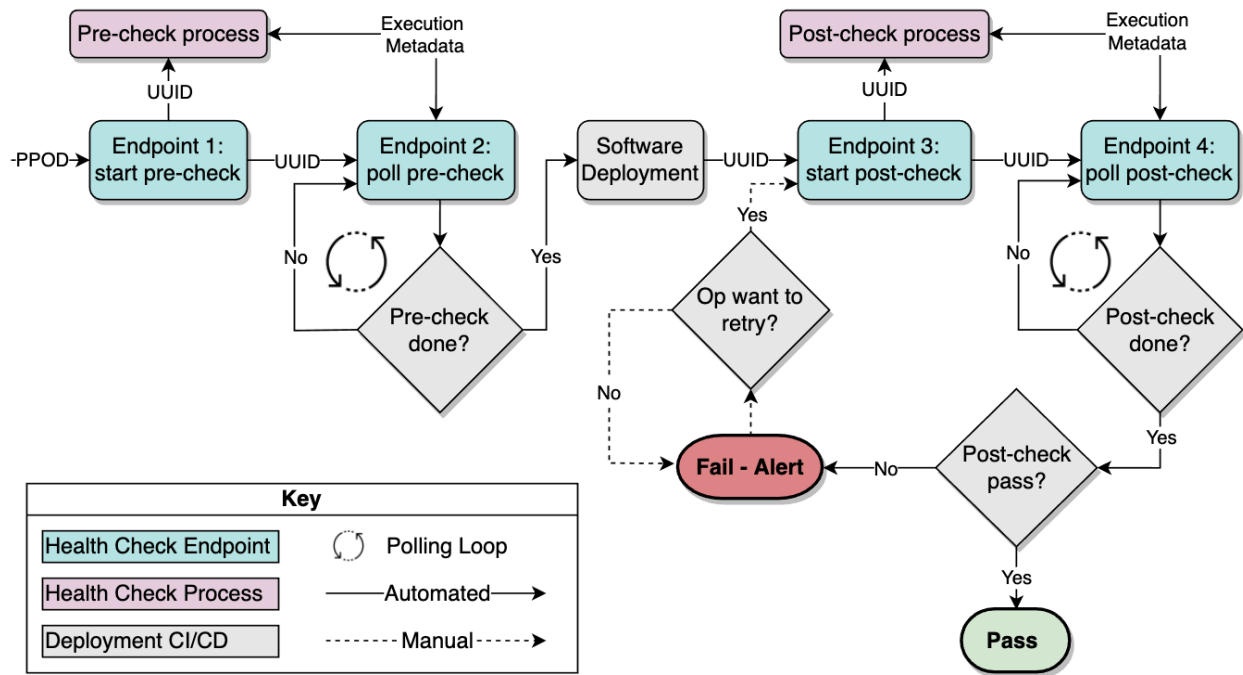

Figure 6: CI/CD integration with health check API — an example workflow

3.4. Health Check Cloud Environment

The health check operates entirely in a cloud environment. The API is hosted using a cloud API gateway service and interacts with a state machine, which orchestrates the health check workflow. A single state machine is used to manage both pre- and post-check, allowing each execution to be defined by the UUID described in the previous section. This is made possible by using callback functionality, which waits for a token to be passed back to the workflow before moving from pre-check to post-check (or from post-check n to post-check $n+1$). Check logic, which includes telemetry queries, comparisons, evaluations, etc., is carried out using serverless cloud workers. Check execution metadata, cached snapshots, and final results are all stored in a cloud database, which can be queried upon calling the API polling endpoints to retrieve the API response. The response should either indicate that a check is still running or deliver the completed check results. Unexpected errors (e.g., errors connecting to or querying from the telemetry database) would also be detailed in the response so that a retry can be performed. Verbose check data intended only for *ad hoc* analysis is also stored in the cloud database. Figure 7 presents a diagram of the health check cloud environment, demonstrating the workflow and interactions among cloud services.

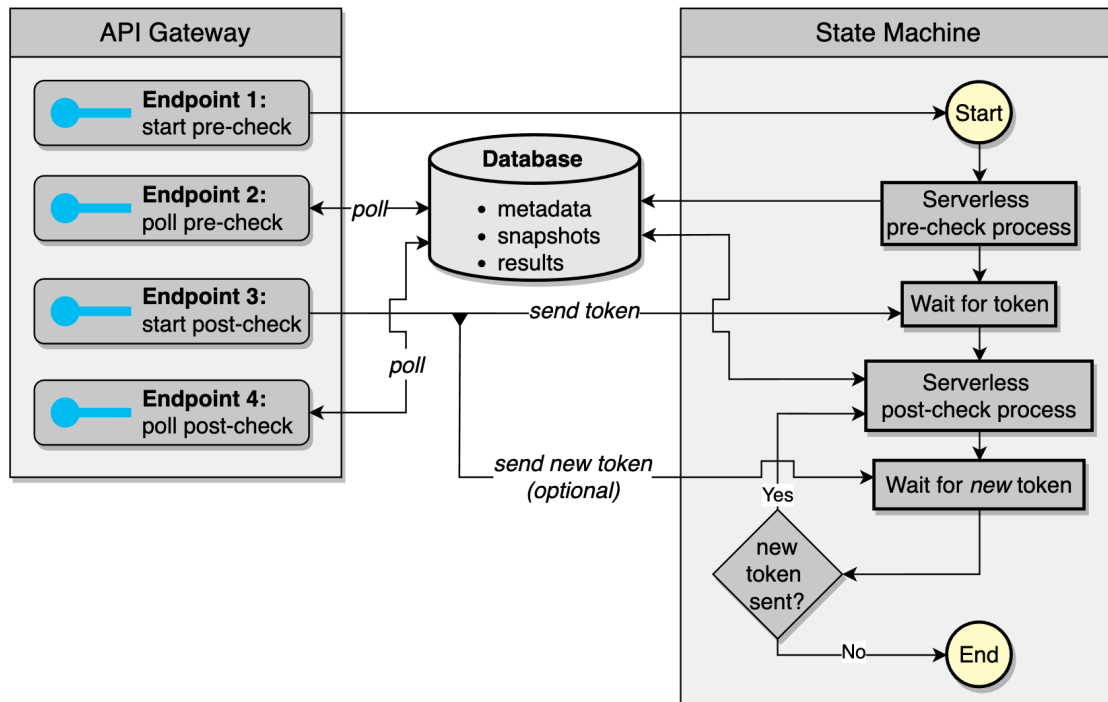

Figure 7: Diagram of cloud environment

4. Discussion

4.1. Usage Analysis

Since the very first production release in 2020, usage of the automated network health check has increased drastically and should continue to increase as Comcast scales DAA deployments. During the initial release stage, API calls were relatively sparse, as the DAA footprint at the time was much smaller, and the automation initiative was only beginning. Nowadays, it is not uncommon to see the API called hundreds, if not thousands, of times per day, depending on the components scheduled for maintenance. The health check is constantly interacting with more and more PPODs, customers, and types of software updates, as DAA continues to scale and engage in automation efforts. As demonstrated in Figure 8, this upward-trending call rate aligns proportionally to the standup of new digital clusters¹, which is a proxy to the growth rate of the DAA footprint.

While this substantial increase in call rate is undoubtedly a testament to the utility of the health check, it is also an indicator that the data sciences team must consistently perform due diligence to ensure that the check infrastructure and selected cloud resources continue to scale to meet the needs of the DAA automation initiative. For instance, cloud environment settings—namely microservice memory, provisioned concurrency settings, and programmed timeouts—are frequently tweaked to maintain reliability and performance of the health check. Additionally, telemetry queries performed in the health check are stress-tested frequently to ensure that the telemetry database can safely handle the large request loads typically seen during a burst of concurrent network health checks.

¹ The health check was released and integrated in 2020; however, health check data was not stored in an optimal format for analytics until later. Therefore, visuals will only show trends for more recent timeframes.

Figure 8: Health check usage

4.2. Analysis of Check Results

To depict failure and warning rates, Figure 9 breaks down the percentages of passes, failures, and warnings for both SA and NSA updates respectively over the past year². As expected, low-risk NSA updates appear to deliver a consistently high pass rate, with a very small percentage of calls resulting in failures. As demonstrated by this data and confirmed by DAA operators and SMEs, the health check has been optimized to a steady state and performs proper due diligence surrounding NSA software updates. The check is capable of alerting the ops team *only* when necessary, but does not over-alert with false indicators of service degradation. Achieving optimal sensitivity is especially important for NSA updates, as they comprise ~91% of all DAA software updates.

As expected, SA updates typically show a higher failure rate, given that customer recovery following an RPD reboot can be a gradual process and the automation can prematurely run the post-check before recovery is complete. Additionally, high-risk SA updates tend to need more network intervention than do low-risk NSA updates, even after a recovery period is observed. While these frequent failures might seem burdensome, they are typically no hindrance to the automation process, given that an operator oversees SA updates as part of maintenance protocol. In these failure scenarios, the main value of the network health check is in the post-check retry capability, not necessarily the alert functionality. The retry capability allows the operator to intervene and repeatedly check all 36 network KPIs with the click of a button, until customer recovery is complete and service is fully restored. As previously mentioned, the operator may also choose to act on warnings during SA updates.

The warning rate for NSA updates consistently hovers around 20%, while SA updates show a more variable warning rate. In both NSA and SA updates, a slight uptick can be seen in recent months, which is attributed to the launch of Comcast's mid-split trials and relevant KPIs recently introduced to the check for testing. These warnings are not necessarily causes for concern, but rather demonstrate the troubleshooting and finetuning process when new KPIs are added. The results of newly added KPIs are often studied on a case-by-case basis, validated against telemetry dashboards, and discussed with DAA

² Prior to August 2021, *warnings* were inconsistently defined and consisted of general comments to the end user in addition to observed KPIs. Therefore, results prior to this date will be omitted from analysis for the sake of consistency.

SMEs in terms of optimal sensitivity. Using this iterative process, we might adjust thresholds, add programmed exceptions, or even break out a single KPI into two KPIs, as seen done in Table 1 and Table 2. In Section 5.1, we will take a deeper dive into the mid-split initiative and discuss next steps for mid-split-related checks.

Figure 9: Health check results

We attempted a correlation analysis to better understand individual KPI result trends, but the findings are somewhat skewed, given that not all KPI results are independent of one another. Additionally, the large variety of component update types further confounds the analysis, but we will continue to seek out ways in which we can glean insight from the expansive data we have collected. We can, however, state that the two most common *independent* modes of check failure are PPOD-level/RPDs-online, which currently requires 100% RPD recovery following a software update, and PPOD-level/CMs-in-partial-service. These two failures have trickle-down effects on other KPIs; for instance, a missing RPD will also manifest as a DSG traffic failure and likely a CM-online failure, but the converses are not necessarily true. As warnings are constantly being tweaked and do not always have optimal thresholds, we will not discuss them in this context.

4.3. Lessons Learned

During the initial development stage of the health check, it was believed that only a few basic metrics—namely variations of RPD recovery, CM recovery, and CMs in partial service—would need to be observed. The initial design, which consisted of a handful of functions, was not well future-proofed, and quickly became unmanageable as DAA progressed and the need to observe new KPIs was realized. The team ended up refactoring the source code using an object-oriented approach to modularize the steps taken—namely metric snapshot querying, comparing snapshots, and evaluating against thresholds—so that new KPIs could easily be added without compromising the existing code. In retrospect, this strategy proved essential in optimizing the check to its current state, which evaluates more-than-triple the number of KPIs at inception. Figure 10 demonstrates the extent to which KPIs have been added over time.

Figure 10: Number of KPIs evaluated in health check over time

Another key lesson learned was “make everything configurable”. Not only are algorithm thresholds configurable, but so are historical-snapshot timeframes and applied percentiles, the ability to assign KPI evaluations to the *warning*, *failure*, or *info* categories, the ability to turn on/turn off programmed algorithm exceptions, etc. This strategy greatly aided in the maintenance of unit testing and allowed finetuning of algorithms with a simple update to a configuration file.

Last but not least, optimizing storage of check data has greatly aided in our analytics, not only for informational purposes (like this paper), but also for debugging specific scenarios and further optimization of the health check based on retrospective analyses. As previously mentioned, we store all API responses, complete with health check results and summaries, in a database, and each is tied to a specific UUID for easy traceability. A verbose version of the check results, which contains more detail than the DevOps team requires but is helpful for our internal analytics and debugging, is also stored per each UUID. Additionally, placing check results in a relational database has vastly improved the efficiency of these analytics and has also enabled network health check results to be featured in other data science applications, such as Stehman et al.’s “Sherlock” analytics tool (2021).

5. Future Work

5.1. Continued Optimization of Network Health Check: Mid-Split Updates

As alluded to previously, the data sciences team is in constant communication with DAA SMEs to discuss the addition of new KPIs and ways in which current KPI algorithms can be improved. This is expected to be an ongoing process as DAA progresses and Comcast launches other initiatives that overlap with DAA, particularly in support of 10G and full duplex (FDX) technology.

On the road to 10G and FDX, Comcast is actively working on deploying mid-splits to enable higher US and DS speeds within its digital footprint. Simply put, this is accomplished by incorporating an orthogonal frequency division multiple access (OFDMA) channel into the broadband spectrum, effectively doubling the available US spectrum (Olfert, n.d.). Enabling mid-split for customers across the DAA footprint requires a handful of configuration changes to each cluster’s custom resource document (CRD). As such, the mid-split enablement process is orchestrated with the standard PPOD software update CI/CD automation, and the network health check is run after each attempted enablement.

To monitor the effectiveness and stability of each attempted mid-split enablement during the trial period, we started by adding several *info* and *warning* KPIs at both the PPOD- and RPD-levels, as it was not immediately clear what pass/fail criteria should be or if they were even needed. These KPIs looked at things like: CMs which successfully became enabled, CMs which became enabled but went into partial

service on the OFDMA channel, CMs which started seeing OFDMA traffic flow, OFDMA channels connected per RPD, etc. As referenced, in Section 4.2, we have seen a slight uptick in overall warnings rates due to this update, as we experiment and continue to tune these KPIs.

Observations like these have prompted further analysis and troubleshooting of the mid-split enablement process and have helped the data sciences team to brainstorm a few new purposeful rule-based algorithms. For instance, one KPI we intend to monitor more strictly in the future is CMs which go into partial service on the OFDMA channel due to mid-split enablement, as this is indicative that field technicians might need to intervene with an RPD's hardware to return network performance to a stable state. As the mid-split initiative expands, we will continually aim to identify meaningful KPIs and finetune algorithms, just as we have been doing throughout the lifetime of the network health check. The hope is that we can add KPIs and algorithms that will help operators to determine intervention strategies when mid-split specific service degradation occurs. Additionally, we will continue to perform analytics on mid-split results—*failure*, *warnings*, and *info*—to look for ways in which network monitoring and diagnostic reports can be improved.

5.2. Continuous Monitoring

The network health check adds tremendous value to the DAA initiative in that it provides thorough network monitoring in the moments *right after* a software update and supports the goal of total automation by eliminating the need for manual observation during maintenance windows. This tool has been optimized to catch many signs of service degradation so that an operator can take quick mitigative action. However, some signs of software-related service degradation do not manifest until several hours, or even days after the deployment. Similarly, some impairments are not easily detected with a quick telemetry sample and require long-term trend analysis to detect. Given that the network health check is only intended to take a quick on-demand snapshot of the network health, it is not a good tool for continuous monitoring. Therefore, there is a need to develop a new tool, which will expand on the network health check approach and add the capability for long-term network health monitoring of each PPOD following a software update. This tool will differ from other production network monitoring tools in that it will try to pinpoint signs of service degradation specifically caused by or correlated with software updates, as opposed to all signs of service degradation in general. This distinction is key in delivering an optimized diagnostic tool designed specifically for DAA operations.

5.2.1. Implementation

With continuous monitoring, post-deployment anomalies will be detected using rule-based and machine learning (ML) algorithms, as well as time series analysis techniques, pushing the network monitoring initiative to the next level with artificial intelligence (AI). The proposed workflow for continuous monitoring is illustrated in Figure 11, which depicts an anomaly detection algorithm consistently observing the network for a set period after deployment. In a similar manner to the live health check, the DAA DevOps team will receive alerts when service degradation is detected or concerning anomalies are noticed. However, the workflow will differ slightly in that the continuous monitoring tool will run as a cron job and periodically push alerts to a publish/subscription (pub/sub) service available to the DAA ops team.

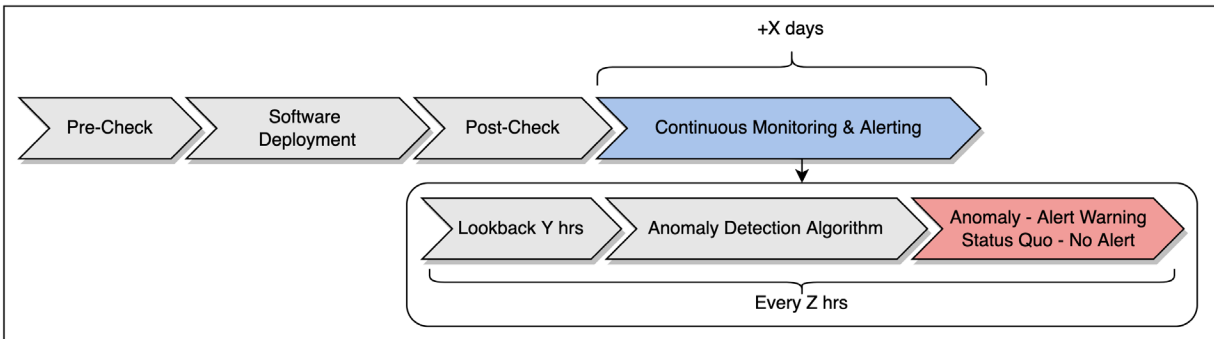

Figure 11: Continuous monitoring workflow

Continuous monitoring is considered an extension of the network health check but will be an independent product due to the magnitude and nature of monitoring metrics, algorithms, and alerts. Metrics in development for continuous monitoring include CM online status, partial service, MD traffic, customer contact metrics, and more. Figure 12 displays a recently noticed anomaly overlayed by a deep learning model in development to detect it. This particular anomaly is characterized by a select subset of CPE device types experiencing random brief service interruptions as a result of an erroneous configuration setting pushed through the deployment automation. This is an example of a scenario that went undetected with the instant telemetry analyses provided by the live network health check. An anomaly like this requires pattern analysis over time, making it an exemplary candidate for continuous monitoring.

Figure 12: Proof-of-concept anomaly and model in development

5.2.2. Expectations

The data sciences team is currently testing the waters with some proof-of-concept models intended to capture anomalies following deployments in the long run. As these models improve and software-related anomalies are better understood, the hope is that continuous monitoring can play an even bigger role in the automation initiative—possibly even rolling back software automatically if it can be determined with near certainty that an erroneous deployment resulted in service degradation. With this initiative, we also hope to perform analytics at an even higher-level aggregation by examining groups of PPODs over the same timeframe following a common software update. Although we had mentioned that this would not be

a good approach for the live network health check, we hope that advanced time series techniques and possibly unsupervised methods, in conjunction with the expansive amount of data available, might be able to help identify problematic PPOD configurations, or even more specifically, erratic configuration/software interactions. In summary, the expectation for continuous monitoring is twofold: *i.* continue to bolster DAA automation by detecting and alerting on known anomalies and *ii.* use advanced analytics to increase our understanding of anomalous network patterns resulting from rapid scaling and constant enhancements occurring as part of the DAA initiative.

6. Conclusion

In response to the DAA engineering team's call to automate, the data sciences team has developed a live network health check meant to replace eyes-on-glass network health monitoring surrounding software updates. This was made possible thanks to the near real-time network telemetry streaming across the DAA footprint, allowing for quick and nimble analysis of network health KPIs. With the guidance of DAA SMEs and consistent feedback from the DevOps team, the data sciences team has been able to finetune and optimize the health check algorithms to achieve the dependable, steady decision engine currently in production today. While there have been a handful of key operational improvements that have supported the expansion of DAA, automated network health monitoring has been particularly impactful given the strict need to preserve the customer experience while performing updates and maintenance. With improvements like this health check, the footprint has been able to expand considerably, as made evident by the substantial increase in vCMTS clusters launched since the health check was first integrated. Despite the rapid growth of the DAA footprint, operational manpower needed to sustain the DAA initiative has mostly remained steady or even reduced in some scenarios, demonstrating the utility of the automated network health check.

While the health check is a valuable tool meant for use during brief maintenance windows, it is limited in that it cannot perform continuous monitoring over a more expansive timeframe following a software update. This is the next key need that the data sciences team will aim to tackle in support of DAA expansion and automation. With the continuous monitoring initiative, we intend to go beyond the scope of quick rule-based evaluations and enter the domain of anomaly detection and ML to deliver an even more thorough, diagnostic view of network health following software updates.

Abbreviations

API	application programming interface
AI	artificial intelligence
BSOD	business services over DOCSIS
CI/CD	continuous integration/continuous deployment
CM	cable modem
COPS	common open policy service
CPE	customer premises equipment
CRD	custom resource document
DAA	Distributed Access Architecture
DOCSIS	Data Over Cable Service Interface Specification
DS	downstream
DSG	DOCSIS set-top gateway
FDX	full duplex
HFC	hybrid fiber/coax
IP	internet protocol
KPI	key performance indicator
MD	MAC domain
MIB	management information base
ML	machine learning
NSA	non-service-affecting
OFDMA	orthogonal frequency division multiple access
PCMM	PacketCable MultiMedia
PPOD	physical point of deployment
PTP	precision time protocol
RPD	remote PHY device
SA	service-affecting
SME	subject matter expert
US	upstream
UUID	universally unique identifier
vCMTS	virtual cable modem termination system

1. Introduction

A “smart amplifier” defines the information model needed to perform both remote configuration and the gathering of status information from RF amplifiers. At the time of this writing, the working group is actively completing its work based on the SCTE 1.8 GHz amplifier standard, [SCTE 279].

This proposed scope of the project is to define a standard information model using the Universal Modeling Language (UML) and then create the YANG data model for communications with broadband amplifiers used in hybrid fiber-coax (HFC) networks. The modeling can apply to all HFC networks including DOCSIS 4.0 applications and is intended to include all required monitoring and control communications with an amplifier, whether accessed over the HFC control plane or locally via direct wired or wireless connection.

The cable industry benefits from having a standardized information model that is used for amplifier configuration and status. A goal of this project is to create an information model that is applicable to both stand-alone distribution amplifiers and to launch amplifiers inside fiber nodes, leveraging existing CableLabs operations system work from the Distributed Access Architecture (DAA) project.

The smart amplifier features and capabilities can be leveraged to enable measurement and reporting of network conditions such that the system can be made more reliable. With this information cable network operations personnel can make modifications necessary to improve conditions and monitor network trends to detect when network improvements are needed.

2. Network Management Architecture

A smart amplifier extends the concept of proactive network maintenance (PNM) to the outside plant (OSP) elements including both the fiber node and amplifiers. PNM introduced data gathering and algorithms for DOCSIS components of the network that attached to the coaxial cable, these being the cable modem termination system (CMTS) and cable modem (CM).

Figure 1 show the DOCSIS CMTS and CMs sending telemetry data to a data store where algorithms can be performed on the information.

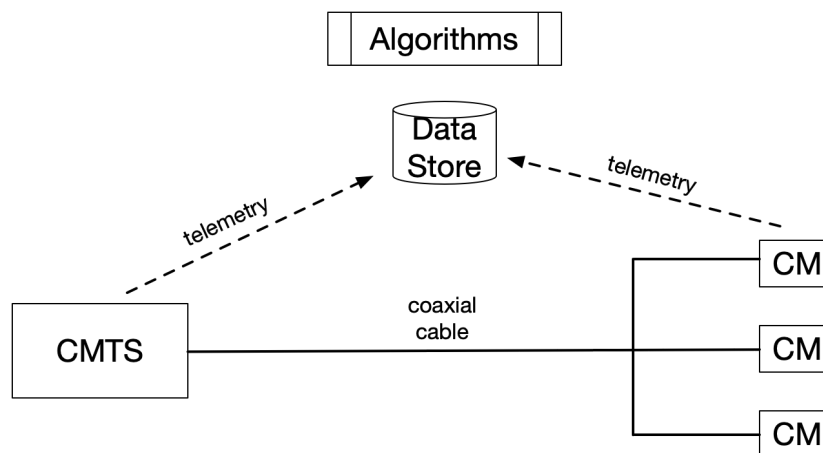

Figure 1 – DOCSIS PNM Architecture

Note that while the DOCSIS equipment directly connects to the coaxial cable network, the traditional elements making up the OSP, including the fiber node and amplifiers, are not sending information to that data store.

Figure 2 shows how the OSP, including both fiber node and amplifiers, can be included in the PNM solution.

Figure 2 – Outside Plant PNM Architecture

The CableLabs DAA project has instrumented the fiber node so that data is available for the part of the CMTS in the node, as well as the RF launch amplifier in the node. The SCTE smart amplifier project is instrumenting the coaxial cable network amplifier, including both the downstream and upstream paths.

With both DAA and smart amplifiers, the active elements of the OSP are instrumented and can provide data to the operator. With these new sources of data, new methods for managing both the OSP and the DOCSIS network can be developed. It is expected that new algorithms will use the combined data from both DOCSIS equipment and OSP equipment for proactively monitoring the cable broadband network.

A goal of the smart amplifier standard is to provide capabilities in the amplifier so monitoring can be performed remotely, for example in a network operations center (NOC), without having to dispatch a technician to the amplifier and open the lid to gather readings. The development of these use cases can be used to make future adjustments to the [SCTE 270] amplifier information model.

3. SCTE 1.8 GHz Amplifier Standard

[SCTE 279] was recently published and defines standard mechanical, environmental, and electrical characteristics for RF amplifiers that support DOCSIS 4.0 frequency division duplex (FDD) capabilities with downstream operation to frequencies up to 1794 MHz and upstream operation to frequencies up to 684 MHz.

The SCTE smart amplifier standard includes a management model for the [SCTE 279] amplifier to allow both remote configuration and status gathering from the amplifier. The same standard tools used for the fiber node information modem in the DAA project are used to develop the amplifier information model and align with the fiber node work.

[SCTE 279] rounds out a group of SCTE standards tied to DOCSIS 4.0 technology that include:

Table 1 – SCTE Standards Supporting DOCSIS 4.0 Technology

Number	Title
[SCTE 264]	Broadband Radio Frequency Hardline Taps for Cable Systems
[SCTE 265]	Broadband Radio Frequency Hardline Passives for Cable Systems
[SCTE 273]	Generic Access Platform (GAP)
[SCTE 279]	1.8 GHz Broadband Radio Frequency Hardline Amplifiers for Cable Systems

In addition to the standards listed, numerous other SCTE standards have been updated for both 1.8 GHz and 3.0 GHz operation as part of the effort for the DOCSIS 4.0 specifications.

4. Smart Amplifier Model

4.1. Introduction

[SCTE 38-10] was the first attempt to create standard instrumentation for an amplifier. The smart amplifier work both builds and extends this early work.

Figure 3 shows the smart amplifier modeled to include both a transponder and an embedded amplifier (eAMP). The eAMP includes amplifier functions defined in [SCTE 279] for both the downstream and upstream signal paths and is the focus of smart amplifier. The transponder is not defined in [SCTE 279] and the choice of transponder is left as a business choice by a cable operator. The transponder could be a DOCSIS modem or some other type of modem.

Figure 3 – Logical Model for Smart Amplifier

The choices of transponder and amplifier capabilities should be made carefully. The transponder and eAMP are separate logical entities and have separate information models. The smart amplifier work focuses on the eAMP logical entity and does not define the transponder.

To support the management model in the smart amplifier standard, it is recommended the transponder implement a high-speed IP connection that supports the types of networking used by the cable operator. Note that the DAA fiber node has direct digital fiber connection and does not use a cable modem as a transponder.

4.1.1. Embedded DOCSIS (eDOCSIS) Model

If the transponder is a DOCSIS modem, then the embedded DOCSIS (eDOCSIS) model is available to operators and suppliers. The eDOCSIS model has been updated in support of the smart amplifier and the relevant CableLabs specifications are listed in Table 2.

Table 2 – CableLabs Embedded DOCSIS Specifications

Designation	Title
CANN	CableLabs Assigned Names and Numbers specification
CANN-DHCP-Reg	CableLabs DHCP Options Registry specification
eDOCSIS	Embedded DOCSIS specification

The eDOCSIS model has successfully been used for embedding modems for digital voice, set-top boxes, and other types of equipment. Cable operators are familiar with this model and have it in use.

Figure 4 shows the transponder being an embedded cable modem which is defined in [eDOCSIS].

Figure 4 – eDOCSIS Model for Smart Amplifier

A short discussion on the DOCSIS version of the eCM transponder. As noted previously, the eCM and eAMP could have different capabilities. The amplifier defined in [SCTE 279] operates to 1794 MHz. A DOCSIS 3.0 eCM is required to operate to only 870 MHz (though many DOCSIS 3.0 modems operate to 1002 MHz) and is not required to have the PNM tools to report on OFDM and OFDMA carriers, which were introduced in the DOCSIS 3.1 specification. Even if the eCM is a DOCSIS 3.1 cable modem, it would be specified to operate to 1218 MHz and not to 1794 MHz.

[SCTE 279] discusses amplifier properties intended for a DOCSIS 4.0 network that include operation to 1794 MHz. [SCTE 279] does not discuss vector signal analyzer (VSA) functions such as OFDM symbol decoding or reporting RxMER on OFDM subcarriers, or other PNM functions that are associated with DOCSIS modems.

Hence the choice of DOCSIS transponder includes discussion on both the frequency range of that transponder as compared to the amplifier, and what if any DOCSIS PNM capabilities might be desirable in that transponder.

Additionally, while a DOCSIS CM supports various PNM capabilities, for these to come into play on each physical port of the amplifier, that CM would need to attach to those physical ports. This could entail a switch that could allow the CM to sample the RF at each port. Figure 3 does not identify a particular port the transponder is attached to and how the transponder may report is not specifically identified.

4.1.2. Other Transponders

The transponder does not have to be a DOCSIS CM; other transponders are possible. Note that the transponder should support a high-speed Internet Protocol (IP) connection.

One example is the SCTE Hybrid Management Subcommittee (HMS) working group specification of a transponder in [SCTE 25-1] and [SCTE 25-2]. The HMS transponder is in use for applications such as OSP power supplies and amplifiers.

Other types of transponders can be provided by suppliers; there are several deployed.

4.2. Embedded Amplifier (eAMP)

Looking again at Figure 3, the smart amplifier work defines an information model for the eAMP logical entity; smart amplifier does not define the transponder. There are no DOCSIS functions in the eAMP. The eAMP represents the [SCTE 279] amplifier functions including parameters such as RF test points, attenuators, and equalizers. From the standpoint of the eAMP, the transponder is simply a method to provide communications to the eAMP.

5. Semantics Around Modeling

5.1. Introduction

An information model is a way of representing and structuring information available from the device being modeled. An information model (as compared to a data model) is an abstraction and only provides a high-level view of relationships and things of interest (i.e., information). It aids in understanding the scope of functions of the device being modeled.

Data models usually specify items in more detail and include protocol specific constructs. The level of abstraction does not depend on the language being used (e.g., XML, IDL, YANG). Such languages allow modeling both at high and low (i.e., detailed) levels. The smart amplifier data model, using YANG, is planned to be available later this calendar year.

5.2. Information Model

The information model is designed using the unified modeling language (UML). A description of how to use UML can be found in [UML Guidelines].

Many network elements have an information model including CMTS, CM, Wi-Fi access points, servers, routers, and switches. This is how the network is managed, through interacting with the information models of these network elements. The DOCSIS CMTS and CM devices have had information models since the DOCSIS 1.0 specifications which have evolved as the DOCSIS specifications have evolved.

5.3. Data Model

A data model is a specific implementation of an information model using a specific set of protocols. For example, the early DOCSIS specifications had data models for the CMTS and CM devices using structure of managed information (SMI) and simple network management protocol (SNMP) which were early network management protocols, designed in the 1990s and were included in DOCSIS 1.0 technology and are still available with the DOCSIS 4.0 specifications.

SMI provides the rules for structuring the information, these structures are commonly referred to as a management information base (MIB), and these MIBs were managed using SNMP. While MIBs and SNMP were used in the past, the migration is toward YANG models and RESTCONF for the future.

YANG and RESTCONF are modern, web scale protocols which were included with DOCSIS 3.0 technology for more saleable network management. YANG is a method of representing the data model and RESTCONF is a protocol based on HTTP (hyper-text transfer protocol) that has proven to be very scalable for use in large networks and includes its own security model.

5.4. FCAPS Modelling

The FCAPS model is a widely used framework that organizes management functions into the categories of fault, configuration, accounting, performance, and security management. Telecommunications operators, including cable operators, commonly use the FCAPS model to manage large networks of devices. This specification uses these management categories to organize the requirements for the configuration and management of the smart amplifier.

- Fault management seeks to identify, isolate, correct, and record system faults.
- Configuration management modifies system configuration variables and collects configuration information.
- Accounting management collects usage statistics for subscribers, sets usage quotas, and bills users according to their use of the system.
- Performance management focuses on the collection of performance metrics, analysis of these metrics and the setting of thresholds and rate limits.
- Security management encompasses identification and authorization of users and equipment, provides audit logs and alerting functions, as well as providing vulnerability assessment.

Each of these management categories is discussed in more detail in the following sections.

5.4.1. *Fault Management*

Fault management is a proactive and on-demand network management function that allows non-standard/abnormal operation on the network to be detected, diagnosed, and corrected. A typical use case involves network elements detecting service-impacting abnormalities; when detected, an autonomous event (often referred to as an alarm notification) is sent to the NOC to alert the operator of a possible fault condition in the network affecting a customer's service. Once the operator receives the event notification, further troubleshooting and diagnostics can be performed by the operator to correct the fault condition and restore the service to proper operation.

5.4.2. *Configuration Management*

Configuration management enables system configuration building and instantiating, installation and system turn up, network and device provisioning, auto-discovery, backup and restore, software download, status, and control (e.g., checking or changing the service state of an interface).

Configuration management is primarily concerned with network control via modifying operating parameters on network elements such as the smart amplifier. Configuration parameters could include both physical resources (for example, a gain stage) and logical objects (for example, a description of the amplifier).

5.4.3. *Accounting Management*

Accounting management allows operators to measure the use of network services by subscribers for the purposes of cost estimation and subscriber billing. No Accounting management has been defined for the smart amplifier at this time.

5.4.4. *Performance Management*

Performance management is a proactive function to gather and analyze data for the purpose of monitoring and correcting the behavior and effectiveness of the network, network equipment, or other equipment and

to aid in planning, provisioning, maintenance, and the measurement of quality. A Performance management use case might include the NOC performing periodic (15 min, for example) collections of output level measurements from each port on the amplifier to perform monitoring and identification of any potential performance issues. With the historical data that has been collected, trending analysis can be performed to identify issues that may be related to certain times of day or other corollary events.

Additional performance management functions include monitoring the amplifier power supply or managing an ingress detection mechanism enabled by the amplifier.

5.4.5. Security Management

Security management provides for network and operator security, as well as providing an umbrella of security for the telecommunications management network functions. Security management functions include authentication, access control, data confidentiality, data integrity, event detection, and reporting. For example, [SCTE 279] requires the amplifier to have a USB port for configuration, and while outside the scope of this work, that USB port needs to be secured from tampering. A sensor is required to provide notification when the amplifier enclosure is opened and closed.

5.5. RESTCONF / YANG

Interfaces to the smart amplifier are defined using YANG-based data models. To manage that data model, RESTCONF is expected to be chosen as the protocol for creating, reading, updating, and deleting instances of YANG objects in the smart amplifier. The YANG models are not yet defined and will be available in the smart amplifier standard.

6. The Smart Amplifier Information Model

6.1. Background

The information model diagrams shown were still under development when this paper was written. While they are substantially complete, changes may occur as the SCTE smart amplifier standard is completed.

For the sake of brevity, not all the UML diagrams will be presented. The intent is to introduce the concepts of an information model and show the applicability to an RF amplifier. The complete UML with text descriptions will be available in the SCTE smart amplifier standard when that becomes available.

Aspects of the information model have been borrowed from the CableLabs Distributed Access Architecture (DAA) project which is defining “Smart Fiber Nodes” for the next generation HFC network. The intent is to have active elements of the OSP, including both fiber nodes and amplifiers, be managed using common systems.

6.2. Introduction

As shown in Figure 5, the smart amplifier information model is organized around three areas:

- SystemGrp, which is system group information including model number and software version
- RfGRP, which is RF Group information and settings for the RF functions on the eAMP
- NetworkingGrp, which provides networking information known to the eAMP

Figure 5 – Smart Amplifier Top-Level Information Model

Each of the three areas will be described in more detail later in this document.

6.2.1. Status and Configuration Modules

The UML diagrams are separated into status models, which provide read-only information, and configuration models which provide read-write information and support configuration of the eAMP.

Status is about reading data information from the eAMP. Status diagrams can show both capabilities of the amplifier and the actual status of components of the eAMP, for example, RF test points on a physical port, the diplex filter in use, as well as any other information described in the UML diagrams and [SCTE 279]. Another example is the amplifier power supply provides status information, to check the input voltage to the power supply, as well as get information on the power rails used inside the amplifier.

Capabilities depend on the specific amplifier and will vary from supplier to supplier. These are capabilities the amplifier can provide.

Configuration allows the amplifier to be set-up or simply adjusted from a remote operations system. This includes changing the output settings of the amplifier or configuring an upstream ingress attenuator, and any other settings specified in [SCTE 279].

Looking back at Figure 5, both the system group and RF group support both status and configuration information. The network group supports just status information as the information is configured during the eAMP DHCP process and is not directly configurable.

6.2.2. Initial Setup

[SCTE 279] requires the amplifier to use a USB port for configuration via an application provided by the supplier. Initial setup is expected to be performed by a technician at the site where the amplifier is installed. Parameters set during this initial configuration will be reflected in the data model of the eAMP that then can be remotely accessed, either to verify the configuration by reading status objects or by adjusting the configuration of the eAMP by setting configuration objects.

6.3. System Group Information

6.3.1. System Status Information

System status information is read-only, and these items are not configurable by the operator.

Figure 6 shows the system group UML diagram and under SystemGrp there are two branches. To the left are system capabilities and beneath are system status information.

Figure 6 – System Status UML Diagram

System capabilities are what is designed into the amplifier and are not changeable by the operator. This information includes the type of amplifier, which is set at manufacture and cannot be changed. [SCTE 279] lists four types of amplifiers including:

- Multiport amplifier which could be a trunk or bridger amplifier.
- Line extender amplifier which typically has one or two outputs.
- Booster amplifier which typically has one output with lower gain and power consumption.
- Compact amplifier can be mounted in a cabinet and can have one or multiple outputs.

System status information includes supplier-provided information about the amplifier including model number and serial number, as well as software and hardware versions running in that amplifier. Information on the power supply is also available, including monitoring the input voltage as well as the output voltages of the various power rails available inside the amplifier.

Unique to smart amplifier is the capability of having sensors in the amplifier that the operator can get status data from. There is a defined lid sensor, to indicate if the housing is open or closed. And there can be additional sensors that could include a temperature or moisture sensor.

6.3.2. System Configuration Information

System configuration information is read-write and can be configured either at the amplifier location or remotely, for example, from a NOC. Figure 7 shows the system configuration UML diagram.

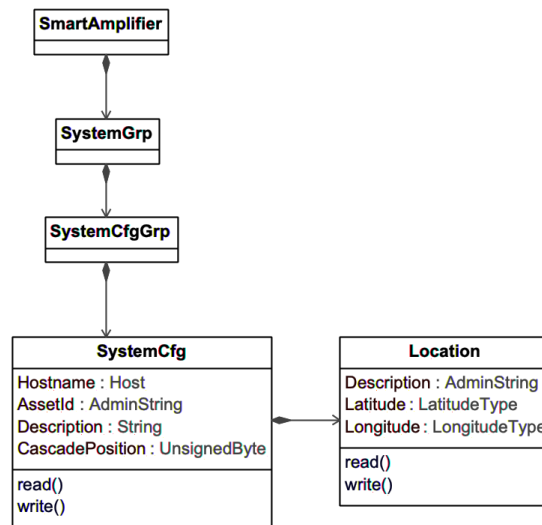

Figure 7 – System Configuration UML Diagram

Items that are writeable include identifying information that can be unique to the operator naming conventions such as hostname, asset identifier and a description of the amplifier. Additionally, the location of the amplifier and its position in the cascade can be written to that amplifier.

6.4. RF Group Information

The RF group contains the details for managing the RF capabilities of the eAMP including RF signal processing functions such as attenuators, equalizers, tilt control, and duplex filters, as well as diagnostic circuitry.

Within the RF UML diagrams, each physical port on the amplifier has logical ports including:

- Downstream logical port
- Upstream logical port
- Bi-directional logical port

This classification exists in both the RF status and configuration UML diagrams.

6.4.1. RF Status Information

Figure 8 shows the RF status UML diagram and under **RfGrp** there are two branches. The RF status information provides a view of how the amplifier is operating. To the right side are RF capabilities and beneath is RF status information.

The RF capabilities include what the amplifier is capable of in terms of downstream, upstream, and duplex filters. These are physical capabilities of the amplifier, including

- the operating frequency ranges
- available duplex filters
- upstream and downstream attenuation and equalization capabilities. Since the [SCTE 279] amplifier is electronically controlled, there are no plug-ins.
- downstream automatic gain control (AGC) capabilities
- upstream ingress attenuator capabilities, i.e., a “wink” switch

- downstream AGC settings
- upstream level control settings

The RF capabilities information is read-only because it is built into the amplifier by the supplier.

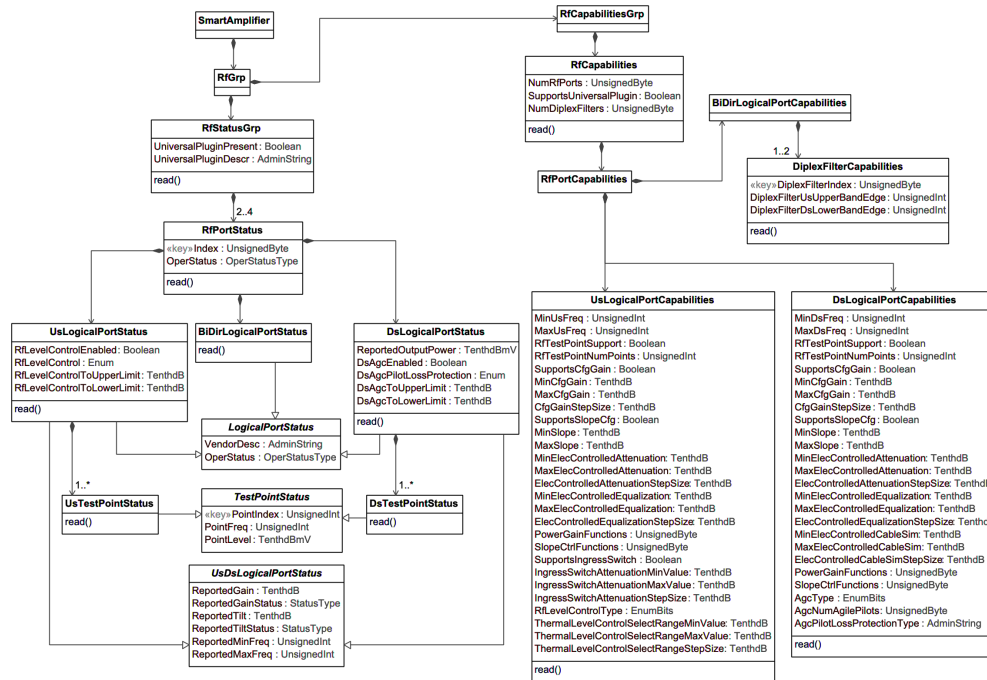

Figure 8 – RF Status UML Diagram

Under the RF status group, available information includes the amount of headroom left in the downstream automatic gain control (AGC) and upstream level control, to allow the operator to learn how the station is performing. Additionally, the upstream and downstream RF test points can be remotely read to give the operator a picture of the output on each port without having to send a tech to that location.

6.4.2. RF Configuration Information

Figure 9 shows the RF configuration information model. These items are described in [SCTE 279] and are read-write to allow remote configuration of the amplifier. For each physical port, common downstream and upstream parameters include adjusting attenuation, and equalization.

Additionally level control is available including downstream AGC including the location of the pilots, and upstream level control. There is also a setting to mute either (or both) the downstream or upstream signals associated with a physical port.

If there is a switchable duplex filter, this is where that choice of duplex filter would be made.

And finally, on the upstream an attenuator can be switched in or out of any upstream path to support locating ingress.

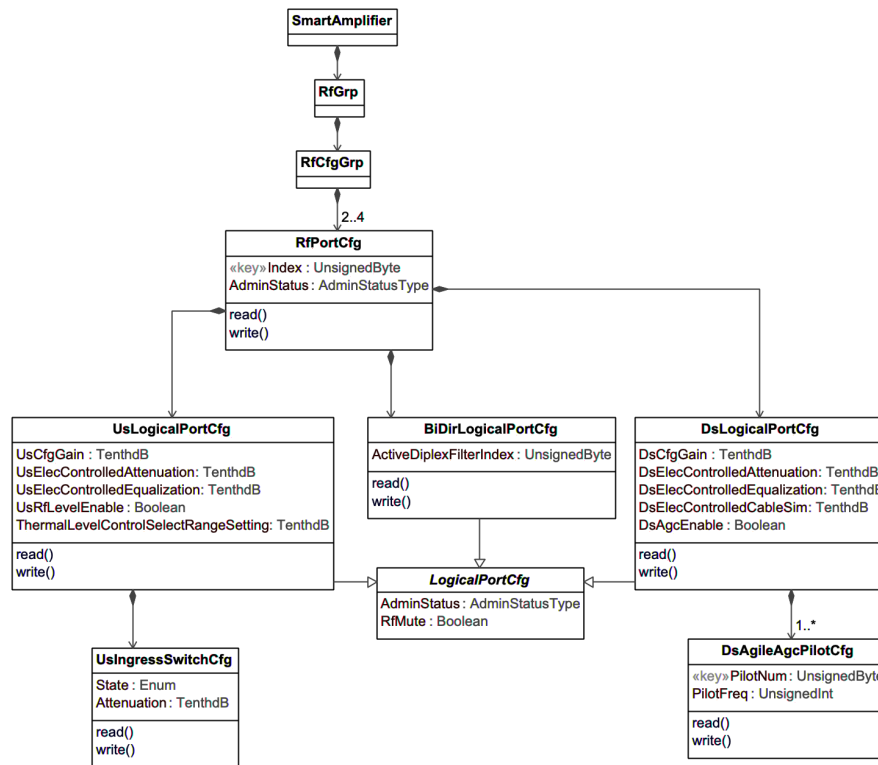

Figure 9 – RF Configuration UML Diagram

These configuration objects allow the eAMP to be adjusted to perform its functions.

6.5. Networking Group Information

Figure 10 shows the networking information model for the eAMP. These items are read-only and are intended to be set during the DHCP exchanges the eAMP has with operator-managed configuration servers.

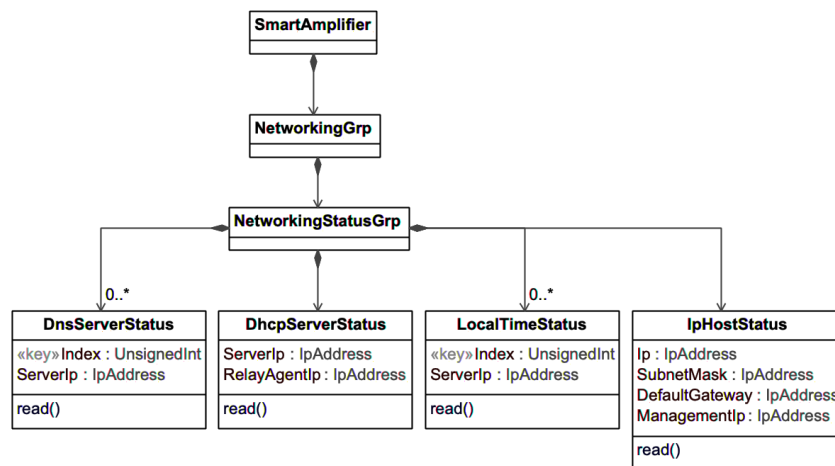

Figure 10 – Network Status UML Diagram

The network status UML diagram shows both internet information for the eAMP and servers the eAMP interacts with, including:

- the IP address of the eAMP
- the DHCP server that provided the IP address to the eAMP
- the IP address of an amplifier management server
- a DNS server that the eAMP uses to resolve IP addresses.
- a server where time is distributed

This information can be useful in debugging network connectivity issues and verifying the eAMP is using the correct servers to send and receive information.

6.6. Additional Information Model Areas

6.6.1. *Reset*

The information model includes capabilities to remotely reboot the amplifier.

6.6.2. *Events*

The information model includes capabilities for a local event log, and for the amplifier to send events to the cloud including a syslog server or using other protocols. Additionally, standard events have been defined for the amplifier.

6.6.3. *File Management*

The amplifier has the capabilities to create two types of files that could be remotely accessed by the operator.

1. A debug file in case the amplifier unexpectedly reboots or has a fault. This file would contain information to allow debugging what caused the issue.
2. A configuration file that provides supplier-specific details on the actual internals of the amplifier and how they are configured.

The information model provides a means to learn which files are on the amplifier, and fetch, rename or delete them.

7. Conclusion

The smart amplifier project provides a method to remotely gather status and configure the amplifier defined in [SCTE 279]. The model is designed to both provide standard management functions and provide room for suppliers to innovate on new products and services.

The smart amplifier work aligns with the CableLabs DAA project so that both fiber nodes and amplifiers have a common management framework. Combined with DOCSIS PNM capabilities, new methods can be developed to increase the reliability of the HFC network.

Abbreviations

AGC	automatic gain control

1. Introduction

While the Internet of Things (IoT) solves some important business concerns for consumers, it also poses significant risks because IoT devices are attractive targets for attack. IoT devices have a history of being vulnerable, they can't be intrinsically protected like less constrained devices, and because they are configured by non-professional/layman users they are ripe for exploitation. Many IoT devices, including everyday objects like kitchen appliances, thermostats, baby monitors, and light control systems, have minimal security built in as compared to full-featured smart devices and are mostly unprotected.

Because they are inexpensive and of limited purpose, IoT devices may have unpatched software flaws. They often have resource-constrained environments with limited processing, memory, and power that make them challenging to secure. Users are mostly non-technical and often lack the knowledge it takes to manage the IoT devices on their networks.

The decline in the overall security profile of homes and offices makes IoT devices a low-hanging fruit for cyberattacks. Attackers can easily get a foothold on the device, exploiting a vulnerability like a weak password or other software flaws. Once a cybercriminal gets access to one device, they can use lateral movement techniques to find other vulnerable devices in the home and conduct severe attacks like ransomware, crypto-mining, password-stuffing, and remote code execution.

There is a critical need for an effective solution that can address the consumer's security concerns and provide state-of-art, enterprise-grade security to homes and business owners. The solution should be able to proactively detect and protect against the security vulnerability which is the primary attack vector in IoT. Communications Service Providers (CSPs) are ideally positioned to play a critical role in mitigating cyberattacks on IoT devices by providing an end-to-end, integrated solution encompassing discovery, detection, monitoring, and resolution.

2. Consumers' Security Concerns

These attack trends have made users wary of the consequences of security breaches, reducing the adoption of IoT. For any transformation, it is essential to build consumer's trust and ensure security is in-built from the design stage. According to a recent survey, consumers have raised concerns (Figure 1) and have called out cyber protection as a requirement.

Figure 1 – Consumer's Security Concerns

IoT clearly presents a security challenge for both homes and small businesses. Based on data gathered from the over 41 million homes and small businesses currently connected to Plume's network, around 67% of homes have high/critical vulnerabilities to attacks on IoT devices. According to analysts, small businesses (SMBs) are the primary targets of cyberattacks and face the most damage in terms of money and customer trust. Around 66% of SMBs in US have been impacted by at least one incident between 2018-2020.

Software vulnerabilities are the primary attack vector for IoT devices and provide an easy foothold for cybercriminals. A recent BotenaGo IoT attack [21] was identified by AT&T Alien Labs in November 2021 as a new malware that exposed millions of IoT devices. The BotenaGo backdoor vulnerability exploits IoT through the open networking port or related modules. There have been countless such incidents in the past and the trend suggests an ongoing increase in these attacks.

3. Understanding IoT Security Challenges

The majority of IoT devices are not built with security-first design principles [23]. As a result, these devices have inherent software vulnerabilities. Many IoT devices cannot be patched with security fixes and, as a result, almost all devices will be at risk. Hackers are now actively targeting IoT devices such as routers and webcams because their inherent lack of security makes them vulnerable and easy to compromise.

These IoT security challenges are partly due to the technical nature of the IoT ecosystem as well as unique security requirements. The technical ecosystem must deal with scalability, distribution, heterogeneity, low energy, and the omnipresent nature of IoT devices. Authentication, confidentiality, integrity, and end-to-end security, on the other hand, are inherent security requirements. Fulfilling all security requirements is difficult given the constraints and limitations in computational and power resources within the devices.

3.1. IoT Ecosystem Challenges

3.1.1. Identity and Authentication

IoT devices need a unique identity on the network to provide mutual authentication, however, there is no consistent mechanism for this. An academic survey found that there are more than 80 different authentication mechanisms proposed or implemented [24]. There is no authentication standard at this point and when many entities (i.e., devices, humans, software, etc.) are involved, authentication becomes difficult. Authentication can also become more complex due to the scale and size of the IoT fabric.

3.1.2. Compute Power

Because IoT devices have limited computing and power capabilities, designing, and implementing encryption or authentication methods is difficult. For maximum IoT security, these cryptographic algorithms must be able to work on small devices and be compatible with the device's compute capabilities. Lightweight and pluggable solutions should be created and deployed to match the limited compute power of IoT devices.

3.1.3. IoT Device Heterogeneity

IoT devices are heterogeneous in their capabilities, communication protocols, technical interfaces, etc. This poses serious challenges when trying to provide an end-to-end security solution that requires devices to share information and collaborate.

3.1.4. User Awareness

Consumers lack awareness about the connected devices installed in their homes and businesses. Often, the devices are unpatched, have weak or default credentials, have vulnerable open ports and services, or are exposed to the internet. Most users are non-technical and lack the expertise to understand the security implication, patch vulnerabilities, or fix the security issues (Figure 2).

Figure 2 – Limited Consumer Security Awareness

3.2. Work-from-home Trends

The pandemic has transformed business functions forever and working from home (WFH) has been growing in popularity. However, WFH comes with a slew of security risks, according to the CISO magazine (Figure 3): The rise of the remote workforce has multiplied the attack surface by adding more endpoints that can be vulnerable to security breaches and device access over insecure network connections. This makes WFH users vulnerable and an easy target for attackers, making the task of security providers even more challenging.

However, rising to this challenge is critical as many users are now doing business-critical work—using sensitive customer data—on machines connected to networks with unknown security weaknesses and populated by many unvetted devices. A joint advisory issued by the US Cybersecurity and Infrastructure Security Agency and the UK's National Cyber Security Centre says the rise of WFH during the COVID-19 pandemic has seen an increase in bad actors targeting individuals and organizations [11].

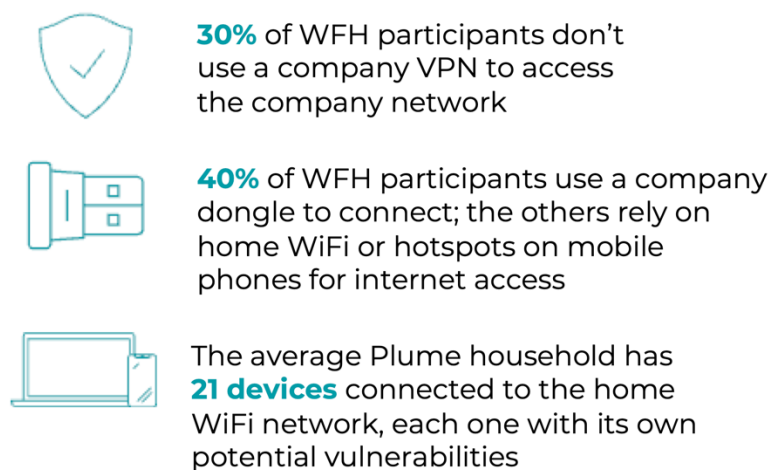

Figure 3 – Work-From-Home Security Concerns

3.3. Attacker Motivations and Challenges

Organizations fail to give enough importance to IoT security as attacker motivations and security risks are not well understood. Security is often completely ignored when, instead, efforts should be focused on critical areas. It is important to understand that the motivation for attacks depends on the attacker and the domain. Attacker types can range from novice, petty thieves, and hactivities to professional crime facilitators. A new class of malicious actors that are knowledgeable and well-funded is emerging.

The primary motives for attackers in the context of homes and small businesses include:

- Financial gain – Attacks geared towards stealing personal and financial information, followed by monetization.
- State-sponsored hacking -
- Recognition and popularity
- Revenge

The challenge lies in intelligently narrowing down the attacker type and motivation for any given home or business. A careful audit and profiling of the assets is essential to identify what would be attractive to attackers. This profiling needs to include the inventory of confidential and sensitive data and the industry that the user belongs to.

Figure 4 – Attack Motivations

4. The Evolving Landscape

The IoT landscape—including IoT adaptation, threats, and solutions—is evolving at a rapid pace. While attacks are becoming more evasive and easier to conduct, the solutions should also evolve using AI-driven, data-centric, cloud-based solutions that allow protections to be adaptive. CSPs need to keep up with the demands of the ever-changing consumer threat landscape.

4.1. Threat Landscape

Everyone with access to the internet must have cybersecurity protection. Cyber-attacks reached a peak in 2021 as data breaches grew by over 17% from 2020, according to the Identity Theft Resource Center. In fact, cybersecurity is now considered a growing human rights issue, with the UN Security Council holding its second-ever cybersecurity meeting in 2020.

Businesses and government organizations aren't the only ones who should be worried about cyber threats. Consumers are increasingly vulnerable to these attacks as they fill their homes with connected devices. Our research has found that the number of devices per Plume-powered US household increased by 38% during the pandemic, with an average of 18 devices per household. And we're not just talking about laptops and smartphones. There was a 223% increase in virtual reality devices, a 132% increase in fitness bikes and trainers, and a 110% increase in smart light bulbs.

Figure 5 – Growth in IoT Devices at Home (Source: Plume)

It was hypothesized that criminals would likely take advantage of the fear, confusion, and increased use of the internet during a pandemic. Sadly, it turns out this was true. Figure 6 below shows the increase in various types of threats before and after COVID-19, with several attack types doubling in frequency. In fact, across the period of this study, 87% of the homes connected to Plume's network experienced some type of cybersecurity attack.

Figure 6 - Cyber-attack Trends

As cyber criminals create new ways to wreak havoc on smart homes, CSPs must stay one step ahead of them. A multi-layered approach to security, with services that act across every potential threat area—from anomaly detection and device quarantining to cyber-intrusion protection—is the answer. Analysis of data taken from the Plume Cloud showed that 87% of households were attacked. 85% of those attacks were DNS-based while preventing dangerous outbound and inbound IP events accounted for 37% and 8% respectively.

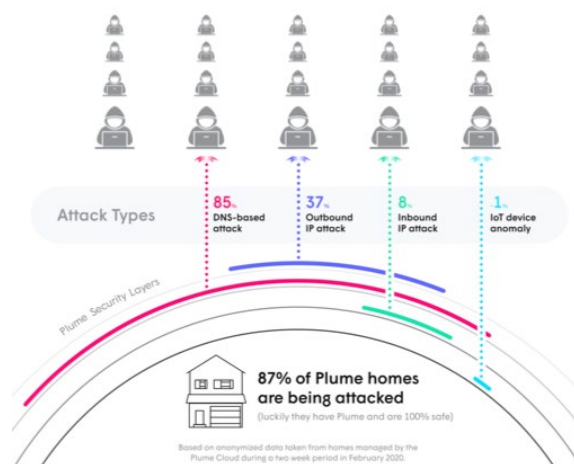

Figure 7 – Cyber-attack Types

4.2. CSP Security Services

Plume predicts that by 2024, connected devices in Plume homes will grow from the current 21 (or so) to exceed 38 devices across all categories—computers, mobile phones, tablets, set-top boxes, voice assistants, smart TVs, printers, surveillance cameras, game consoles, and more. Each of these devices opens a unique door to potential attacks. These attacks could be from websites and the servers they connect to. They could be the result of exploiting weak or reused passwords and unpatched software, and they could take the form of targeted phishing, spam, fraud attacks, and more.

CSPs are in the best position to deliver security to homes and small businesses. In addition, they can differentiate themselves by helping customers create a more secure environment—with more control over, and visibility into, their personal IT security. CSPs that adopt this role stand a good chance of achieving significant revenue gains; it's a win-win for CSPs and consumers.

CSPs can choose to build a complex and robust architecture that delivers a unified, multi-layer security service network, CPE, and endpoint that takes care of all the intricacies for the end users. This is time consuming and slows the delivery and adoption of services. Alternately the CSP can adopt a cloud-based, security-as-service model eliminating the dependencies and limitations of hardware-based solutions. The ongoing silicon shortage [22] continues to affect consumers' ability to get new hardware—be it a dishwasher, laptop, or network server. CSPs who rely too heavily on their hardware may have their hands tied by this issue. But those who offer cloud-based solutions can continue to adapt and expand.

Now that consumers are welcoming cloud-based services into their homes, CSPs should leverage this shift and set up the delivery platform to offer new value-added services quickly, using the same hardware already deployed on customer premises.

5. Vulnerabilities Life Cycle and Risks

Vulnerabilities are the primary source of attacks. A vulnerability lifecycle is divided into the following phases: Discovery, Disclosure, Patch, and Patch installed. Each of these life cycle phases has a corresponding risk exposure phase with unique characteristics and criticality. Risk exposure phases are discussed below (Figure 8).

It is challenging for a non-technical user to track vulnerabilities across the entire life cycle; however, they are constantly at risk right from the discovery until the patch installation phase.

5.1. Risk exposure phases

5.1.1. High Risk

High-risk phases live between the Discovery and Disclosure phases of the vulnerability lifecycle. In this phase, a subset of motivated attackers could be aware of this vulnerability and would already be engaged in developing an exploit. There is no public knowledge, resolution, or patch available in this phase. In this phase, behavior anomaly detection techniques are most relevant and effective to detect attacks and protect against compromises.

5.1.2. Elevated Risk

This phase exists when a vulnerability is discovered and disclosed publicly. Vendors are still working on a fix/patch and release plans while users wait. Exploits could already be publicly available for ready use by a wider community of attackers. It is very likely that the attacks are already active, making it the riskiest zone. In addition to the protection techniques of the high-risk phase, proactive vulnerability scanning, detection, and protection are the keys to safeguarding against attacks in this phase. A virtual patch to remediate the vulnerability is effective in restricting the exploits before the official patch is available.

5.1.3. Medium Risk

This is the period between patch availability and patch installation. Exposure during this period is under the direct control of users and vendors. The successful protection strategy includes publishing the vulnerability and patch availability, providing a patch installation mechanism, and ensuring that the patch is applied to the devices. Success in this phase relies on a collaborative approach between users and vendors.

A good security solution works on all the above phases and provides an end-to-end solution by breaking the cycle with complete vulnerability remediation.

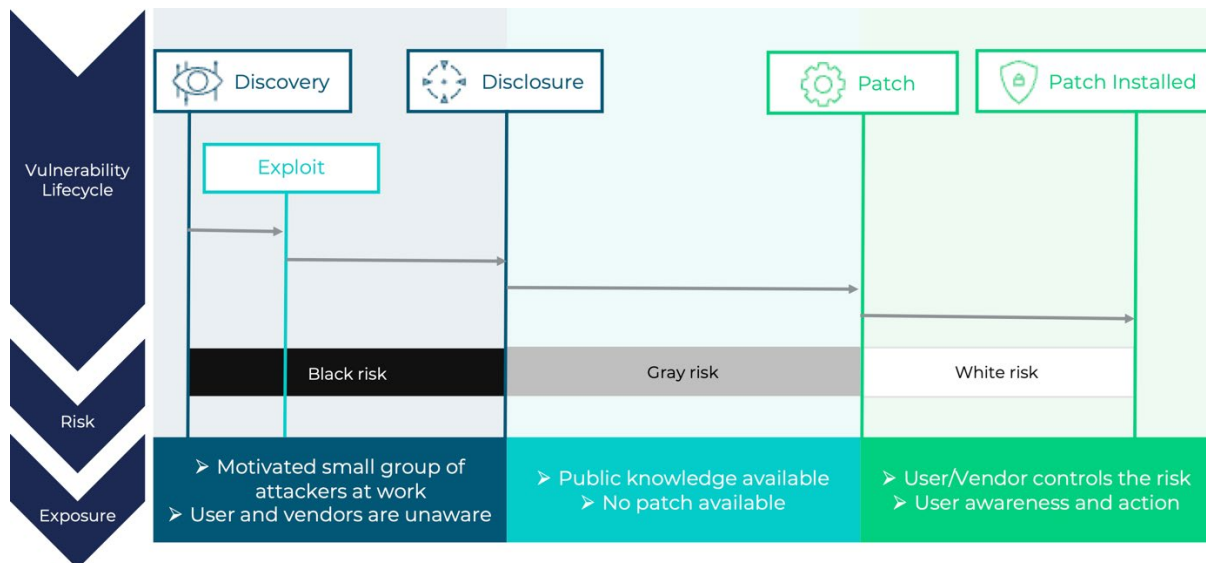

Figure 8 – Attack Lifecycle and Exposure Zones

5.2. Vulnerabilities and Open doors

5.2.1. Open ports

According to the latest stats from Shodan there are too many IoT devices operating with open ports. These open ports are like ticking time bombs, ready to be scanned by automated botnet crawlers, uncovering the known vulnerabilities, and leading to compromises and attacks.

Open and exposed ports are problematic as the services listening on the ports are often vulnerable to exploits. The open ports increase the attack surface for an attacker to exploit. As per a previous study by F5 [3] in total, 2,171,934 IoT ports were found to be exposed. Focusing on the most important 119 IoT ports, the top 10 exposed ports and their services are shown in Table 1 below. The listed 10 ports account for 84.7% of exposed ports in the Irish IP address space.

Table 1 - Top 10 Open IoT Ports

TCP Port	Service	Ports Open	% of Overall Exposed
443	HTTPS	772,258	35.6%
80	HTTP	670,789	30.9%
22	SSH	184,848	8.5%
3389	RDP	40,893	1.9%
8443	HTTPS-Alt	391,000	1.8%
8080	HTTP_Alt	30,502	1.4%
21	FTP	30,059	1.4%
8081	HTTP_Alt	27,187	1.3%
25	SMTP	23,901	1.1%
8000	Applications	21,028	1.0%

UPnP port is another critical port that is dangerous and a popular attack vector. UPnP allows zero-configuration connection implying no authentication is required to establish connections. Ports are forwarded automatically to establish a connection for a UPnP request, making it easy for attackers to establish an internet connection with the devices behind the firewall and exploit vulnerabilities. While the intended purpose of UPnP is convenience, it poses a serious threat to device security. UPnP is yet another technology that trades convenience for security. The enormity of the problem is apparent from the fact that there are 6M+ open UPnP ports worldwide. These are easily discoverable over Shodan (Figure 9). As per the July 2022 stats, most of these open ports are reported from devices in USA (12%) and China (11%) [4].

Total Results

6,201,899

Top Countries

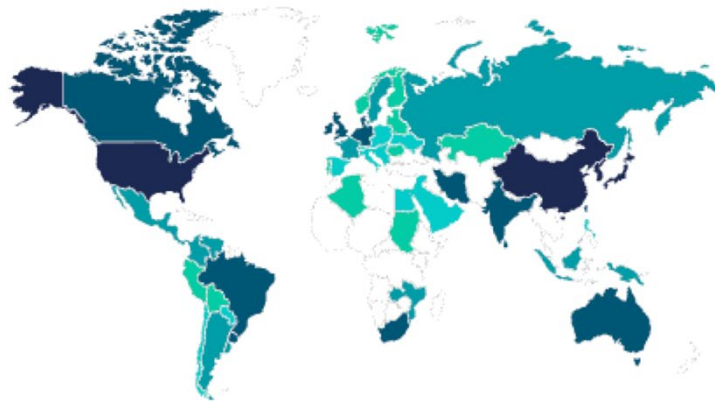

Figure 9 - Open UPnP Ports Globally (Shodan)

From the analyst reports, the top IoT device types that are exposed are routers, media devices, game console, NAS, printers, and smart TVs. The brands include some of the top names.

A recent attack (in the long list of attacks) was discovered in February 2022. Eternal Silence [1] (a UPnP based attack campaign) exposed 1.7 million devices to attacks via UPnPProxy abuse. UPnPProxy was reported back in 2018 by Akamai [2] researchers. The attackers targeted the routers vulnerable to UPnPProxy and exploited the unpatched vulnerabilities—EternalBlue (CVE-2017-0144) and EternalRed (CVE-2017-7494)—on unpatched Windows and Linux systems.

5.2.2. Vulnerability Numbers on the Rise

The number of vulnerabilities is increasing exponentially every year. In 2021, 20,169 new vulnerabilities were reported. Halfway through 2022, we already have 13,948 new vulnerabilities reported and counting.

Figure 10 – Vulnerabilities Reported Each Year

[12] Software vulnerabilities are one of the primary attack vectors in cyber incidents. Software vulnerabilities—together with phishing—make up 70% of the attacks [6] while software vulnerabilities alone contribute to 31%. Between high risk phase and the medium risk phase (Figure 8), attackers scan the network for known vulnerabilities and exploit them even before vendors can release and apply the patches. Time to patch these vulnerabilities is getting shorter and the vulnerability exploits are getting much faster, almost practically coinciding with the patch. For example, Palo Alto Networks released a Threat Prevention signature for the F5 BIG-IP Authentication Bypass Vulnerability (CVE-2022-1388), and within just 10 hours, the signature triggered 2,552 times due to vulnerability scanning and active exploitation attempts [6].

Figure 11 – Common Attack Vectors

The CISA [5] maintains a list of known exploited vulnerabilities. As per the list, 789 vulnerabilities have been recently exploited in the last year. New vulnerabilities are added to this list frequently based on the evidence of active exploitation.

Figure 12 – Most Exploited Vulnerabilities

Log4j remains the most highly exploited zero-day vulnerability in 2021-2022.

5.3. Vulnerability Prioritization

The following table shows vulnerability severity scores and their percentage distribution over the past year. It is important to note that more than 30% of the vulnerabilities reported were high- or critical-severity issues (CVSS >7). This implies that 30% have high attack and damage potential. It does not take advanced technical skills to exploit these vulnerabilities.

Table 2 – Distribution of All Vulnerabilities by CVSS Scores

CVSS Score	Number of Vulnerabilities	Percentage
0-1	1,007	0.60
1-2	1,196	0.70
2-3	8,327	4.60
3-4	9,460	5.20
4-5	42,973	23.70
5-6	34,116	18.80
6-7	27,136	15.00
7-8	36,000	19.90
8-9	895	0.50
9-10	19,978	11.00
Total	181,088	

What is CVSS?

The Common Vulnerability Scoring System (CVSS) is an open framework for communicating the characteristics and severity of software vulnerabilities. The NIST National Vulnerability Database [8] (NVD) defines the CVSS score as a mechanism for organizations to properly assess and prioritize their vulnerability management processes.

CVSS comprises three metrics: Base, Temporal and Environmental. Base metrics provide a static score ranging from 0 to 10. Temporal scores define metrics that change over time due to events external to the vulnerability. Environmental scores define metrics customized to reflect the impact of the vulnerability on your organization. The Base score can then be modified by scoring the Temporal and Environmental metrics. The NVD does not currently provide “temporal scores” or “environmental scores”. NVD does provide a CVSS calculator to allow an organization to compute the Temporal and Environmental score data.

Consumer organization and security solutions should augment the CVSS system with a risk-based vulnerability prioritization system for isolating the immediate focus areas. Exploitability is the primary factor that decides the vulnerability priority and includes an analysis of essential factors such as threat landscape, attack taxonomy, industry vertical and geolocation, etc. In addition, the

security solutions also need to leverage the data feeds from the sources like CISA [5] and prioritize remediating vulnerabilities that are actively exploited.

6. Vulnerability And Attack Taxonomy

6.1. IoT architecture

A generic IoT architecture is a hierarchical model with four layers: Application, Middle, Network, and Device [9].

6.1.1. Application

This layer implements different applications for different IoT scenarios and business verticals. As this is the front end for IoT solutions, the security issues mainly arise from authentication, illegal access, data theft, and permissions. Attackers can exploit software vulnerabilities to attack systems and disrupt functionality.

6.1.2. Middle layer

The middleware layer or the service support layer sits between the network layer and backend cloud systems. This layer obtains the data from the network layer and connects the system to the cloud and data repositories. This layer is also responsible for data processing and storage. Data repository security and cloud security are the main concerns in the middleware layer, as these can affect the quality of service in the application layer.

6.1.3. Network

This layer is responsible for the connectivity of the IoT infrastructure. It also collects data from the device layer and transmits it to the upper layer. The transmission medium can be wired or wireless, and the main technologies are ZigBee, Wi-Fi, Bluetooth, 3G, and so on. Attacks on the network layer are diverse, typically affecting the coordination of work and information-sharing among devices.

6.1.4. Device

The main challenges for this layer are the attacks on sensors and identification technology, which interfere with the collection of data from devices. An attack can send incorrect device states and other crucial statistics interrupting the entire system.

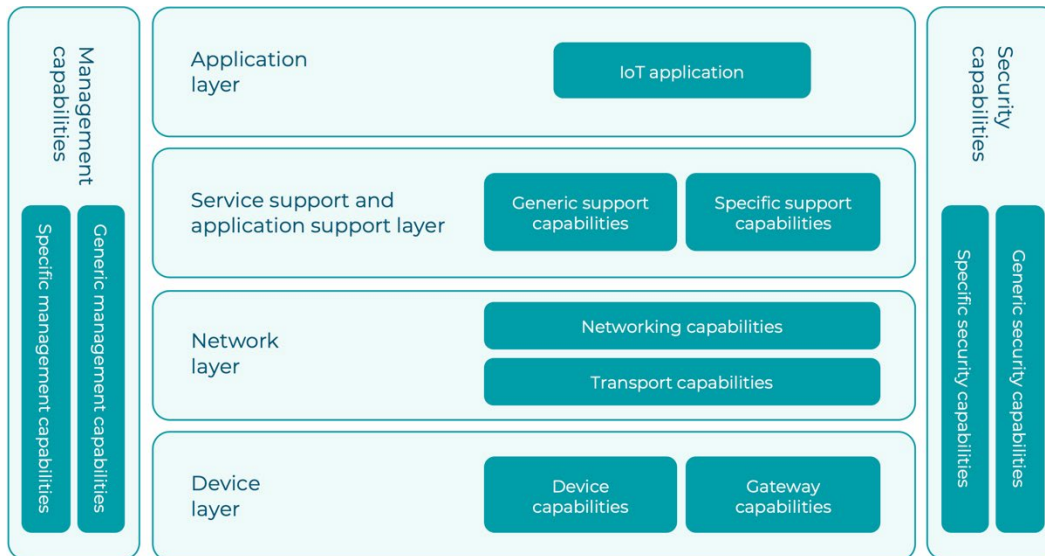

Figure 13 – IoT Reference Model

6.2. The Taxonomy of Vulnerabilities in IoT

To understand the IoT vulnerabilities and their impact, this section discusses vulnerability taxonomy. This taxonomy provides a good reference for CSPs and network defenders.

6.2.1. Weak authentication mechanisms

The interfaces in the IoT ecosystem like mobile, cloud, firmware, and web should be secured with strong authentication mechanisms. Weak, guessable, and hardcoded passwords on these interfaces give attackers unauthorized access to the IoT ecosystem. These vulnerabilities can be exploited in numerous ways and are used as one of the entry points into the network. Some common attacks that leverage authentication vulnerabilities are DDos attacks, Dictionary attacks, Sybil attacks, etc.

The Mirai attack [13], which almost brought down the internet, was carried out by compromising various IoT devices that were configured with default weak credentials (say: admin/admin).

6.2.2. Insecure network services

Unwanted and vulnerable network services exposed and listening on devices are easily compromised to gain access to the device itself, to inject malicious code, modify firmware, bypass security, move laterally to scan other devices, and infect more devices. A wide range of attacks can be launched via these open ports.

Such vulnerabilities are fatal, especially when exposed over the internet. The attackers can gain access to the devices and remote control the network.

An SSH port (22) with an old and vulnerable service version is one of the main attack vectors used in Ransomware attacks.

6.2.3. Lacking privacy and data protection

Users' personally identifiable information (PII) and other personal data are stored everywhere in the ecosystem including devices, the middle layer, and the network layer. If the data is stored, accessed, or processed without proper access control policies and encryption, it can lead to data breaches/losses with a significant damaging impact on personal lives and businesses.

Data breach incidents have been rated topmost when it comes to revenue, brand value, and customer trust loss. In addition, stolen personal information is available and sold on the dark web [17] for minimal cost.

Most IoT devices use wireless communication media, like Zigbee, LoRa, 802.11. a, SigFox, and 802.15.4. These protocols are less reliable and as a result, the devices are more susceptible to data leakage attacks.

Organizations must comply with regulatory guidelines such as CCPA and GDPR when handling personal and business sensitive data. Country-specific guidelines should be followed to safeguard the users when handling of their personal information. IoT devices require a central security policy [16] to correctly handle personal data including detecting, operating, collecting, and storing data. PKI should be used, where possible, to provide a robust encryption methodology rather than relying on hard-coded secrets to authenticate. The data-in-motion should be securely transmitted over the network ensuring that confidentiality, integrity, and availability are guaranteed.

6.2.4. Weak device hardening

The device boot process is vulnerable to attacks if the secure boot is not implemented. Malicious actors can compromise the firmware, boot loader, and boot process sequence by replacing legit executables with a malicious component. With a Secure Boot process in place, the reboot process would identify the malicious executable file and prevent it from running.

Different types of rootkits load at different phases of the boot process: Device manufacturers should follow the best practices and implement secure boot on the devices. Various types of rootkits have been discovered and discussed previously [15]

The recent UFEI rootkit, CosmicStrand [14], discovered in July 2022 is a classic example that rootkits are not rare.

The discussion above explains how IoT vulnerabilities open up a plethora of attack vectors for adversaries and the possible attacks that originate from each vulnerability. Alternatively, the figure below (Fig: 14) provides a view of the layer-based examination of the potential attacks concerning each layer of the IoT architecture.

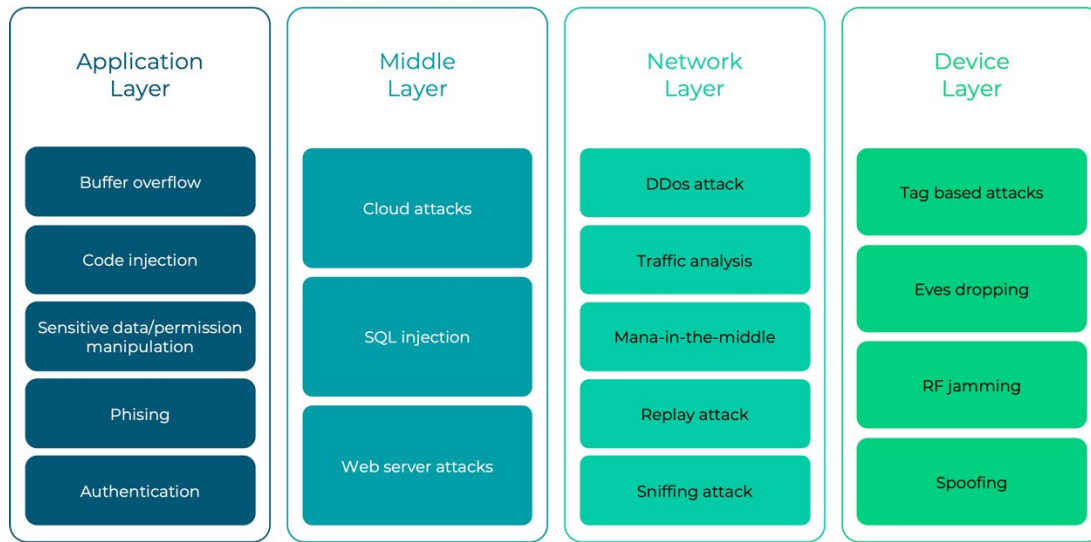

Figure 14 – IoT Reference Model Taxonomy

6.3. IoT Attack Flow

6.3.1. Use-case of Ransomware

According to leading analysts' reports, the use of ransomware is on the rise, with an average of 144% increase in demands. Attackers use multi-extortion techniques including encryption and name-shaming.

Ransomware is emerging as a productive business model enabling even a novice attacker with little to no technical knowledge to rapidly launch an attack. There are ransomware kits and services available to cybercriminals that remove technical hurdles and lower the bar for participation.

Software vulnerabilities are the primary attack vector for ransomware. In 2021, attackers exploited multiple high-profile vulnerabilities to gain a foothold in homes and small businesses. The duration between vulnerability disclosure and exploit availability has reduced considerably. If vulnerabilities are available, attackers will exploit them and launch attacks. This has made it challenging for organizations and security solutions. Security solutions need to detect and remediate vulnerabilities rapidly.

Log4J is an example of how vulnerabilities are weaponized and exploited at a rapid pace. The following vulnerabilities were exploited in a ransomware attack path [7].

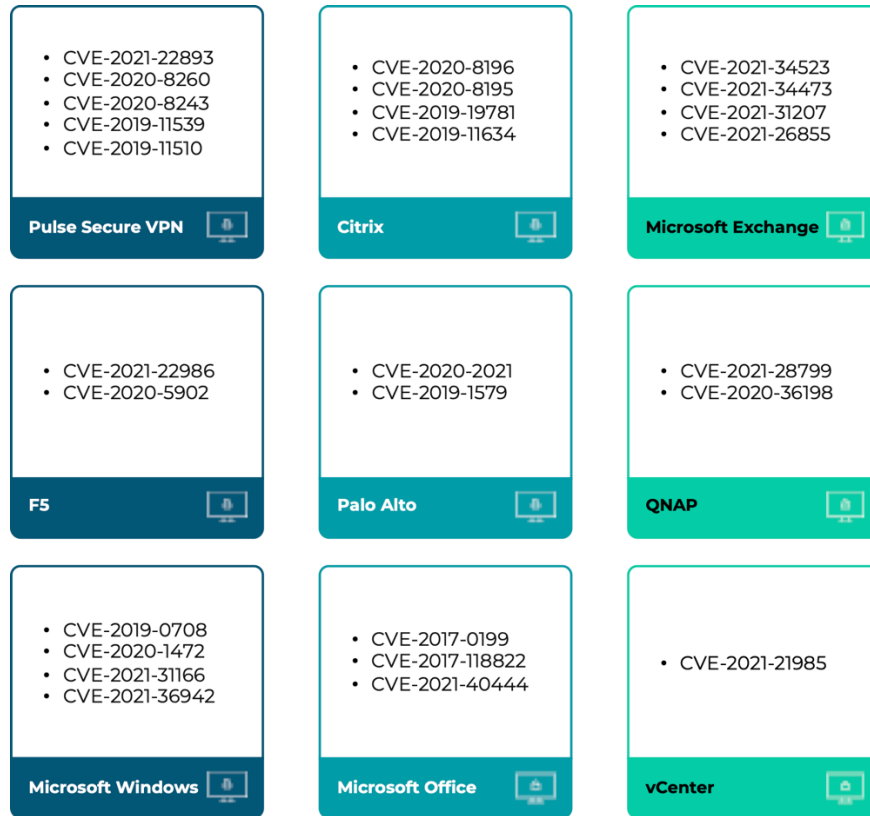

Figure 15 – Vulnerabilities exploited in Log4J

Table 3 – Vulnerabilities Exploited in Ransomware Attack Path

Vulnerability identified	CVE-2021-44228 , CVE-2021-45046 , CVE-2021-44832 , CVE-2017-5645 , CVE-2021-45105 , CVE-2019-17571
Vulnerability category	Remote code execution, denial of service

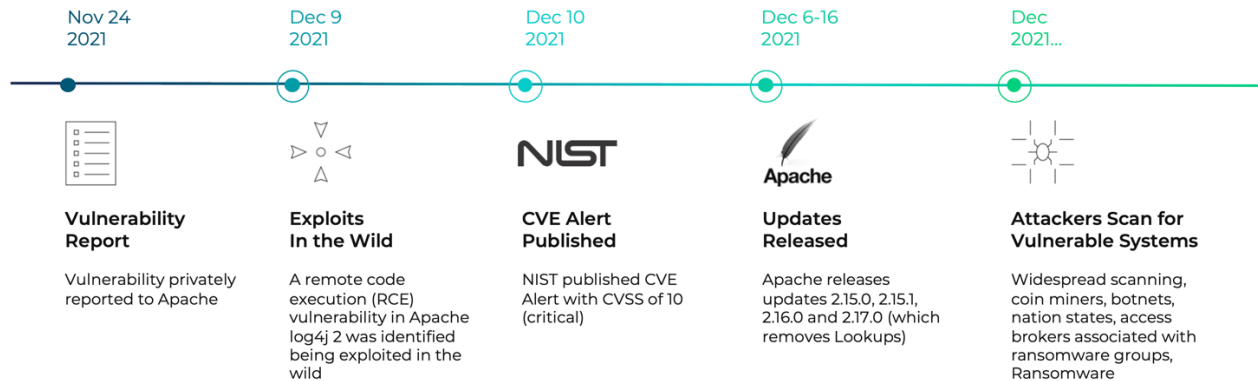

Figure 16 – Log4J Attack Timeline

6.3.2. Taxonomy of Ransomware

A ransomware attack typically follows a path with three stages. In stage one, it tries to gain access to the home or business. This is done using internet-facing devices, vulnerable devices, and devices with default credentials. In the second stage, it moves laterally, infecting other devices and scanning for business-critical, sensitive, or personal data. In the last stage, the attacker launches the attack by stealing, locking, or destroying data.

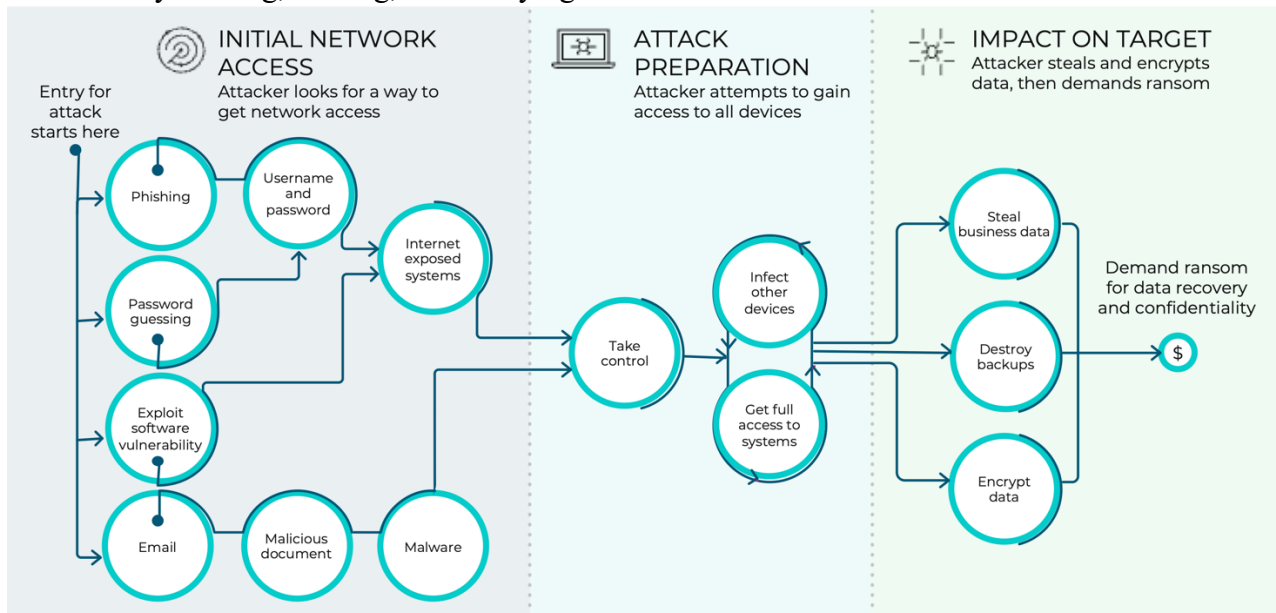

Figure 17 – Ransomware Attack Path

7. Solution

In the ITU IoT (Figure 13) reference models, different layers have different security requirements:

- Application layer – This layer needs the authorization, authentication, application data confidentiality, and integrity protection, privacy protection, security audit, and anti-virus.
- Network layer – This layer needs authorization, authentication, user data and signaling data confidentiality, and signaling integrity protection.
- Device layer – This layer need authentication, authorization, device integrity validation, access control, data confidentiality, and integrity protection.

Specific security capabilities are closely coupled with application-specific requirements, for example, mobile payment and security requirements.

When designing the security for IoT devices, Plume considers it important to take custom security procedures into account in addition to conventional security procedures. It would be best if the solution assures device security, network security, and the overall security of the IoT architecture and system.

Top analysts rate software vulnerabilities as the most popular attack vector among the cybercriminal community. The following section describes how CSPs can solve many of the problems associated with insecure IoT by providing proactive and continuous vulnerability protection.

7.1. Vulnerability Detection and Protection

Vulnerability insight is part of a multi-layered security strategy and improves the overall network defenses and zero-trust. It is a preventive strategy, and its job is to proactively inform users of known vulnerabilities in devices and help them fix the issues by taking proactive, preventative action.

The solution should protect routers and other devices in the network that are subject to attacks from open ports (capable of infiltrating network defenses) putting user data, finances, and privacy at risk.

A vulnerability management solution has three key components: Detection, protection, and reporting. The section below discusses them in detail (Figure 18). Asset discovery and inventory is a pre-requisite for this solution. Organizations can leverage their existing methods — the details of doing that are out of the scope of this paper.

Figure 18 – Vulnerability Detection and Protection Solution

7.1.1. Detection

Visibility and an accurate picture of the network is the key to helping CSPs provide an effective solution. The detection phase is critical to identifying, exposing, and prioritizing the possible threats and weaknesses in the network.

Discovery scan

Detection requires continuous scanning and monitoring of the devices inside the home and small business network. The goal of this scanning is to generate insights about the security posture of the home or business. This is achieved by detecting the device characteristics like firmware, OS, open ports, the services running on those ports, and any port forwarding (UPnP) configuration. All these characteristics should be analyzed and mapped to the known vulnerabilities on the devices. Then vulnerable devices can be automatically blocked from accessing other devices on the home and business network.

Vulnerability scan

Detect if the open ports and the services running on them are vulnerable to brute force or password stuffing attacks. To do this, CPS should be able to find out if the OS running on the devices has any known vulnerabilities. Use opensource or homegrown network scanning tools, like nmap [18] to identify the ports open on the devices on the network and the service versions running on them. Leverage the vulnerabilities databases like NIST [19] and MITRE [20] to identify any known vulnerabilities reported in the discovered services.

In addition, scan the services to detect if the service login credentials are weak or default. Any services running with weak passwords are vulnerable to brute force attacks.

7.1.2. Prevent and Protection

Protection approaches can vary based on the technical knowledge and capability of the user. They can range from a complex patch update to step-by-step guided remediation. The goals resolve the

issue with minimal user engagement. The following are the possible remediation methods that a good vulnerability protection solution should provide:

Vendor advisory or patch

Provide the link to the vendor advisory or patch where available. The user can follow the advisory and resolve the issue themselves. Example: Firmware upgrade steps, a password change, or temporarily removing a device from the network.

Credential brute force protection

Alert the user if the credentials on the devices are default, weak, and easily hackable. Alert users if the same username/passwords are used for multiple devices/services.

Best practices and guidelines

Provides device-type-specific and a well-curated list of best practices. Provide password hygiene guidelines like a reminder to enable 2FA on the devices, a reminder to change passwords periodically, and a reminder not to repeat passwords for multiple devices.

Virtual patch - continuous protection

The complete vulnerability detection and protection life cycle is very long. It includes the following vulnerability exploitation factors->patch availability-> patch application. The system is vulnerable to attacks during this phase. The virtual patch is a concept that provides vulnerability-specific rules to prevent malicious traffic from targeting the device.

- Pre-patch protection - Detect and prevent traffic exploiting the vulnerability
 - IDS/IPS rules for the vulnerabilities found on the device.
 - Alert when the rule triggers to update the user that they have been protected against the vulnerability.
- Post patch protection - be on the lookout for the vendor patch availability and update the user when the patch is available.

Enhanced security level

Create and deploy a security policy for enhanced and stricter controls for vulnerable devices and homes. Possible policies include:

- Full DPI-based malware protection.
- Block malicious IP/domains.
- Prioritize DOOR alerts for the impacted devices.

Limit device internet exposure

Alert the user if the vulnerable device is exposed on the internet. Proactively limit network access paths to the device and consider disabling UPnP on the vulnerable device.

Internal honey pot

Install a passive detection system in the network. This creates a virtual IP with the most common ports open. Any connection attempt to these services will throw an alert to flag a potential threat. Users can blacklist the connecting IP to proactively protect the network.

Chatbot

Provide a specialized and trained chatbot to guide the user through the remediation steps.

- Provide the user with the unique problem ID w.r.t. The vulnerability
 - E.g.: Say for [CVE-2020-25687](#), Id is “Vuln-2020-25687”
- Problem specific guidelines
 - The user can use the chatbot with the given ID and get step to resolve the problem.

Call support

Solution providers should provide a support center where the user can get help resolving issues. Customers can choose to call vendor support directly or the solution provider. Alternately, CSPs can partner with the vendor support and report issues on behalf of the end user.

7.1.3. Reporting

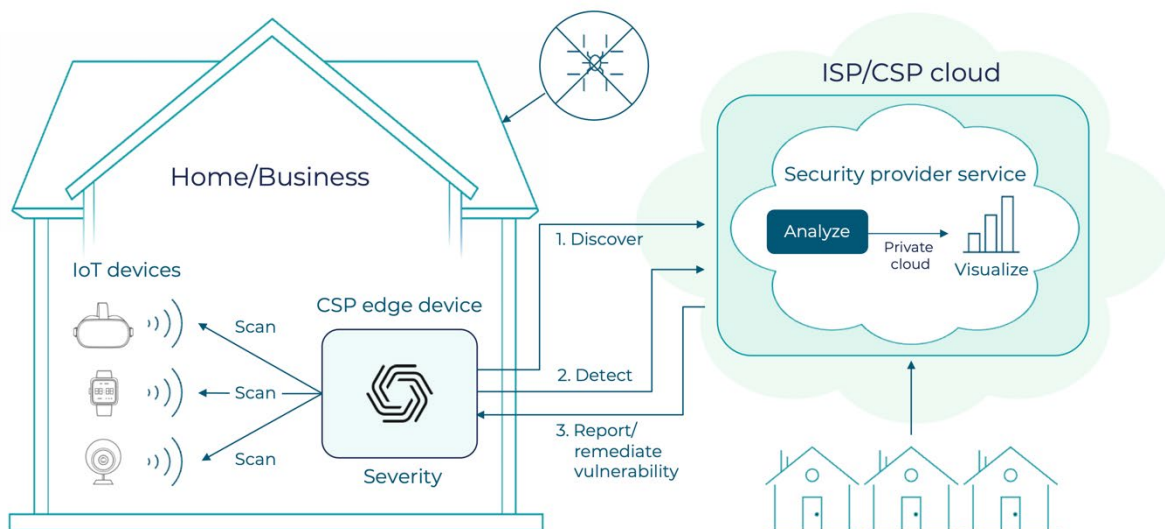

Figure 19 – Reporting as part of the vulnerability protection solution

Reporting is a critical part of the vulnerability protection solution and should focus on providing an actionable, prioritized subset of vulnerabilities to the user or administrator. An overall threat score would give a consolidated view of the security posture of the network. The security score would comprise of several factors to measure the security state i.e., number and severity of vulnerabilities, exploitability, time of exposure to a vulnerability, and more.

8. Conclusion

IoT for homes and small businesses has its merits, but also comes with significant security challenges due to rapid technology transformation and a lack of knowledge. IoT is like an open door with lucrative low-hanging fruit for attackers. Openly available attack kits are further lowering the bar for attackers. Software vulnerabilities, weak passwords, and open ports are the primary attack vectors. It is possible, however, for CSPs to provide value-added security services and safeguard consumers against cyber threats. This is a win-win scenario for both CSPs and users. We need an intelligent vulnerability detection and remediation solution that can continuously scan and flag vulnerabilities and well scan for weak passwords and provide remediation guidance to users. Considering the evasive nature of attacks and the short time spans within which they take place, we need to invest in an AI-based behavioral solution that will provide proactive alerts when a device exhibits malicious behavior and take action to protect the network.

Let's use IoT safely and improve our productivity. Let's close the door on attackers before they close your business.

9. Abbreviations

AI	artificial intelligence

1. Introduction

Technologies such as wearables, smart homes, smart cities, and smart industries are changing customer expectations for internet services. These new technologies prioritize consistency and responsiveness over sheer volume. Customers expect their smart devices to be responsive and always on. Customers want their wearables and smart home devices such as thermostats, windows, doors, smoke & fire detectors, and security systems to respond to them in near real time. Similarly, smart city and smart industries also have business requirements for low latency and internet service consistency. Customers and businesses are less tolerant of issues regarding network connectivity and latency variability as the demand for “connectedness” is ever increasing amongst internet users and machines.

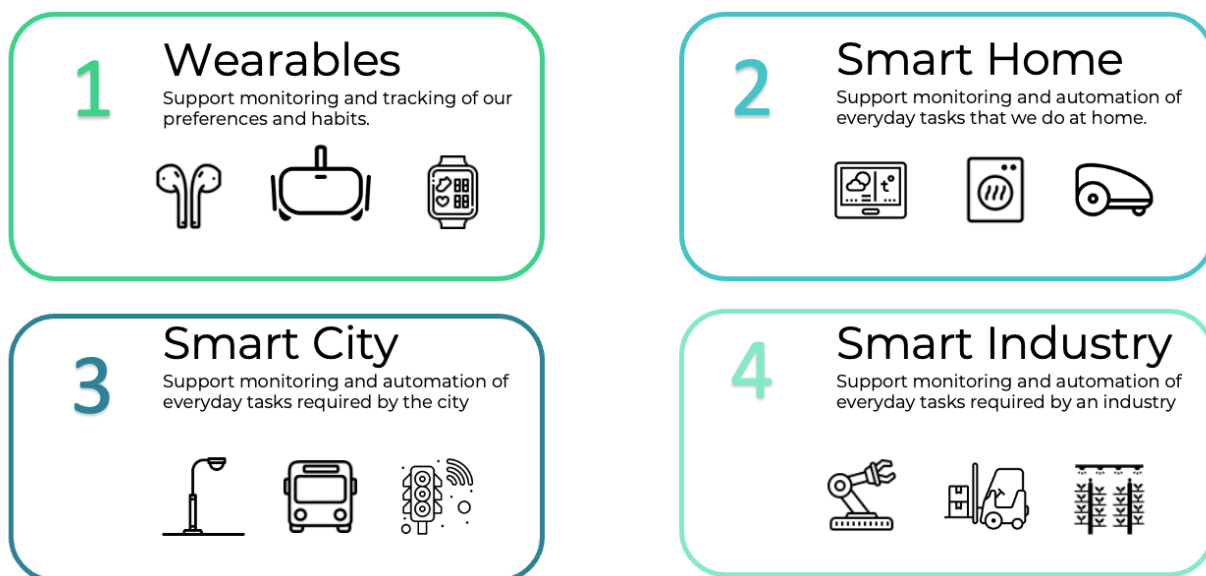

Figure 1 - Future of Connectivity

Operators are developing new methods to better understand their customers’ service experiences. Operators will need to measure variability of service in addition to threshold performance.

Traditional radio frequency (RF) diagnostic tools measure current and historical values based on manufacturer thresholds and are effective at fault detection. This means assessing if a CM has exceeded a performance threshold that may cause performance degradation. We need a different method for determining the stability of service or degree of variation in service. The lower the variability means the more reliable the service. High variability would indicate that additional measures are required to stabilize the service.

Statistical Process Control (SPC) is a cornerstone of heavily adopted process improvement methodologies such as Six Sigma. SPC can provide operators with the tools to measure and monitor service stability, which can result in improved service quality and reliability to meet the needs of advancing technologies.

2. Statistical Process Control

SPC is a statistics methodology for measuring and monitoring the variability of a desired process and can be implemented as a tool. SPC can provide us with insights about variability based on changes of averages, upper control limits, and lower control limits calculated using conventional statistics methodology. Control charts in SPC are an effective way to visually communicate variability in a concise and easily understandable graph.

In the 1920s, American physicist, engineer, and statistician Walter A. Shewhart developed the control chart used in statistical process control. The application of his detection methodology at Bell allowed engineers to observe and measure the stability of their system and thereby improve quality and reliability of Bell's transmission systems.

Today Shewhart's control charts are still in use in process improvement methodologies such as Six Sigma. In Six Sigma control charts are used to determine quality characteristics.

The primary rule or Shewhart's rule identifies assignable cause whenever a single point falls outside the three-sigma limits. Shewhart—and later Lloyd S. Nelson and Western Electric—developed additional rules that can be used to further increase detection sensitivity to variance at the cost of a higher false positive rate.

Using SPC we can improve process quality and reliability by measuring and monitoring the effectiveness of applied controls to our processes.

2.1. Control Charts

Control charts are graphs that can help us visualize the state of control for a given process. There are various types of control charts used to depict different aspects of SPC.

The center line denoted as \bar{x} is the average of individual values of the samples collected and is calculated using:

$$\bar{x} = \frac{\sum_{i=1}^n x_i}{n - 1}$$

x_i = Each of the values of the data

n = The number of data points

The upper control limit (UCL) or 3σ and the lower control limit (LCL) or -3σ are calculated using the standard deviation of a sample formula:

$$\sigma \text{ (sample rather than population)} = \sqrt{\frac{\sum_{i=1}^n (x_i - \bar{x})^2}{n - 1}}$$

n = The number of data points in sample

x_i = Each of the values of the data

\bar{x} = The mean of x_i

Common-cause variation (or noise) is the natural or expected variation in a process. Generally, noise is found between the upper and lower control limits. There are exceptions where distinct patterns within the upper and lower control limits have been identified by Shewhart, Nelson, and Western Electric as special cause variation; however, those rules will not be covered in this paper.

Special-cause variation (or signal) is the unexpected variation that results from unusual occurrences. Generally, signal is found above the UCL or below the LCL; however, there are exceptions where this would not be the case.

Figure 2 - Anatomy of a Control Chart

3. CM RF vs Service Metrics

CM RF metrics describe RF signal quality and performance. These metrics can be collected from CMs via simple network management protocol (SNMP). Regular collection of RF metric data has a negligible effect on the service performance of a cable modem. Hence, it is possible to collect this data at a higher frequency than internet service metrics which results in a higher resolution analysis of RF signal quality. It is important to understand that RF signal quality is strongly correlated with internet service quality but cannot be used directly quantify the internet service experience.

Consider the following:

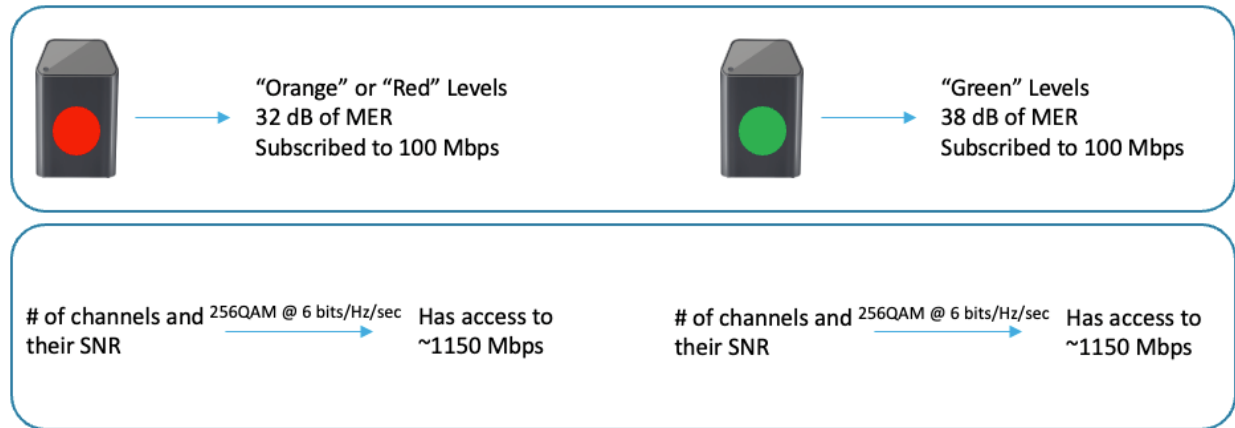

Figure 3 – CM RF Signal Quality vs Internet Speed

When CM RF metrics degrade, they do not correlate to an equivalent degradation of internet service metrics. For example, the CM RF signal to noise ratio (SNR) degrading a few dB does not equate to a consistent drop in upload or download speeds. There are thresholds, such that once exceeded, there is an observable impact to internet service metrics as seen below in Figure 4 and Figure 5.

Internet service metrics such as upload speed, download speed, latency, and jitter which are a true representation of the internet service experience is more challenging to collect. The collection of this data can be customer impacting during the collection process and thus, would be scheduled less often and during non-peak hours which may not be representative of internet service under stress.

The scatter plots below depict a correlation between SNR and uncorrectable codewords (denoted as Error %). We observe an increase in the presence of uncorrectable codewords as the SNR degrades below ~32dB for the downstream orthogonal frequency-division multiplexing (OFDM) channel in Figure 4, and below ~35dB for downstream single carrier quadrature amplitude modulation (SC-QAM) in Figure 5.

The figures below depict variability in the correlation strength of data points, which suggests that individual CMs may be impacted differently by degraded SNRs, leading to varying amounts of Error%.

SPC would allow an operator to measure each CM against itself to determine variance of a given metric. CMs that have a high degree of variability in RF or internet service metrics would require further diagnostics.

Figure 4 - CM DS OFDM Channel SNR vs Error Percentage

Figure 5 depicts more variability in correlation strength between SNR and Error %, hence the addition of a regression line (in red) to better represent this relationship.

Figure 5 - CM DS SC-QAM SNR vs Error percentage

4. CM RF Control Charts

CM RF metrics such as modem flaps, SNR, receive power level, and % of errors are captured in the control charts below. CM RF metrics are sampled at regular intervals, except for codewords, which are calculated as a percentage from a cumulative counter residing on the modem. An increase or decrease in variation in one metric does not reflect consistently in other metrics.

CM flap or CM de-registration occurs when a CM loses connection to the cable modem termination system (CMTS). This metric can also be considered an internet service metric as it is an important indicator of the customer service experience. An increase in the average count or range between the UCL and LCL of this metric would likely impact the customer experience and should be prioritized over other RF metrics.

Figure 6 - Control Chart of CM Flap

SNR, transmit, and receive power levels can fluctuate based on many external variables. The tolerance of these metrics can be vendor, model, and device specific. Variability in these metrics below or above the manufacturer specification can result in intermittent service but would be a lower priority than CM flaps and error %.

Figure 7 - Control Chart of CM DS OFDM Channel SNR

Figure 8 - Control Chart of CM DS OFDM Channel Receive Level

Uncorrectable error % is an important RF metric that can impact internet service experience. Even a small increase in this metric can be impacting to customers (between 0 and 1% of total codewords).

Figure 9 - Control Chart of CM DS OFDM Channel Error%

CM RF control charts depict variation of RF signal quality over time. The upper and lower control limits help us to quickly visualize the range of variation and if metric values can be classified as special cause. Many operators may find it difficult to determine if the overall effect of a device firmware change was positive or negative for a given device. Using this methodology, an operator can quickly visualize and quantify if a network change has improved or degraded service stability for devices in its network.

We would expect that a good change will narrow the range of variation in RF metrics meaning the UCL and LCL will be closer together and align the center line closer to the mean of the manufacturer specifications. Conversely a bad change would increase variability and move the center line closer to the threshold limits.

In either case, the control charts will continue to be effective as the UCL and LCL are calculated using the third standard deviation of the metrics. Hence, as the variation decreases then the sensitivity will increase and vice versa.

5. Internet Service Control Charts

The following control charts depict internet service stability using data from upstream speed test, downstream speed test, jitter, and latency. CM RF metrics are normally sampled at regular intervals on CMs in the field. However, at the time these control charts were created, CM RF metrics were not being collected from CM devices at regular intervals and as such we are unable to correlate insights between the CM RF and CM internet service metrics directly.

Upstream (US) and downstream (DS) speed tests have a direct relationship to the customer service experience. US and DS speed tests are affected by many external variables and tend to vary over time. A control chart is an ideal method for evaluating US and DS speed test performance over time. The control chart centerline should meet or exceed the advertised speed. The UCL and LCL should not exceed the degree of variation that the internet service provider (ISP) has specified and would allow ISP to quantify and proactively address service experience issues before a customer may notice.

Figure 10 and Figure 11 depict a control chart for a 15 Mbps US service package. The centerline for Figure 10 is at 16 Mbps while the centerline for Figure 11 is at 14 Mbps. Since Figure 11 has achieved an US speed tier (16 Mbps) higher than the advertised US speed (15 Mbps), it is possible that this CM may not have registered as a priority for service maintenance compared to other services which may have achieved a lower speed tier. However, the UCL and LCL clearly depict a different story. The service

shown in Figure 11 is clearly unstable and shows a large degree of variation which would be impacting the customer's service experience.

Figure 10 – Control Chart of CM US Speed Test of Higher Stability Service

Upper control limit was cropped from this chart as upstream speed is capped at 16mbps whereas the upper control limit was 25mbps

Figure 11 - Control Chart of CM US Speed Test of Lower Stability Service

The control charts shown below for DS speed tests tell a similar story to the US speed tests seen above. Both Figure 12 and Figure 13 show services that have met and exceed the advertised DS speed tier (150 Mbps) however, the amount variation seen in Figure 13 and the frequency of tests crossing the LCL is concerning.

Figure 12 - Control Chart of CM DS Speed Test of Higher Stability Service

Figure 13 - Control Chart of CM DS Speed Test of Lower Stability Service

Latency and jitter are increasingly important metrics for driving positive customer experiences. The control charts below clearly depict the level of variation as well as the centerline target. Figure 14 and Figure 16 are highly stable services with a satisfactory UCL and LCL whereas Figure 15 and Figure 17 are unstable and poorly performing services.

Figure 14 - Control Chart of CM DS Latency of Higher Stability Service

Figure 15 - Control Chart of CM DS Latency of Lower Stability Service

Figure 16 - Control Chart of CM DS Jitter of Higher Stability Service

Figure 17 - Control Chart of CM DS Jitter of Lower Stability Service

Control charts provide an intuitive way of measuring variance of internet service metrics. Using control charts, we can immediately observe the mean and range of the internet service metrics delivered to a customer. Improving internet service metrics average and tightening CLs will lead to improved reliability and overall customer experience by minimizing bandwidth margins. More importantly, operators that leverage SPC will be able to deliver services ready for the next generation of “always on” users and compete to win and retain customers.

6. Operationalization

The effort to operationalize these techniques at Shaw are in progress. The control charts shown in the previous sections are rendered from historical samples of Shaw production CM data and visualized using Tableau. The post processing engine is written in python and the logic can be incorporated into current RF and service metric performance indicators. Control charts can be rendered on the current data to evaluate the service stability of Shaw’s internet services using current data.

An effort is in place to develop the ability to initiate and collect CM US and DS speed test data on a regular scheduled interval so that we may directly measure customer experience using a more statistically relevant data set. Shaw also believes that increasing the data acquisition interval of CM RF data will improve the visibility of stability fluctuations in RF metrics further helping to improve CM reliability and performance.

These insights will drive new processes to improve service stability.

7. Future Work

The results from the operationalization of these techniques will be covered in a future paper. Prioritization and resolution of service issues will differ when we start to leverage SPC as seen in section 5.

8. Conclusion

Advancements in technologies like wearables, smart home, smart city, and smart industry are increasing the extent to which customers rely on connectivity for their livelihoods and well-being. It is expected that these customers will prioritize service quality and reliability over upload and download speeds, and as such, operators will be differentiated by their abilities to provide quality connectivity experiences. Detecting and controlling special-cause variances in networks and network devices are important steps in improving service stability and reliability.

Figure 18 - Speed to Service Stability Readiness

Control charts are well suited to observing and monitoring service stability, and control charts capturing internet service metrics are particularly interesting. While RF control charts can be useful in identifying problem areas for CMs, Internet service capabilities such as upload speed, download speed, latency, jitter, and bandwidth determine the competitiveness of the product offered. As seen in Section 5 of this paper, each of these internet service metrics can be captured within a control chart to be measured and validated to determine quality of service.

Operators that choose to leverage SPC will gain access to immediate eye-opening insights on how to truly measure and validate the quality of the services provided to their customers, thereby improving the overall customer experience, and preparing their networks for technologies of the future.

Abbreviations

CL	control limit
CM	cable modem
CPE	customer premises equipment
DS	downstream

1. Introduction

Over time, the rate of advancement in new technology tends to accelerate. As technology companies, we are continually faced with the challenge of not only keeping up, but also keeping ahead of the technology wave so we can use it to drive success. To do this, we need to support a continuous flow of new ideas into our companies and vet these ideas to determine relevance and assign priority. The ideas that rise to the top need to be quickly integrated without exceeding budgetary constraints, overwhelming employees, and negatively impacting customers.

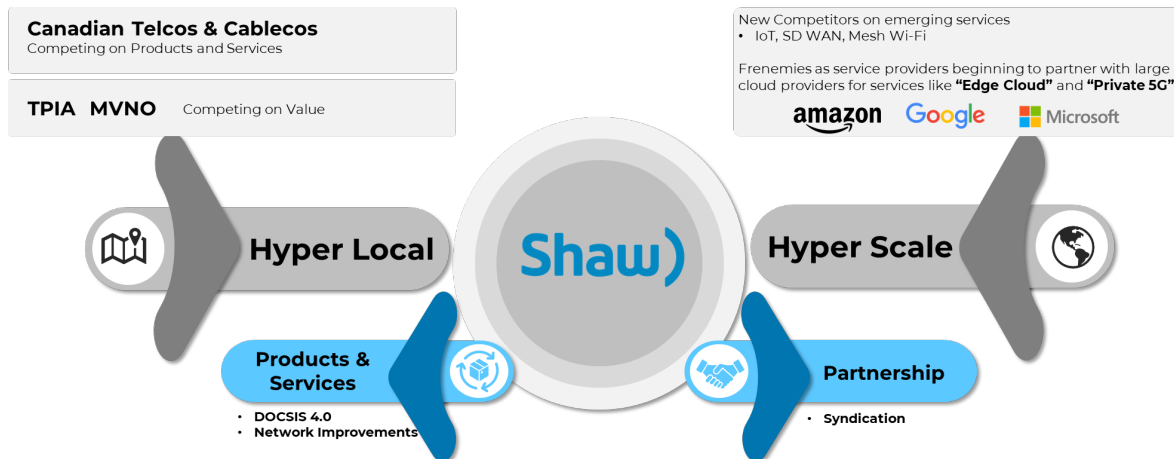

Figure 1 - Current Business Environment

Service providers face competition from two primary sources. The first source is direct competition from other service providers in the same primary business and geography. This hyperlocal competition is evident through price competition and feature competition. The price competition tends towards selling certain popular products and services and little or no profit in the hope of enticing customers to switch providers. Such offers are clearly not sustainable in the long run, so the bilateral churn leads to commoditized pricing.

The second major competition is from *Hyperscalers*. These are large multinational companies that can afford to compete on price because they are pursuing markets that are not primary sources of revenue. In addition, they often negotiate preferential pricing from vendors due to their scale. This competitive landscape severely constrains the competitive options for service provider.

The competitive landscape may require us to radically change our approach towards technology as a whole and adopt emerging technologies intelligently. If we can accomplish this, there are numerous benefits. We can anticipate rather than react to market changes. We can increase internal efficiency and improve customer products to benefit the customer experience. And as an additional bonus, we can provide employees with more interesting and valuable work, which consistently establishes a reputation for an interesting work environment and attracts new talent. Then the cycle repeats.

In this paper, we will discuss how we are trying to leverage and improve the intelligent adoption of new technology and this virtuous cycle at Shaw Communications.

2. Industry Perspective

Cable operators work in a competitive environment and must respond to global and industry-specific challenges such as supply chain issues due to COVID 19, geopolitical events, the rise and encroachment of *Hyperscalers* in the telecom domain, evolving customer demands and expectations, and cybersecurity and privacy issues. As these challenges increase, so too does the pressure to commercialize our core products and services. To meet these challenges, cable operators need to find sustainable advantages.

Our Emerging Technology Strategy is formed in combination of self-reflection (our strengths and areas of opportunities) and researching where the industry is heading (through peers, technology pioneers, and academics). As part of our research, we found multiple points of view that helped us identify our areas of focus.

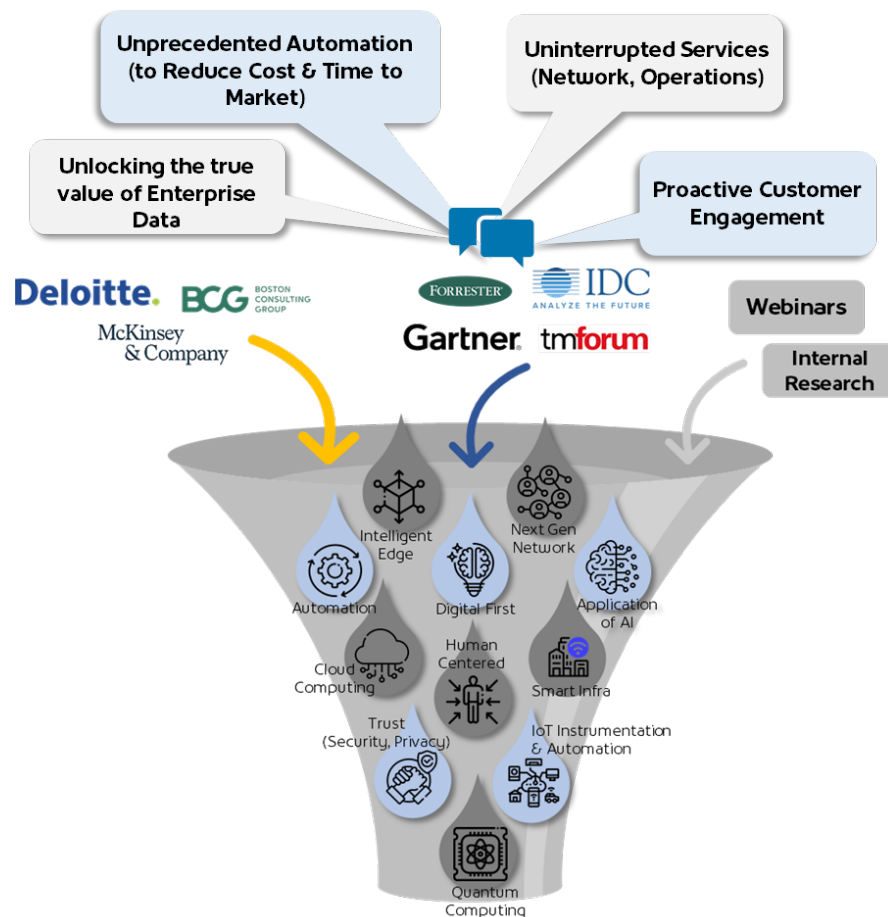

Figure 2 - Emerging Technology Research Process

Gartner's Technology trends 2021 [1] and 2022 [2] helped us narrow our research down to the following nine technology themes that operate together to build and reinforce each other.

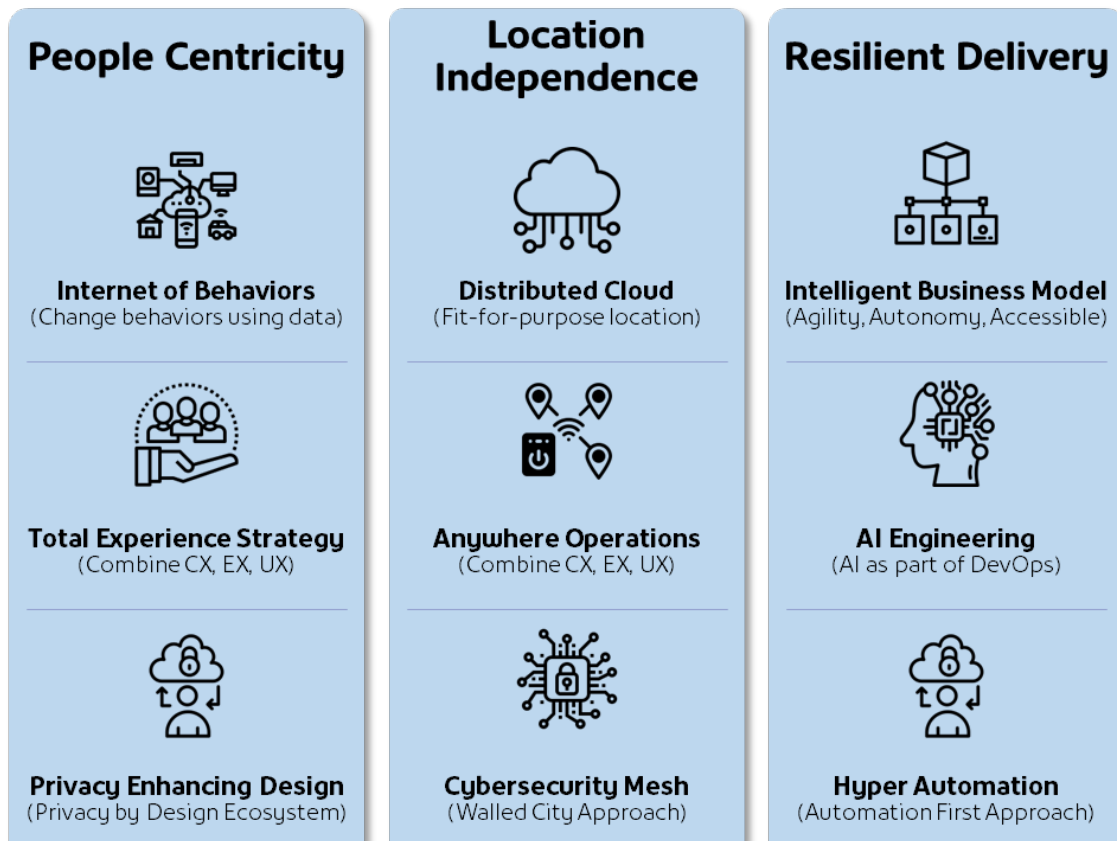

Figure 3 - Industry Perspective - Emerging Technology Themes

- **People Centricity:**
 - **Internet of Behaviors** – Internet of Behaviors is taking Internet of Things (IoT) to the next level. It refers to the ability to use the data collected to determine patterns and influence customer decisions.
 - **Total Experience Strategy** – Traditionally, experience strategies have been very siloed. The concept of *Total Experience* combines these disciplines (customer experience, employee experience, agent experience, and user experience) and links them to create a better overall experience for all parties.
 - **Privacy Enhancing Design** – Privacy Enhancing Design refers to creating an ecosystem of trust that enables organizations to safely store, share, process, and protect customer and employee data that is growing at an exponential rate.
- **Location Independence:**
 - **Distributed Cloud** – Distributed Cloud refers to providing an efficient multi-cloud environment or an “invisible cloud” environment. Essentially, users should be responsible for the maintenance, operation, and evolution of their services and not worry about physical infrastructure. The right cloud (public, private, or hybrid) backbone will

power users' needs around latency, performance, resiliency, and data sovereignty perspective.

- **Anywhere Operations** – Anywhere Operations refers to an operating model designed to support end users anywhere and everywhere and manage the deployment of business services across a robust distributed infrastructure. The model for Anywhere Operations is “digital first, remote first”.
- **Cybersecurity Mesh** – The Cybersecurity Mesh is a distributed architectural approach to scalable, flexible, and reliable cybersecurity control. It enables any person or device to securely access products and services, no matter the location, while providing an optimum level of security.
- **Resilient Delivery:**
 - **Intelligent Business Model** – Intelligent Business Model refers to agility and resiliency in the business process that can withstand disruptions. Business models and process should provide the following traits: agility, autonomy, and accessibility.
 - **AI Engineering** – AI Engineering refers to combining the best of both the worlds—human and software engineering—using a human-centered design powered by the performance and scale of software engineering. A robust AI engineering strategy will facilitate performance, scalability, interpretability, and reliability to ensure it can be used in day-to-day life and reap the full value of the investments.
 - **Hyper Automation** – Hyper-automation or an automation first approach is a practice in which organizations automate as many processes as possible using modern tools. For example, using automation to hyperscale agility and time to market.

Starting from these themes, we researched how large enterprises are responding to trends and quickly concluded that the competitive landscape requires us to radically change our approach towards technology as a whole and adopt emerging technologies intelligently into our day-to-day business operations.

3. Framework Approach at Shaw

The following sections describe a framework for innovation that leverages existing core infrastructure and builds upon that foundation.

3.1. Shaw's Emerging Technology Strategy Introduction

Shaw's Emerging Technology strategy and existing areas of focus suggest that we should leverage the core strength of our network as a foundation, while building technology services to provide a competitive advantage to differentiate us from our competition. Shaw's approach to emerging technology is based on the following building blocks:

Figure 4 - Shaw's Emerging Technology Focus Areas

- ✓ **Network Modernization** – Construction of networks that optimize speed, latency, and density.
- ✓ **Data Ecosystem** – Collection of more data from more sources more often.
- ✓ **Decision Intelligence** – Installation of tools to interpret the collected information both in real-time and offline using big data principles.
- ✓ **Autonomous Action** – Enabling the ability to act on the interpreted data for ultimate optimization.

- ✓ **Total Experience** – Creation of radically simplified and differentiated products using these tools.
- ✓ **Trust** – Achievement of the above with security and privacy as absolute requirements designed in from the start to build trust.

3.2. Network Modernization

Over the past several years, Shaw has pursued an aggressive plan to modernize our networks. Our networks are not only the basis of our business, but over time—as communication networks have increased in speed, latency, availability, and reliability—they have become essential infrastructure in the world economy. They are the basis of business for many of our customers. The COVID-19 pandemic proved this beyond any doubt as people became more reliant on networks to communicate and get business done when in-person activities were restricted.

The pressures of the pandemic have begun to ease, but many of the network activities that were initially undertaken to address pandemic related concerns continue to operate on the network now by choice. These activities were generally expected to increase operational efficiencies and reliability on the network until the pandemic drove the need for fast improvements.

The way forward involves improving all aspects of the network. This includes data throughput (how long it takes to send a certain amount of data), latency (how long it takes a specific piece of data to travel from point A to B), and density (how many streams of data can be moving on the same network at the same time).

Let us look at each of these features individually.

3.2.1. Data Throughput

Traditionally, this is the measurement that is commonly referred to as speed. If you run a speed test on your network connection, you will get a download and upload number in megabits-per-second (Mbps). This figure is an average performed over several seconds and does not provide a lot of detail about how long it took an individual message to traverse the distance. If we think of the network path as a freeway, throughput is the capacity of the freeway in general; it does not consider fast lanes or on- and off-ramps.

3.2.2. Data Latency

Data latency measures the time it takes an individual message to travel from point A to B. In many cases, this may not be critical. When loading a web page, for example, you will likely be more interested in loading the entire page rather than any particular word on the page. If, however, you are relying on the communication of a particular command to your self-driving car or the remote surgery to remove an appendix, timing is critical. Advanced networks can reduce latency and even potentially make some guarantees to meet time-critical requirements.

3.2.3. Data Density

A dense data network can run more simultaneous network paths in the same amount of space. This feature is useful in locations like stadiums, where thousands of people may be trying to access the network at the same time. Networks that allow more simultaneous networking streams will enable more users to be on the network at the same time in the same amount of space.

3.2.4. Preparing for the Future

The networking features identified above are some of the most common features in modern networks such as 5G wireless and advanced wireline networks.

Fortunately, Shaw's emphasis on modernizing our networking infrastructure sufficiently prepared us in advance of the pandemic. Maintaining and expanding our network during a pandemic was challenging, but our preparation kept the networks viable when they were under extreme pressure.

We were not alone in this, however. The networks of market competitors also performed well.

Source: Speedtest Intelligence Q1 2022 [3]

Preparing our network is essential to our success, but it is not sufficient. Networking will always be under commoditization pressure, and as service providers, it is important that we move up the stack.

3.3. Data Ecosystem

While basic networking is always improving, most emerging technologies of particular interest to cable operators sit above the basic Open Systems Interconnection (OSI) stack. The enabling networks are assumed to be available and able to meet requirements of complex applications. An increasingly common thread of these emerging technologies is a reliance on data—a lot of data.

“Big data,” as it is commonly identified, is data that is so abundant that it is difficult to comprehend without extensive processing by computers. Big data processing can identify subtle correlations and anomalies in a data set that would be nearly impossible to notice otherwise. These identifying features of large data sets can be used to extract important insights. Computers, however, are not always aware of the

relevance of data features to human priorities. Data scientists are needed to decide how to process the data and what information to look for.

Often, important insights are not clear when the data is originally collected. Therefore, it is important to store the data for long periods of time. While the cost of data storage can be expensive, it has dropped dramatically in recent years and helped to make the use of big data more practical.

Simultaneously, the advent of the IoT has led to the instrumentation of everything imaginable. Part of this instrumentation includes the collection and networked transmission of the data for immediate processing and instantaneous interpretation, as well as data storage for later analysis.

3.4. Decision Intelligence

Automatic analysis of massive amounts of data can not only bring timely insight, but in many cases, can also be interpreted with enough reliability that it can be used to make immediate decisions. Artificial intelligence (AI) can be used to make both analytical and intuitive decisions. Machine learning (ML), as a form of AI, uses massive amounts of data to draw correlations between observations and actions. This can be leveraged by training an ML algorithm with data that is clearly tied to specific outcomes. Additionally, as more data is collected, it can be incorporated into the training and used to improve accurate analysis over time.

In fact, some correlations are particularly predictive and can allow AI algorithms to notice potential problems before they become actual problems. For example, telltale vibrations coming from a piece of machinery can indicate that a part needs to be replaced soon. The part can then be replaced at a convenient time without bringing the machine down during production or risk causing further damage.

3.5. Autonomous Action

Autonomous action is the ability to act on interpretation. It refers to self-managing and self-healing systems that use the insights of and provide feedback to the decision intelligence systems, so that it can learn from its surroundings. This helps form a closed loop environment that focuses on end-to-end services and not just segments. The concept of autonomous actions offers a unique opportunity to provide highly resilient and repeatable services at scale. Allowing our people to be more successful and our customers to be more satisfied with their services and ensuring we get the most out of our resources and technology investments.

Organizations cannot scale manually at the rate that is required to meet the business needs and customer expectations. Here, relying on governed and monitored automation can help us to not only keep up with the pace of change, but also deliver cost effective, reliable, and productive solutions (e.g., automatically handle simple problems, notification and actions). Human intervention can be reserved for more complex problems.

3.6. Total Experience

In today's world, organizations do not independently decide how customer experience (CX), or employee experience (EX) works. It is best determined by the end-users. Total Experience that unifies the end-user experience could not only help control costs and provide sustainable growth, but also build long-term relationships with our customers and employees and improve brand trust.

- ✓ **Customer Experience** – Customer experience aims to provide an experience where we know our customers and are delivering a simplified, personalized, relevant experience to them through the channel of their choice.
- ✓ **Employee Experience** – Employers can use talent and culture as a competitive differentiator. We strongly believe in investing in people first, and that our talent is scarcer than other resources. Studies have shown a positive correlation between talent experience and organizational performance. That is, happy employees respond to customer needs more quickly and adapt to business changes faster.

3.7. Trust

Companies cannot expect to retain customers in the long-term without trust. Building and maintaining trust is of paramount importance to an organization as customer behaviors change and trusted products increasingly include claims like “locally-sourced” and “sustainable”. For service providers, taking a pragmatic and proactive approach towards trust (i.e., privacy, security, and data protection) is not an option, but a necessity.

The concept of building trust with our customers is not a new idea, but with increases in digital working environments and amounts of data being collected and processed—and the emphasis on and complexity of building trust—it has increased manyfold. As the “new normal” and actions of organizations come under intense scrutiny, companies’ actions have greater consequences and influence customer opinions. These actions will determine if existing customers choose to continue their relationships with a brand and whether new customers will choose to start them. With so much at stake, it is important to rethink our approach, skills, processes, and technologies that support a Trust Ecosystem.

Shaw undertook a current state assessment to understand where we stand on these areas of focus and to identify opportunities and mechanisms to operationalize our Emerging Technology Strategy.

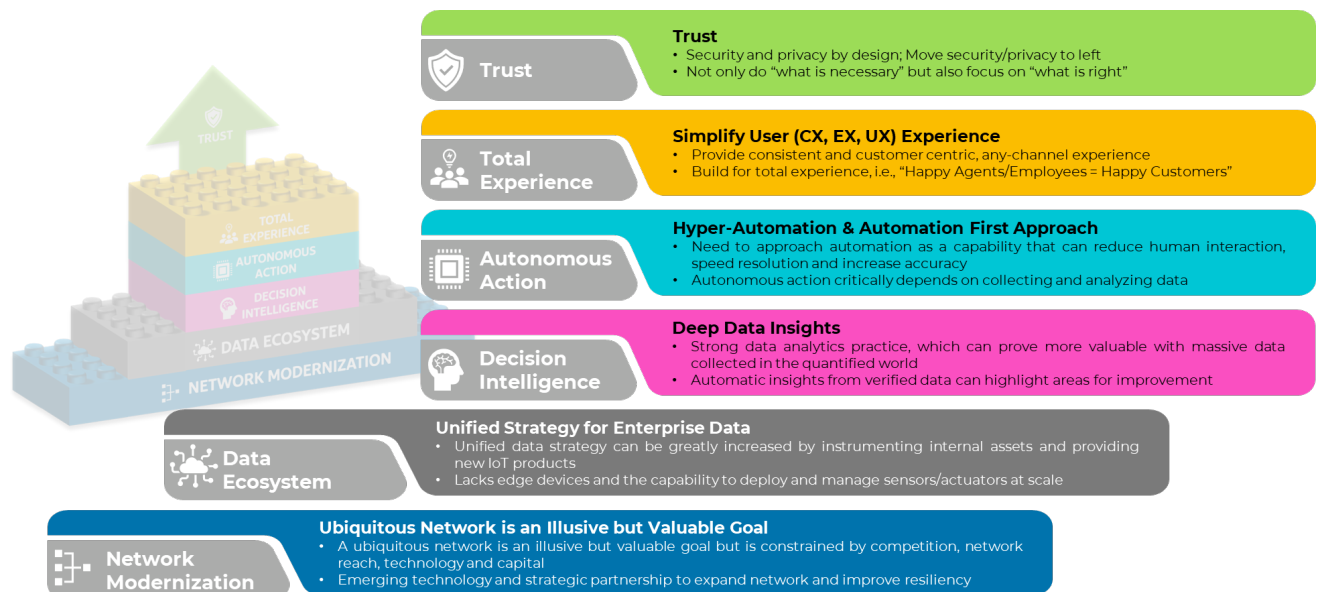

Figure 5 - Emerging Technology Deep Dive

4. How to Operationalize?

In this paper, we have laid out a logical structure for integrating emerging technologies into a cable operator's business model and suggested the benefits of doing so. However, to operationalize this structure and successfully integrate new technologies into the business, it is important to consider current operations. While it may be possible and at times necessary to swap out technologies completely and quickly (for example, after a security breach), a well-considered transition that minimizes current operational disruption would produce better, more sustainable results.

It is important to have a long-term strategy. When a new technology is introduced, there are serious practical considerations. Why is the change necessary? How much will it cost? What are the expected cost savings or revenue increases? How will employees and customers react? A long-term strategy should directly address these and similar questions. Resistance to change will be reduced when the reasons for the change are clear.

Communication is also critical. Adoption of a new technology cannot be accomplished without the assistance of those who will be implementing it. They need to understand the motivation, but also the information to plan thoroughly to minimize downtime for employees and customers. A proof-of-concept (PoC) trial may be advisable to verify the details of how the technology will be installed and connect with existing systems. Furthermore, the deployment plan must be carefully created and executed. For example, it may make sense for the technology to be introduced using an already planned operational upgrade rather than creating new projects.

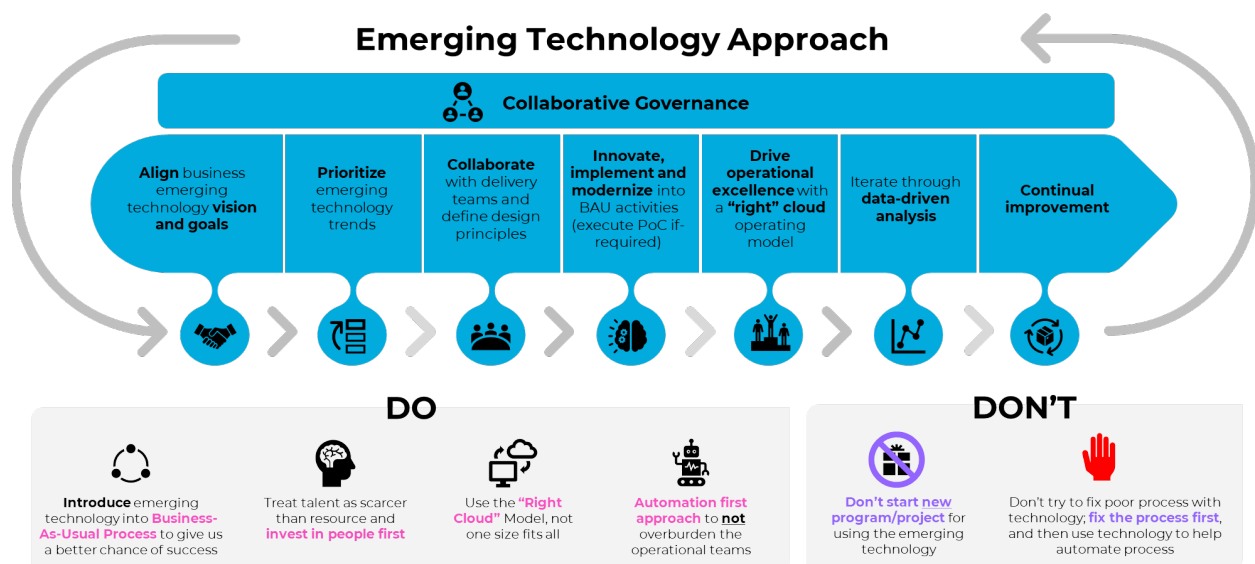

Figure 6 - Emerging Technology Operationalization Approach

The introduction of the technology through the deployment plan should be clearly communicated to all impacted groups—and potentially even to groups who would not be impacted by the upgrade but would support if technical issues arise. When people are aware that a change is happening, regardless of how minimal it is expected to be, they can anticipate that change and plan appropriately.

It is also important to establish roles and responsibilities. Those impacted by the transition should know exactly who to ask when they have questions. Who is responsible for making decisions? Who has the information that will inform those decisions? Who needs to complete which tasks and on what timeline? Are there executives or other people who need to be informed of the progress and alerted when problems arise?

Operating Model Stage	Shared Responsibility Model			
	Responsible	Accountable	Consulted	Informed
 Collaborative Governance				
 Business Alignment			 	
 Prioritization			 	
 Planning & Design	 			
 Innovate, Implement & Modernize

 Data Driven Analysis	 			
 Continual Improvement	   			

Internal Teams

-  Business Team
-  IT Team
-  Operations Team

External Teams

-  Technology Partners

Figure 7 – Hypothetical Shared Responsibility Model

For those who will be using the new technology, a thorough training plan is likely necessary. Training should be planned sufficiently in advance of the actual change so employees are as comfortable as possible during the transition.

With instrumentation and data collection intrinsic in modern business, all operational considerations can be handled more efficiently, and sometimes even automatically.

Referring to our framework, the network lies at the foundation. Information must be instantly and reliably communicated. This includes not only information between people, but also information between machines, sensors, actuators, and data systems. Data must be collected from every conceivable source, the verity of that data must be dependable and timely, and it must be reliably delivered to the appropriate destinations over the network. Where possible, the data should be used for accurate analysis and automated action. Finally, all these interactions need to be protected with strong security that can quickly react to breaches.

The fundamental operations of the business do not change. Businesses still create products and sell them to customers. For cable operators, we have both end customers who use our products to enrich their lives and business customers who use our products to support their own customers. We can better serve both types of customers when we operationalize new technologies into our business.

New products often rely on new technology and new capabilities, but many new technologies will now include instrumentation that will allow products to be monitored for health and usage. In some cases, problems can be diagnosed and fixed before the customer even notices them. Important data about how

the product is being used and how it can be improved can keep product teams informed on what improvements to consider and additional markets that will embrace the same product. The product development cycle does not fundamentally change; it becomes more efficient. In this new cycle, the product team can better meet the needs of customers, customers are more satisfied with the products, and customer care teams can more accurately diagnose problems or avoid them altogether since they can be diagnosed and repaired without human interaction.

Operationalizing emerging technology is a success-based cycle. With a careful integration plan, initial disruption can be minimized. As the benefits of the new technology are observed, enthusiasm for the technology increases for all involved parties, which encourages the adoption of more relevant technologies. As employees see that technologies are being adopted to solve problems rather than for technology's sake, they are more willing to trust management. As the value of emerging technologies is operationalized, employees at all levels have greater job satisfaction, which in turn attracts new employees in a very tight job market.

5. Conclusion

While not all emerging technologies are based on networking, data, and IoT, a very large number of technologies are improved by these features. The cable industry has been extremely successful over many decades because we observed early on that our networks, originally designed for broader distribution of live television, could be used for much more than that. Indeed, we find ourselves at the nexus of the information age with advanced, industry-leading, reliable networks that are becoming essential infrastructure to modern society.

As with any valuable resource, many companies want a share. The value of networks will always be subject to competitive forces that will push them toward commoditization. In order to overcome the gravity of commoditization and continue to operate as profitable businesses, cable operators need to continually look for new revenue opportunities.

At Shaw, we have observed that there will be an increasing need to measure, analyze and automatically react to information, regardless of the source. Fortunately, we are well-positioned at the center of that revolution. There is a great opportunity now for cable operators to adopt fundamental technologies and create new lines of business in order to participate in new waves of opportunity in the future.

As cable operators, it is essential that we build the flexible infrastructure required for the information, intelligence, and automation that will ride on our networks. We need integration, deployment, maintenance, and automation systems that will scale to accelerating consumer demand. This will provide new revenue opportunities in the future and set us up for the next information revolution—one that even we have yet to imagine.

1. Introduction

As the newest generation of the Data over Cable Service Interface Specification (DOCSIS) ecosystem takes shape, multiple system operators (MSOs) are contemplating upgrading their hybrid fibre coax (HFC) networks. Whether an operator chooses the full duplex (FDX) or frequency division duplex (FDD) variant of DOCSIS 4.0, all amplifiers in the network will need to be replaced by newer versions. Historically, amplifiers were simple devices set up during install and only revisited during routine maintenance or troubleshooting. However, there is an opportunity to enhance the functionality of these devices with the aim of decreasing the total cost of ownership (TCO) of the HFC network and to reduce the incidence and duration of customer impacting outages. This paper will present a fresh perspective on smart amplifier functionality and evaluate the potential benefits of deployment.

2. Background

2.1. Hybrid Fibre Coax Networks

In HFC networks, signals are combined in a hub site and transmitted over fibre optic cable to an optical node in the field. An analog optical node performs an optical to radio frequency (RF) transition and sends signals onto coax cables. Coax cable design follows a tree-and-branch topology, which was developed prior to the introduction of fibre optics when the function of the network was to distribute analog television channels [1]. Signals propagate through a cascade of amplifiers separated by coax cable and passives such that the gain of the amplifiers cancels out the loss of the cable and passives. This high-level topology is shown in Figure 1.

Figure 1 – Hybrid Fibre Coax Topology

HFC networks are designed to deliver signals to customer premises equipment (CPE) roughly at equal power across frequency to optimize signal quality. A complicating factor is that coax cable and passive devices have higher loss at higher frequencies. To correct for this effect, amplifier outputs are tilted so that signals at higher frequencies have higher output power than signals at lower frequencies.

2.2. Amplifier Functionality

Coaxial cable attenuation increases with the square root of frequency, as shown for CommScope QR540 cable in Figure 2.

Figure 2 – Cable Attenuation with Frequency – CommScope QR540 [2]

Similarly, passives such as taps, splitters, and couplers have higher insertion loss at higher frequencies, as shown in Figure 3 for an ATX GigaXtend XST-24-20 model tap.

Figure 3 – Insertion Loss with Frequency – ATX GigaXtend XST-24-20 [3]

To optimize signal quality while compensating for frequency specific losses, amplifiers accept an input signal, condition it to be as flat across frequency as possible, amplify the signal, and then tilt the output. This allows a signal to be transmitted through a cascade of amplifiers and ultimately to homes with optimal quality. HFC networks are generally designed so that each amplifier has the same output levels, signified by the power level in the lowest and highest downstream channels. For instance, RF output levels can be 35/49 dBmV at 54/1000 MHz, as shown in Figure 4.

Figure 4 – Amplifier Output Levels

Amplifier signals are designed to stay within an optimal range of power level, such that they are not too close to the noise floor on the low end, or in danger of distortion at the high end. When designed and implemented correctly, signals can pass through a long cascade of amplifiers with little degradation in performance. Figure 5 shows the power level of a signal over frequency as it passes through a cascade of amplifiers and a tap to the customer premises.

Figure 5 – Amplifier Cascade

2.3. Amplifier Block Diagram

Signals pass through many discrete steps inside an amplifier. A simplified amplifier block diagram is shown in Figure 6.

Figure 6 – Simplified Amplifier Block Diagram

Starting from the left, a downstream signal enters the amplifier and is directed along the top path by a diplex filter, signified as a box with an H (high frequency) and L (low frequency). An equalizer removes any frequency tilt remaining in the signal after traversing the cable and passives in the previous network segment, and an attenuator or pad ensures the signal level is in the optimal range for the preamplifier gain stage. Interstage attenuation controls the output level, while slope control sets the output tilt. The signal then goes through an additional diplex filter to be reunited with the upstream signal and exits the amplifier.

In the upstream, the signal flow is simpler, as losses at low frequency are smaller, allowing for a single gain stage. Starting from the right, an upstream signal enters the amplifier and is directed to the upstream gain stage, after which the signal is equalized, attenuated, and reunited with the downstream signal. Attenuation and equalization are generally accomplished using plug-in components such as attenuators and equalizers, which can be varied to achieve the desired levels.

An additional function not shown in Figure 6 is temperature compensation, commonly included in amplifiers as the attenuation of components such as cable increase with higher temperatures. Without temperature compensation, amplifiers that are set up on a hot day may amplify signals beyond specified levels on a cold day, and amplifiers set up on a cold day may not amplify signals enough as the temperature rises. Signal level changes due to temperature swings are more significant in the downstream because the attenuation is greater. Downstream temperature compensation systems use a feedback control loop, which attempts to keep a specific portion of the signal at a specified power level. If the level drops the system increases the gain, and if the level increases the system lowers the gain. In the upstream, a thermal attenuator can provide some compensation without the need for a control loop.

Amplifiers have historically been relatively simple devices that are set up during HFC network construction and only visited during routine maintenance or troubleshooting. However, smart enhancement can provide opportunities for greater network reliability and improve the customer experience. Now that amplifier functionality has been examined, smart enhancement will be discussed in following section.

3. Smart Amplifiers

Many amplifiers come with smart features that aim to improve the functionality of these devices. But what exactly is a smart amplifier, and what benefits do they bring to operators?

3.1. What Constitutes a Smart Amplifier?

The term smart amplifier is often used in two main contexts. The first is smart functionality that is local to the device, such as electronically selectable attenuation and equalization settings. It is expected that all 1.8 GHz amplifiers will have these features. The second is the ability to remotely communicate with the amplifier. This paper briefly discusses the first context but focuses on the second, as communications capability is expected to be optional, and MSOs will have to choose whether to make this investment.

3.2. Smart Setup

As mentioned earlier, amplifiers have generally used discrete plug-in components to vary settings such as attenuation and equalization. This requires HFC technicians to carry a stock of these components for setup and maintenance. In addition to added expense, this creates potential logistical issues. It is possible for a technician to *not* have the correct value component and be forced to use the closest value in their possession, resulting in a non-optimal setup. Plug-in components are a possible source of failure, as are their connections to the amplifier board. Even small failure rates of these components can cause an operational headache, and intermittent failures can be especially difficult to troubleshoot. For example, an attenuator that fails at high temperature may be tracked to an amplifier, only to have the problem cease when the amplifier is opened and the internal heat dissipated. Additionally, the mechanical joint between the component and the amplifier board can create unexpected problems when an incomplete connection is made. Wiggling or reseating the component may fix the problem, but a technician may end up discarding the component and installing a new one, fearing the problem will return.

An amplifier can be designed so that some or all configurable features are electronically selectable, either through a wired or wireless connection to a hand-held device. There are benefits to this type of system beyond avoiding issues with plug-in components. A greater range of potential settings and a larger number of incremental steps can be designed, allowing for a more precise setup. Additionally, authorization to make changes to amplifier setup can be more easily controlled, either by access to the required hardware or through restricted access via software.

3.3. Communication

While amplifiers with electronically configurable components can be referred to as smart amplifiers, a fundamental capability for this category of amplifier is the ability to communicate. Communication can be achieved either through a proprietary signaling protocol that uses upstream and downstream frequencies separate from end-user signals, or in-band through DOCSIS. There are pros and cons to both methods. Proprietary systems can use inexpensive transponders, especially if the quantity of data sent back and forth is small, but they require exclusive use of some amount of spectrum. DOCSIS communication can be more costly but has the benefit of sharing spectrum with other services, meaning that bandwidth is only used when amplifiers are sending or receiving data. In both scenarios, communication enables monitoring and control of smart amplifiers, however it adds both additional cost and complexity.

3.4. Monitoring

There are many different data points that can be monitored in a smart amplifier. These include:

- Configuration settings
- Power status
- Lid status (open/shut)

- Input/Output RF levels
- Diplex filter frequencies
- Temperature compensation

Input and output RF level monitoring requires additional hardware to evaluate signal strength. This can be done at specific frequencies or across the band with spectrum analysis functionality.

3.5. Control

It is possible to implement different levels of control in a smart amplifier. The simplest is remote setup via electronically configurable components. Combined with the ability to monitor input and output levels, a standard network setup can be achieved by a technician in an operations center, rather than sending a field technician to perform the work locally. More complex systems that control diplex frequency based on an evaluation of traffic requirements can also be designed.

DOCSIS 4.0 specifications allow for several diplex frequencies between 204 and 684 MHz [4]. A diplex frequency at 204 MHz would accommodate more downstream and less upstream traffic, while a diplex frequency at 684 MHz would accommodate more upstream and less downstream traffic. The ability to remotely change the diplex frequency would enable each node to be optimized for its traffic demand. For example, a node with many business customers might have a more symmetric traffic pattern when compared to a residential node. In the latter case, a diplex frequency of 300 MHz might be optimal, while in the former case, 684 MHz would likely best match the traffic pattern. Upstream and downstream spectrum allocation and associated ratios for each diplex frequency is found in Table 1.

Table 1 – DS to US Ratio of Different Diplex Splits

US Diplex Frequency (MHz)	US Spectrum (MHz)	DS Spectrum (MHz)	DS/US Spectrum Ratio
204	199	1536	7.7
300	295	1422	4.8
396	391	1302	3.3
492	487	1188	2.4
684	679	960	1.4

This table assumes worst-case downstream lower band edges and uses spectrum, not capacity, in calculating downstream to upstream ratio. Since upstream modulation rates tend to be lower than downstream modulation rates, the downstream to upstream capacity ratio would be slightly higher.

3.6. Automation

Electronically configurable attenuation and equalization, along with monitored signal levels, would allow for automated setup in smart amplifiers. This setup could be achieved locally at the amplifier through an application or push-button functionality. This would require logic to be implemented locally to the amplifier or in a hand-held device. Alternatively, if the device has communication capabilities, this logic could exist in a back-office system where the device is automatically configured to a predefined state when communication is first established after install.

4. Operational Considerations

While additional levels of intelligence in amplifiers can be beneficial, it is important to recognize that this intelligence will also change the operational model for setup, maintenance, and troubleshooting of amplifiers, with the goal of lowering lifecycle cost.

4.1. Amplifier Operations

In the absence of smart amplifier communication, all activities concerning those amplifiers require a technician to be physically present at the device. Adding smart features changes the way that HFC networks are set up and maintained.

4.1.1. Initial Setup

During the setup of new HFC networks, each amplifier is installed and configured by field technicians in the order of its position in the cascade. This is because the configuration of all amplifiers upstream will impact signal levels downstream. Consequently, amplifier setup happens sequentially, and a single technician may start at the first amplifier and physically move down the cascade, installing and setting up each device. However, if the amplifier is capable of remote configuration and signal level monitoring, amplifier setup can be completed by staff in an operations center. This would allow field technicians to install the amplifiers in the most efficient manner and configuration to happen remotely, without the requirement of being present at each device.

4.1.2. Maintenance

Routine maintenance of amplifiers is accomplished through sweep programs, where a group of technicians visit each amplifier in a node and confirm that signal levels are appropriate. Signal levels may change over time owing to different causes such as equipment aging, temperature swings, and deliberate changes that solve localized problems but create others. For example, a technician may increase signal level at a drop by raising the output signal level at the preceding amplifier, solving the immediate problem but potentially causing issues further downstream in the cascade.

Sweep programs are time-consuming as technicians must drive to each amplifier location, access the amplifier, open it up, connect it to a field meter and confirm whether setup is appropriate, and make any changes necessary. In the case of aerial plant, a bucket truck is required to access devices, whereas in underground plant, vaults and pedestals need to be accessed. Access can also be restricted in some extenuating circumstances, such as where amplifiers in buildings require special access, or when underground infrastructure is flooded. In the worst cases, access can require days or weeks of advance notice and fees to be paid. In addition, HFC spectrum has expanded and overlapped with mobile spectrum, creating another source of interference—through both mobile signals to the HFC network and HFC signals to the mobile network—and opening amplifier housings during a sweep program can exacerbate this issue. The extent to which MSOs utilize a sweep program can vary significantly, with some enacting rules about how often an amplifier is visited over time by a sweep program, while others may avoid them completely.

If a smart amplifier can monitor RF levels and be configured remotely, then a sweep program would be unnecessary or performed from the operations center, removing the requirements for field travel and amplifier access, ultimately creating operational efficiencies. However, the extent to which this eliminates effort depends on how a sweep is implemented at the operator level.

4.1.3. Troubleshooting

Amplifiers are potential points of failure as well as locations to subdivide the network during troubleshooting. Troubleshooting downstream issues can be achieved by working back from where the issue is reported. For example, if a modem is not receiving sufficient signal strength, a technician may visit the tap. If levels are poor at the tap, the technician will move upstream to the amplifier. If the amplifier has poor output levels, the technician can continue upstream through the amplifier cascade, ultimately to the node or hub site, to find the source of the problem. In the downstream, modem statistics can also be used to localize an issue. If there is only one modem suffering from low signal level, the problem is likely in-home or at the drop. If many modems are experiencing the issue, the common point of failure can be determined by an operations center, and technicians dispatched directly to the problem.

Figure 7 – Downstream Troubleshooting

Troubleshooting noise in the upstream cannot be accomplished by correlating modem statistics, as all upstream signals terminate at the same location in the hub site or at the node in distributed access architecture (DAA). In this case, technicians use a brute-force technique, working out from the node and looking at each output leg for noise. The noise is followed until it no longer presents, at which point it is determined that the noise is entering the network between that location and the last place it was observed.

Figure 8 – Upstream Troubleshooting

Chasing intermittent noise can be difficult, time-consuming, and frustrating. It is not uncommon for a technician to be dispatched to troubleshoot upstream noise, only to have it disappear. The noise may return shortly after the technician has moved on to other activities, or it may not return for days, weeks, or at all.

The ability of smart amplifiers to aid in finding noise remotely is very useful. A remote system makes use of a spectrum analyzer in the hub site as well as the ability to temporarily increase the attenuation on each leg of a multiple-port amplifier one-by-one. If the noise presenting at the spectrum analyzer decreases when a specific amplifier leg is attenuated, it can be deduced that the noise is coming from that leg. This uses the same brute-force method used by field technicians, but eliminates the time required to drive to each location. It also allows a technician in the operations center to quickly address the issue when it is present in the case of intermittency.

To support the ability to remotely chase upstream noise, operators could also choose to only place modems or transponders in multiple-output amplifiers where noise would be entering the device from a single leg. The extent to which this strategy would work depends on how often the HFC network makes use of passive splitters instead of multiple-output amplifiers to split the network. Even in the case of splitter use, putting a modem or transponder in the first single-output amplifier downstream of a splitter leg would allow full functionality of a noise chasing system, but this could create logistical challenges as it can be difficult to ensure that the transponder or modem is put into the correct amplifiers.

4.2. Shaw Statistics

To estimate the amount of effort that could be eliminated with the implementation of smart amplifiers, it is important to have good statistics on technicians' activities. Ticketing systems for field technicians are used to assign work but are often not designed for statistical analysis. For example, drop-down boxes with a subset of potential problem categories and solutions often do not allow the flexibility to properly describe their activities, while free-form entries will vary in description from person to person and are

difficult to analyze. Despite these issues, this data remains the best source of intelligence on how technicians use their time and where smart amplifiers can be most impactful.

Field technicians are often grouped by the function they provide, or by the area of the network they focus on. Some possible delineations include in-home, service, maintenance, construction, and plant. This section will only focus on troubleshooting activities and will exclude installs and disconnects.

Service calls are generated when a customer calls in with an issue that cannot be resolved over the phone. Customer service representatives create a ticket, enter a brief description of the issue from the customer's point of view, and include details from tools they have access to. The top 10 keywords are shown in Figure 9 as a percentage of use in ticket creation.

Figure 9 – Keyword Occurrence in Ticket Creation

Keyword analysis can give a high-level view of the issues that customers are experiencing but is inherently problematic as these words can be used in many contexts. As an example, the keyword “RF” can exist in the description “Poor RF Signal Levels” and “RF Signal Levels OK”. Despite this, it can be observed that a common description from a customer perspective is the behaviour of the hardware or service. Descriptions such as “Modem won’t turn on” or “Internet down” are common. Tickets are then assigned to field technicians who will investigate the issue at the customer premises. After investigating and resolving the issue, the ticket is closed, and an additional description is included in completion notes. The top 10 keywords used in ticket completion notes are shown in Figure 10.

Figure 10 – Keyword Occurrence in Ticket Completion

The ticket completion notes provide insight into what the solution to the issue was. From the use of the keywords “swap”, “install”, and “replaced”, it can be inferred that changing out CPE is the most common solution to customer issues. The keywords “splitter” and “connector” are likely indicators of issues within the in-home wiring. The use of “tap” and “drop” point to issues outside of the home. Service or in-home technicians generally do not troubleshoot beyond the tap, so if an issue is traced to a cause beyond the tap, a ticket is opened for a maintenance or outside plant (OSP) technician to continue troubleshooting.

Outside plant tickets can also be created by the operations center when alarms occur or when customer issues are correlated to a single source. The number of in-home tickets is much larger than the number of outside plant tickets, as shown in Figure 11.

Figure 11 – In-Home vs Outside Plant Tickets

This figure represents the absolute number of tickets, and not time spent or cost incurred. In general, outside plant tickets take longer to resolve than in-home tickets and are more costly.

Outside plant referrals can be organized in a hierarchy using categorization data to estimate the number of tickets where work could be aided by smart amplifiers. Figure 12 shows the categories in the hierarchy pertinent to the discussion.

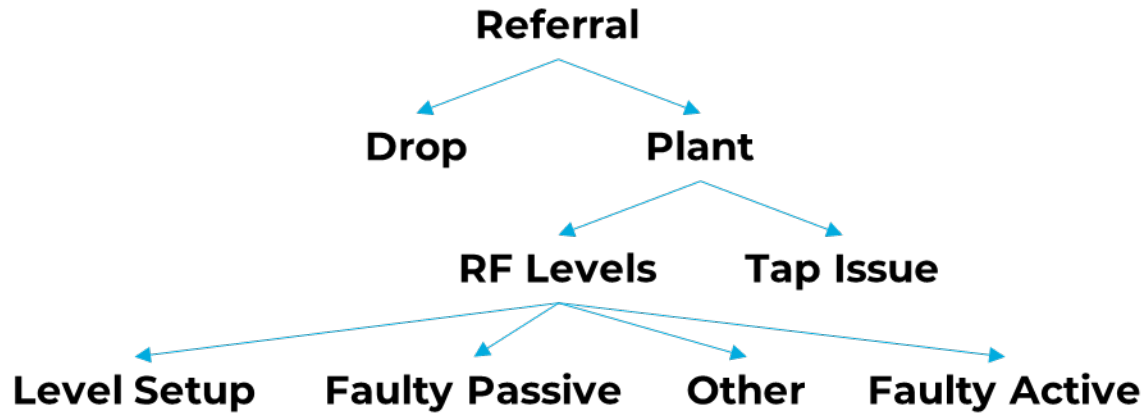

Figure 12 – Outside Plant Referral Hierarchy

One-third of plant referrals are for drop replacements while two-thirds involve issues at the tap or further into the network. Figure 13 is a Sankey diagram that visualizes the many-to-many relationship between categorizations within outside plant tickets.

Figure 13 – Outside Plant Referral Tickets

The “Other” category above includes issues such as fibre-to-the-home (FTTH) tickets, logistical requests (e.g., for installing a larger pedestal), requests from the planning department, and no fault found scenarios.

While there are many different causes of plant issues, the majority will require checking RF levels at multiple locations. Smart amplifiers could be of help in this case, both by allowing remote RF level observation to find problems and for RF levels to be changed remotely. The degree to which a smart amplifier system would aid in solving the problem depends on where the specific issue is found. In the case of a damaged tap, the solution ultimately requires the tap to be changed out by a technician, but a smart amplifier system could localize the problem to a specific plant segment, saving troubleshooting time. Systems that correlate modem levels can also be used to determine the location of the problem, potentially to a greater degree owing to the larger number of modems.

A plant incident ticket hierarchy is shown in Figure 14. Only categories pertinent to upstream noise are shown.

Figure 14 – Outside Plant Incident Hierarchy

Approximately one-third of incident tickets are for downstream outages while two-thirds are for upstream noise, which can be caused by a variety of different issues. Much of the ingress from homes is caused by telco noise, which is created when customers are connected to the HFC network and using their in-home coax wiring to pass signals using HFC upstream frequencies. The solution is to disconnect their drops at the tap, reconnecting them only if they become HFC customers in the future. Noise also enters the HFC network through weaknesses such as loose connectors and damaged cables. Again, a Sankey diagram can be used to see the many-to-many relationship between incident ticket categorizations in Figure 15.

Figure 15 – Outside Plant Incident Tickets

As noted earlier, the clearest benefit of a smart amplifier system is in chasing upstream noise, as this cannot be achieved through correlating modem levels or any other systems due to the noise funneling effect. Noise tickets are estimated to be approximately 3% of all tickets involving HFC in-home and outside plant troubleshooting. While this is a small number, it must be stated that noise chasing is among the most challenging and time-consuming activities that field technicians deal with.

4.3. Potential Value of Smart Amplifiers

Smart amplifiers can provide benefits by reducing required components such as attenuators and equalizers, saving time for field technicians, and reducing outage times for customers. The scale of the potential opportunity has changed over time owing to multiple factors that will be discussed below.

4.3.1. Node Size Reduction

The process of increasing capacity per home passed by building fibre deeper into the HFC network has reduced node sizes, both in terms of homes passed and the number of amplifiers. This has the effect of reducing the failure domain, increasing the uptime for all customers, and reducing the physical scope of troubleshooting. A node that has 1,000 homes passed and 100 amplifiers inherently has more potential sources of failure and is more difficult to troubleshoot than a node with 250 homes passed and fifteen amplifiers. Node sizes have decreased substantially in the past decades and will continue to do so going forward in response to increased traffic demands.

4.3.2. Proactive Network Maintenance

Proactive network maintenance (PNM) programs use performance statistics from modems to detect and fix HFC network problems before they cause customer impacting events [5]. Upstream equalizer settings can be correlated to find and fix impedance mismatches caused by weaknesses like cracked cables and loose connectors. A properly executed PNM program can ensure that the HFC network is in good shape, reducing issues in the network and direct impacts to customers.

4.3.3. Full Band Capture

Modems with full band capture (FBC) provide remote access to spectrum analyzer functionality. This allows for remote troubleshooting of several potential issues. Downstream troubleshooting, as described in 4.1.3, can be accomplished by using modems instead of taking readings at amplifiers.

4.3.4. Gateway Architecture

Legacy in-home wiring can consist of several splitters connecting a number of video, data, and phone CPE. In place of this arrangement, many operators are moving to a gateway architecture, where a single DOCSIS gateway connects to the HFC network and all services are accessed from this device. These two scenarios are shown in Figure 16.

Figure 16 – In-home Networks

Moving to a gateway architecture has two main benefits. The first is that the signal level required to support a single CPE per home is lesser when compared with legacy architectures that involve splitting and will therefore suffer additional loss. This puts less pressure on the HFC network to provide sufficient signal level to support multiple boxes and reduces the need for drop amplifiers, which can amplify upstream noise in addition to desired signals. Secondly, a smaller number of endpoints reduces the potential for noise to enter the HFC network.

Smart amplifiers would have been more useful in years past when HFC networks were larger and more difficult to troubleshoot. Their value may have increased, however, due to the shift to work-from-home

and hybrid-work situations driven by the COVID-19 pandemic, which has made customers less tolerant of unplanned outages.

5. Smart Amplifier Systems

Smart amplifiers that are remotely monitored and controlled require software to facilitate operation. There is potentially a large amount of data to be polled from amplifiers, and the number of amplifiers in an HFC network is large, requiring any system to be designed for usability. As of today, there are no industry standards, which means that systems are proprietary and only cover certain amplifier models. HFC networks tend to have amplifiers from multiple manufacturers for either historic reasons or in order to maintain multiple suppliers from a strategic sourcing perspective. The Society of Cable Telecommunication Engineers (SCTE) Smart Amplifier project, which launched last year, aims to create standards that the industry can use to develop smart amplifiers for DOCSIS 4.0.

5.1. Operational Shift

While smart amplifiers can reduce the workload for field technicians, it will create more work for technicians in operations centers. Amplifier setup and maintenance, and HFC technical work in general, has a large craft component and field technicians will often learn best practices over time with senior staff. This body of knowledge needs to be transferred to operations centers, as the ability to change the configuration of amplifiers in the field remotely should not be accessible to the uninitiated.

5.2. Maintenance

Making amplifiers smart adds new maintenance requirements and potential failure modes. Modems or transponders can go offline, requiring a technician to visit the amplifier to reset them. Power supply monitoring modems often suffer from this issue, but when they go offline the network continues to function. Because there is no direct customer impact to these types of modems going offline, it can be a low priority send a technician to bring them back online. This leaves operational teams with an incomplete picture of the health of the network. There is a significantly greater number of amplifiers than power supplies in the network, and as such the problem has the potential to be a magnitude larger, underscoring the need for smart amplifier components to be extremely reliable.

5.3. Additional Powering Requirement

The addition of a transponder or DOCSIS modem to each amplifier will create incremental powering requirements that will both increase operational costs due to the increased power usage and drive the need for additional power supplies. While this requirement is small in the overall context of powering the HFC network, it adds to other demands expected over the next few years. Additional power demands are expected to come from the transition to DAA, the use of small cells powered and backhauled using the HFC network and moving to 1.8 GHz. In addition to the added power requirement, a DOCSIS modem or transponder will add more heat that needs to be dissipated in an amplifier housing—something that may be challenging with 1.8 GHz amplifiers.

6. Strategic Value

HFC maintenance programs are often difficult to justify on financial arguments alone, especially as metrics such as “truck rolls avoided” are theoretical and subject to many different factors. Smart amplifiers also have strategic value that is not necessarily reflected in a financial analysis.

6.1. Smart Amplifiers in the Path to DOCSIS 4.0

Increasingly, HFC networks are competing against FTTH networks. In Canada, telcos have built out FTTH networks to most of their homes passed, and in the United States, telcos are not far behind. Current HFC networks can compete with gigabit passive optical network (GPON) downstream speeds, and high-split HFC networks can enable upstream speeds competitive with GPON. To compete with Ten Gigabit Symmetric Passive Optical Network (XGS-PON), HFC networks will have to be upgraded to DOCSIS 4.0, which enables 10 Gbps downstream and 6 Gbps upstream [6].

As customers look beyond speed when selecting a service provider, features such as latency and reliability become more important. While DOCSIS 4.0 will come with improvements in these areas, smart amplifiers have the potential to further improve HFC networks by reducing the incidence and duration of outages, making the overall network more reliable.

7. Financial Analysis

A financial analysis can be undertaken using data from ticketing systems and assuming high-level costs for smart amplifiers and field technicians' activities. This analysis should be considered directional as there are many uncertainties using both ticketing data and high-level cost assumptions.

7.1. Costs Avoided

The activity that is most affected by the introduction of smart amplifiers is upstream noise chasing. Smart amplifiers would allow noise to be located to a specific section of plant, at which point a field technician could be dispatched much closer to the source of ingress than would be the case otherwise. It can be assumed that 75% of upstream troubleshooting effort is eliminated by smart amplifiers, and a sensitivity analysis can be performed to gauge how that assumption impacts the net present value (NPV). While there is the potential to eliminate downstream troubleshooting efforts and prevent outside plant issues from causing needless in-home service calls, most of this functionality is available through PNM or similar modem performance analysis tools. Because of this, the assumption is made that smart amplifiers would not eliminate any effort for in-home or downstream issues. The estimated percentages for each category of activity are shown in Table 2.

Table 2 – Cost Avoidance Assumptions

Category	Percent Avoided
In-home	0%
OSP – DS Issues	0%
OSP – US Noise	75%

Assuming \$300 for outside plant activities and \$100 for in-home activities, the costs potentially avoided on a per-home passed, per-year basis is calculated as \$0.75.

7.2. Smart Amplifier Costs

If an incremental cost of \$50 per smart amplifier is assumed and there are 20 homes passed per amplifier, this leads to a figure of \$2.50 per home passed. Yearly costs of a smart amplifier system in terms of maintenance and licensing are more difficult to estimate as they will vary with operator and solution. A cost of \$0.50 per home passed per year with no capital start-up costs is assumed. An operator could alternatively develop a system in-house, in which case the yearly operational costs would be lower but the start-up costs would be potentially higher.

7.3. Net Present Value and Sensitivity Analysis

With the assumed costs and savings spread over a ten-year amplifier lifespan, the NPV of a smart amplifier system comes in at approximately \$0. This means that for a positive NPV, either the costs must be lower than assumed, or the benefits be greater. A simple sensitivity analysis shows how the NPV is impacted by a change in the input variables.

7.3.1. Costs Avoided

Assuming other inputs remain the same, Figure 17 shows how the NPV is impacted by the costs avoided per home passed.

Figure 17 – Costs Avoided Sensitivity

A savings of \$0.75 per home passed per year is a conservative estimate, which does not consider cost savings due to foregoing a sweep program, or due to the ability to remotely troubleshoot amplifiers that are difficult to access locally.

7.3.2. Maintenance Costs

Yearly maintenance costs, which include software licensing fees and costs related to system upkeep, would have to be higher than \$0.50 per home passed per year before the system NPV would be negative, as shown in Figure 18.

Figure 18 – Maintenance Cost Sensitivity

Maintenance costs are where companies offering smart amplifier back-office systems recoup their investment in development. Any systems that are over-engineered may risk becoming uneconomic and therefore unappealing to MSOs. Operators with in-house development capacity may be able to design and build their own systems once smart amplifier standards become available.

7.3.3. Incremental Amplifier Cost

The incremental cost of a smart amplifier would have to increase to over \$50 per amplifier to turn the NPV negative.

Figure 19 – Incremental Amplifier Cost Sensitivity

An effort has been made to use conservative costs and savings in this high-level financial analysis. The directional conclusion is that the value of a smart amplifier system under the assumptions used above is neutral, and a smart amplifier system would have to be carefully designed and properly executed to ensure a return on investment.

7.4. Context

It has been reported by Jeff Baumgartner at Light Reading that the costs to upgrade to DOCSIS 4.0 may reach \$250-\$400 per home passed [7]. The NPV of smart amplifiers should be thought of in this context,

and whether the ultimate NPV is slightly positive or slightly negative, it represents a very small fraction of expected HFC network expenditure.

8. Conclusion

Smart amplifiers can reduce HFC network TCO and increase reliability by lowering the number of network outages and reducing the time required to troubleshoot issues. While PNM systems can provide this functionality in the downstream using modem-level data, locating the source of upstream noise is more challenging. This represents the greatest value for smart amplifiers. Analyzing data from operational ticketing systems can help in estimating the scope of potential savings. Using this analysis, a simple financial model shows that costs saved by reducing upstream troubleshooting effort pays for the investment in smart amplifiers. This must be taken in the context of DOCSIS 4.0 deployments, which will allow MSOs to compete against FTTH competitors. Any smart amplifier development should be designed carefully to avoid delaying equipment availability and made optional to allow MSOs to choose whether to make the investment.

Abbreviations

CPE	customer premises equipment
DAA	distributed access architecture
dB	decibel
dBmV	decibels relative to a millivolt
DOCSIS	Data Over Cable Service Interface Specification
FBC	full band capture

1. Introduction

The idea of using automation to reduce human error and speed up infrastructure deployments is not new, however, choosing the “right” tools can be challenging. Tool selection has, in some ways, become an engineering challenge on its own. Many large cable operators are not all in on a single cloud provider, automation framework, or container orchestration engine.

The authors will review a set of cloud agnostic infrastructure-as-code (IaC) modules, continuous deployment pipelines, and a GitOps/Configuration Management interface that facilitates changes. This framework can deliver an internal observability platform that hosts millions of time-series metrics, including visualization and a unified search interface.

2. Problem Statement

As cable operators expand workloads into public cloud providers, teams will be tasked with providing a solution to time series metrics collection that is cloud agnostic. Many cable operators already use some form of on-premises infrastructure and the expansion to public cloud provides an opportunity to re-think how monitoring infrastructure is built. One primary goal is to give clients a storage and query interface to their metric data, without having to manage the system on their own. This will in turn enable client teams to focus on the things that bring the most value to their customers. This platform must be robust enough to handle outage scenarios such that the clients can access their time series data to perform troubleshooting or triage for their application.

2.1. Operating in a hybrid cloud environment

A best practice for time series platforms is to collect and store samples as close to the source application as possible. Given that this team was building a platform for other teams within the company, they would need to be able to deploy wherever the clients are deployed. This meant that the platform would need to deploy into both public and private clouds. Deploying into a hybrid cloud environment can get complicated quickly if you want to maintain a consistent way to deploy across all clouds. Each cloud has its own APIs and preferred methods for interacting with the infrastructure that you’re building. In addition, service offerings such as load balancing, secret management, and auto-scaling are different across each cloud.

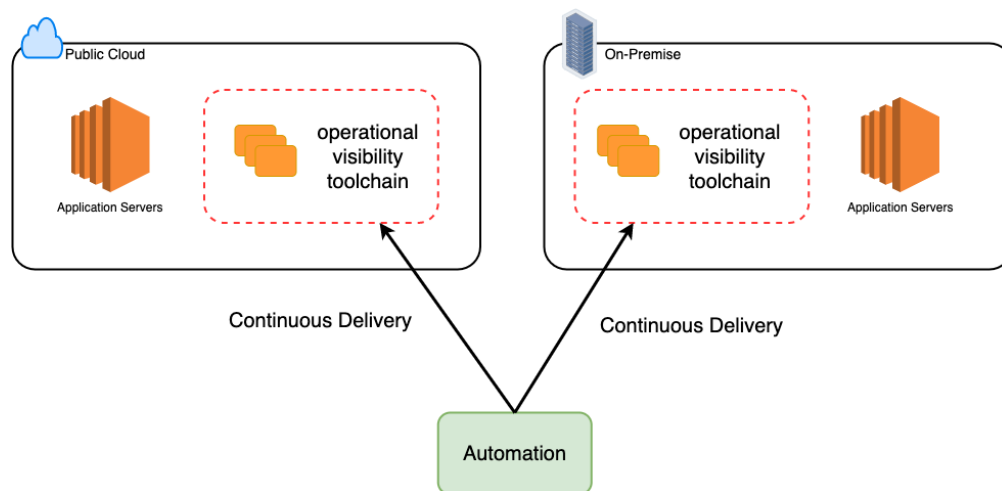

Figure 1 - Observability Toolchain

Choosing a set of abstractions can help with these challenges. The team chose to use Terraform and treat the Terraform configuration just as we would any other piece of code. This practice is commonly referred to as Infrastructure as Code. This enabled them to predictably and repeatably build infrastructure into any cloud that had a Terraform provider. This significantly decreased the complexity of deploying to multiple clouds. Once this pattern was established, they were effectively able to extract the functionality into a set of Terraform modules and fill in provider specific details.

2.2. Simplifying application developer choice

Large companies tend to have a huge breadth of choice in terms of tool sets and platforms application developers can use to deploy and monitor their applications. This can frequently lead to analysis paralysis from a developer's perspective since there can be so many options, some seemingly competing with one another. It can also be difficult as a developer to discover what tools or platforms are available to you since documentation for these tools or platforms tends to be siloed within a given team or organization. From the company's perspective this spread of similar tools and platforms doing the same or similar things, and their potential lack of discoverability, is challenging in terms of budget dollars. There could be lots of engineering hours spent developing a tool set or platform that might already exist. Teams or organizations might purchase a vendor solution for a problem that has already been solved in other parts of the company.

A goal is to avoid these pitfalls, making use of their own platform so easy that it would not even be presented as a choice. Users would be compelled to use the system because there would be little to no friction involved in getting it set up or interacting with it. This meant that not only did they need to spend a significant amount of time up front thinking about the user experience, but they also had to make sure that every decision made would not negatively impact the user experience if it could be avoided. For the team, that meant hiding as much of the complexity as they could from the user. To achieve that goal, they built a web portal for the clients to interact with that would guide them through the process of providing the required information to deploy the infrastructure into their chosen environment. Rather than require users to setup a meeting or fill out a ticket, they were given the ability to go to a web page and onboard in an entirely self-service manner.

2.3. Benefits of time series metrics over logs

Time series data is a collection of numeric measurements, made over time. There are many uses for time series data, plotting points on a graph being one of the most popular. Time series data exists in many domains outside of software systems, stock prices, heartbeats per minute, etc. For a web application, time series data may be requests per second, or for a database this might be number of active connections or active queries. [1]

Historically, applications relied heavily on application logs for observability. Application logs being text-based messages that contain informational events, warnings, and errors. Whether this was for application alerting, creating dashboards, or debugging the system, logs were the standard. The team was tasked with building a time series collection platform to reduce log ingestion and shift teams towards a "metrics first" approach. Most application teams would write verbose logs and extract metrics from those logs in downstream log analytics tools. As a result, there are often high log volumes and large storage costs associated with many applications.

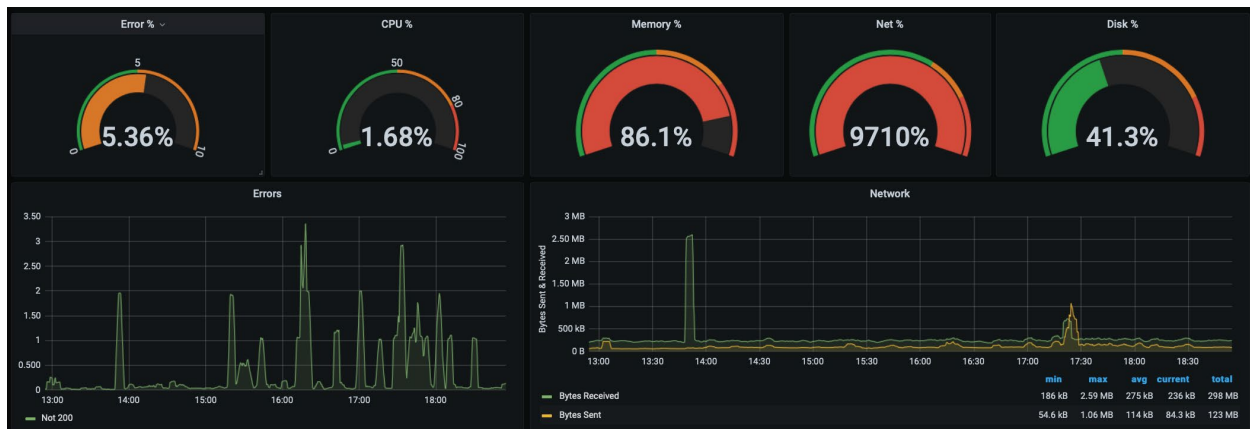

Figure 2 - Time Series Data Graph

“By and large, the biggest advantage of metrics-based monitoring over logs is that unlike log generation and storage, metrics transfer and storage have a constant overhead. Unlike logs, the cost of metrics doesn’t increase in lockstep with user traffic or any other system activity that could result in a sharp uptick in data.

With metrics, an increase in traffic to an application will not incur a significant increase in disk utilization, processing complexity, speed of visualization, and operational costs the way logs do. Metrics storage increases with more permutations of label values (e.g., when more hosts or containers are spun up, or when new services get added or when existing services get instrumented more), but client-side aggregation can ensure that metric traffic doesn’t increase proportionally with user traffic.” [2]

3. Building the platform

At the outset of the project, the team made the choice to build a metrics collection platform, instead of buying an off-the-shelf product. They also decided to avoid so called “cloud native” toolsets that existed within public cloud platforms. Each public cloud offers a suite of observability tools that integrate into their infrastructure services.

A primary goal of the project was to build an easily maintainable and scalable platform to deploy metrics infrastructure for application teams. The target for this infrastructure ranged from on-premises datacenters to public cloud providers, with the initial target being on public clouds. Many vendors offer platforms that provide metrics storage “as a Service”, however, the team’s research found the cost and compatibility with the various internal applications and tools incompatible. Many public cloud vendors offer their own hosted tools that provide these features; however, they wanted a single solution for all teams regardless of where they chose to host their application.

3.1. Standardized toolset over cloud native

The team chose Prometheus [1] as the time series database, primarily for its wide adoption as an open-source standard for monitoring and alerting. Using Prometheus as the base allowed them to focus their efforts on building out the platform around a common tool versus worrying about how to automate and support each cloud vendors specific product. In addition, this allowed them to offer a single solution regardless of an application teams intended deployment location.

In addition to choosing a standard tool to deploy across clouds, the team also decided to keep their deployment simple by using Virtual Machines (VM) instead of cloud specific orchestration platforms. Since each cloud platform offers its own unique orchestration service and on-premises datacenters are unique, choosing the lowest common denominator simplified the architecture. There were a few drawbacks to this, namely losing key features like auto-scaling, but they were able to work around these with proper alerting and health checks.

Moreover, this enabled the team to build upon a single common image that could be deployed to whichever cloud, be it public or private, with minimal effort to add cloud specific instruction sets for the VM. This gave the benefit of only needing to fetch a single image which has been patched or updated and build on top of it. These changes could then be easily propagated out to the client stacks without needing to remember or think about cloud VM specific patching.

3.2. Choosing the open source path

As mentioned earlier, Prometheus was selected as the base software tool for metrics collection and storage. The next focus was to choose how they wanted to manage and deploy Prometheus plus any customizations and client specific configuration that would be needed. They decided to continue with open-source, modular tools and made the following selections:

- **Terraform:** For Infrastructure as Code automation
- **Packer and Ansible:** Building Base Cloud AMIs/Images
- **Git:** Version control of Terraform modules and client configuration
- **Concourse:** Continuous Integration and Deployment

Using Terraform allowed them to take advantage of existing providers for many public clouds and, on-premises private clouds like OpenStack.

3.3. Centralized versus distributed

Another challenge they faced was whether the collection and storage of application metrics should be centralized versus distributed. More specifically, whether the collection and storage of an application's metrics should stay within the cloud and region where they originate. If they chose to distribute, then querying could be challenging, but if they chose to centralize, they'd have to deal with a centralized cost and chargeback model.

The team chose to keep collection and storage local to the application's virtual networking environment. This had a few advantages, namely:

- Prometheus uses a pull model for metrics collection, so this simplified network and access control as scrapers were local to an applications network.
- Cost was managed by deploying into a client's local network, so no chargeback or show back was necessary
- A network outage would not cause any loss in metrics collection

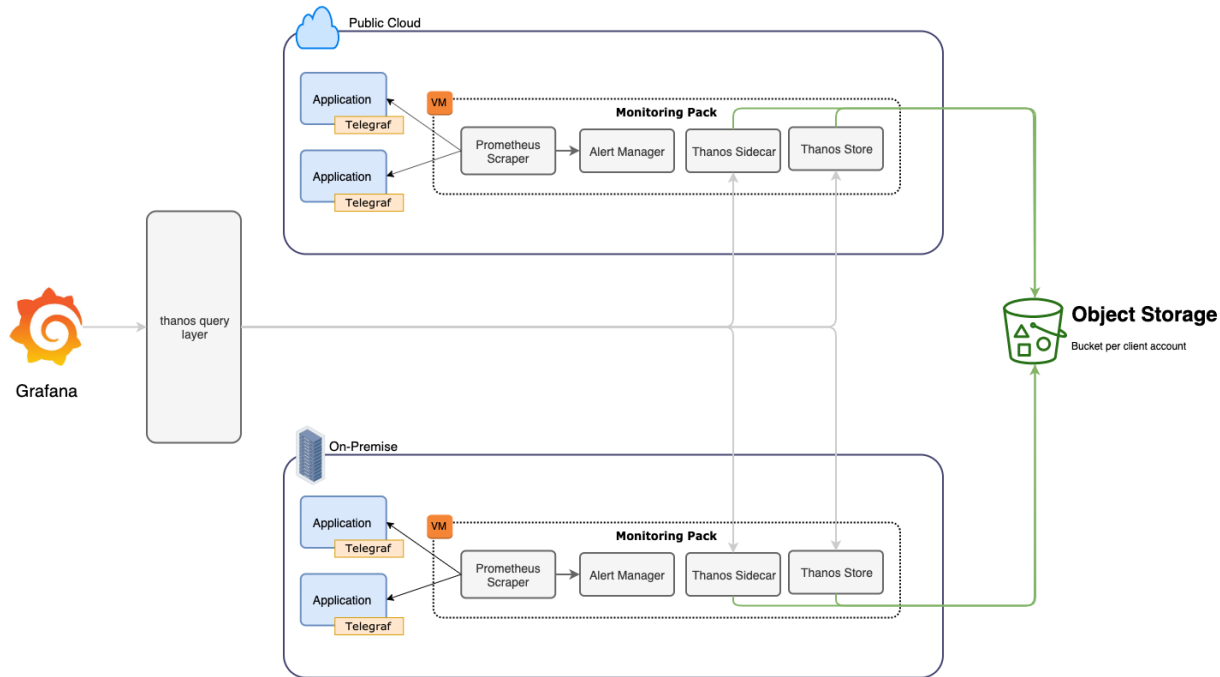

Figure 3 – Centralized Query Layer

A distributed model posed a challenge however for querying all metrics for a given client at once. This challenge was solved by deploying Thanos, an open-source Prometheus compatible tool with global querying capabilities as shown in Figure 3. The Thanos Query component, specifically, enabled deployment of a centralized set of instances that could access all regions, across all clouds and offer a single interface for client queries.

It was also decided to use the selected tool chain to deploy the monitoring as a client of infrastructure. This provided valuable insights into pain points the clients might experience, find places where there were gaps in the automation, and get comfortable with using the tools were being recommended that other teams adopt. This experience created a robust set of documentation, which in turn helped to reduce the support burden on the team.

4. Building modular components

Segmenting each concern into its own module allowed the platform to be deployable to any current or future cloud platform. The platform was broken down into Terraform modules, application container images, VM image builds, and client configuration.

4.1. Terraform Modules

The Terraform modules are primarily responsible for deploying a set of application container images, via docker, onto a virtual machine in the specified cloud environment. The logic for each cloud provider is encapsulated into each module, which includes details on instance types, disk sizes, cloud initialization instructions, etc. The set of container images can be customized per cloud and per client as needed.

4.2. Container Images

The application container images, which includes Prometheus, are the main software tools in the system. They provide the functionality for the metrics collection and storage. It's worth noting however, that the platform is agnostic to the container images deployed. Adding new container images or swapping all of them out for a different set of software tools would be trivial.

4.3. Image Builds

Since each cloud platform requires its own image type, cloud specific logic was extracted from the automation. A set of images were then built to be deployed across all clouds at once, with the same set of requirements driven by Ansible playbooks.

4.4. Client Configuration

Each client of the platform has a set of custom configurations that need to be applied at deployment time. These range from what hosts Prometheus needs to scrape, alerting rules, metric retention time, etc. This configuration is kept in version control (git) and updates to these files drive deployments to the various clouds and regions that are supported.

4.5. Client Onboarding

Clients are provided with a single URL at which they can onboard and manage their stacks. This was done to simplify how a client can start using the stack. The website has links to all the relevant documentation for any pre-requisite steps they might need to perform, as well as a simple form which takes in all the required information for the automation to build the stack for them. With a single click the client has their git directory and file structure created, has the minimal set of configurations for the containers to run, has the pipeline to deploy the stack created, and the stack is deployed. The client is presented with links to all the relevant sites and can immediately configure their stack for their use case. The whole process is entirely automated which allows the platform developers to focus on providing more value to the client and allows the client to more quickly get their stack running and configured since they don't need any touch points with the platform team.

5. Deployment & Continuous Delivery

The final step is integrating all the various components and modules into continuous delivery pipelines, using Concourse. This is where the core intelligence and logic of the platform comes together. At the outset of the project, they built each pipeline manually for each client by stringing together:

- The set of necessary Terraform modules for the target cloud platforms
- The logic for what regions were necessary
- The set of container images that matched the client configuration

This process became very tedious over time, especially when the number of clients grew beyond a handful and the number of regions for each client increased. To address to this, a templating application was created using Golang to automate the creation of each client pipeline.

5.1. Pipeline Generation

Concourse pipelines are written using YAML, which can be very verbose given its declarative nature. To simplify the management of the pipeline YAML files, which could range from 5,000 to 20,000 lines, it was decided to write an application that generate these files, given a defined set of inputs. The inputs included:

- Target cloud platform(s)
- Cloud region(s)
- Container image(s)
- Cloud platform account details

Given this set of inputs, a templated YAML file was created that was fed into the Golang program. When a client onboards or adds additional stacks to their deployment the program will re-generate the pipeline entirely rather than trying to insert just the pieces that change. This is possible because the pipeline generation is deterministic.

5.2. Concourse Interface

The generated YAML is used to create a pipeline within the Concourse platform as shown in Figure 4. This interface allows for manual triggering a region deployment if necessary, viewing logs, and tracking progress of deployments.

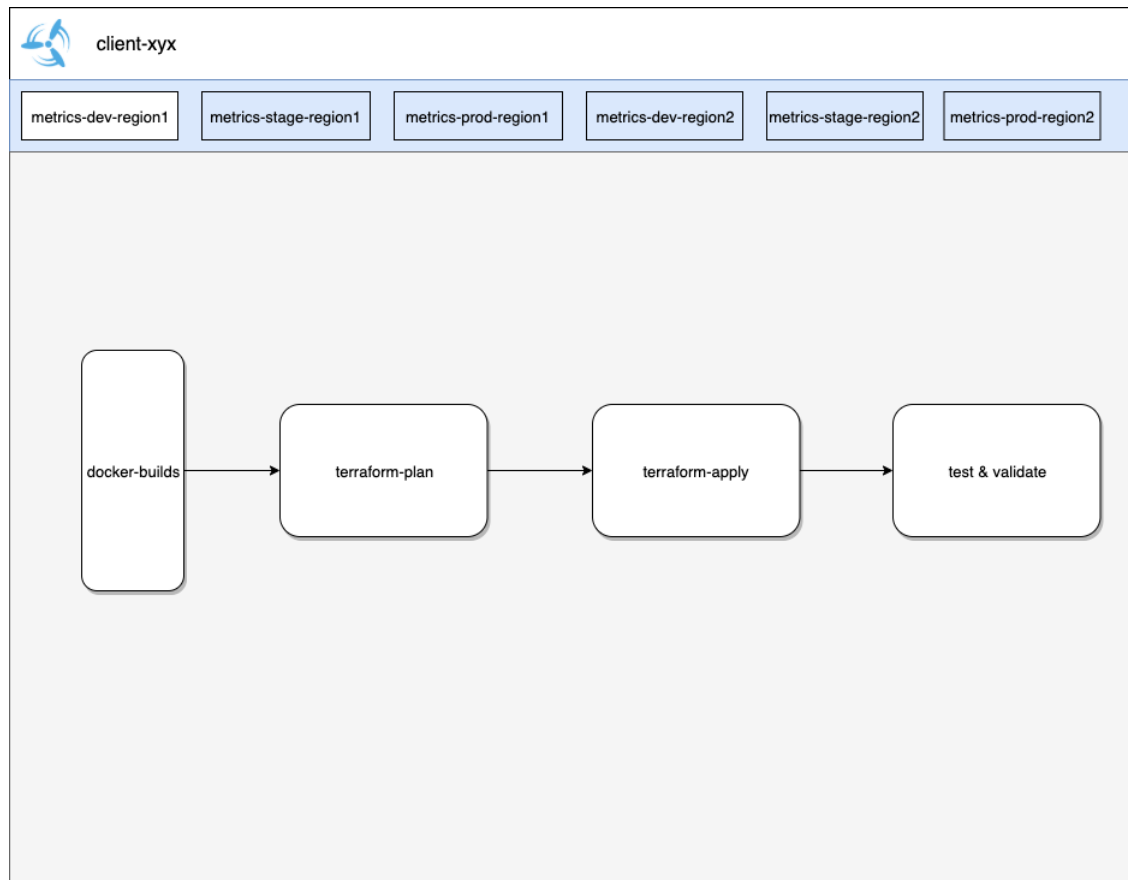

Figure 4 – Concourse User Interface

5.3. Delivery Automation

Once the Concourse pipeline is generated and applied in the Concourse platform, updates made to client configuration in git will trigger a deployment. The trigger is executed via webhooks through the version control system. A change made to a file in git will send a HTTP request to Concourse and kick off a deployment. The set of jobs run for each cloud do not need any manual intervention from the team, unless an error occurs. Any errors will trigger an alert to the team and error logs can be viewed within the Concourse user interface (UI).

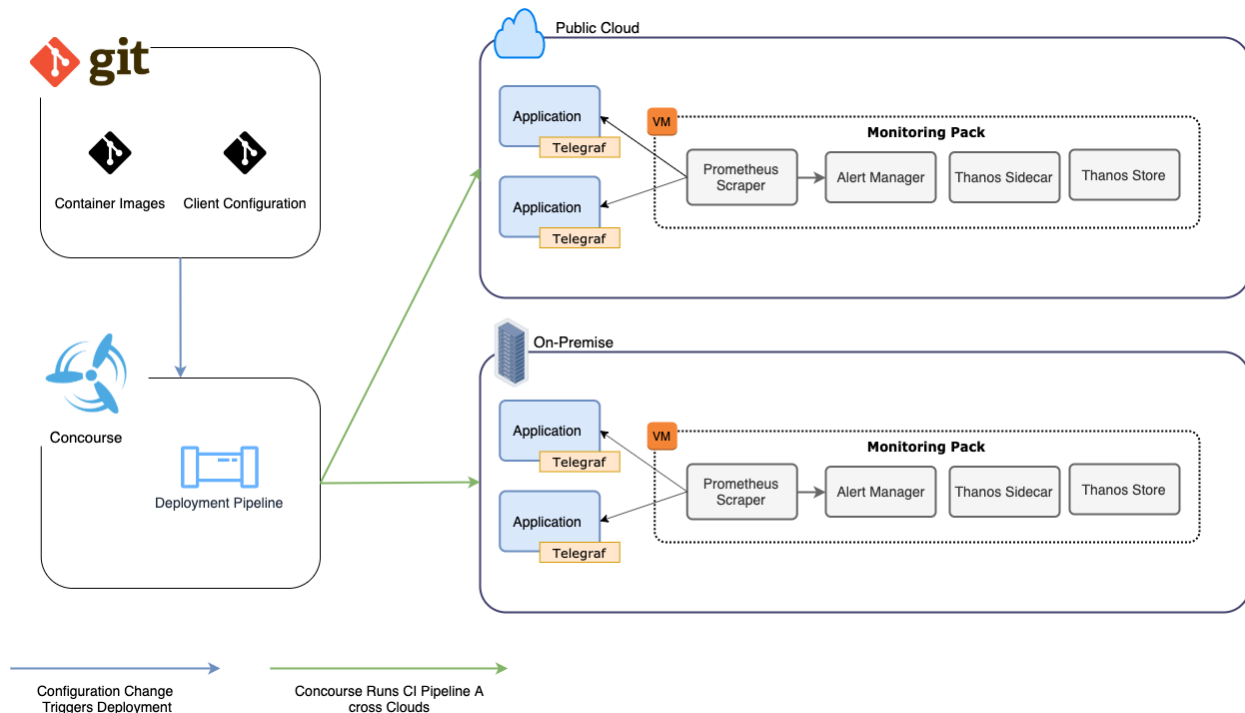

Figure 5 - Deployment Orchestration

6. Conclusion

As cable operators grow their on-premises cloud offerings and expanded into public clouds, there becomes a need for simplified abstractions to deploying infrastructure across environments. This team was tasked with providing this abstraction, specifically for observability tooling, available to all teams. They approached the problem by breaking down the areas into modularized components, capable of abstracting away the complexities of the target cloud environment, application type, and regionality. Focusing on clients' needs helped frame how to abstract the application architecture and functionality. This made the platform easy to use, quick to change and deploy seamlessly. All of this was possible because at each decision point, the software landscape was evaluated. A decision was made to go with proven, open-source tools that would meet the case. This, in turn, allowed the team to rapidly develop and scale the platform to serve any clients who need it, wherever their applications are running.

1. Introduction

Contemporary networks are playing a critical role in sustaining business continuity in every vertical of the industry. The customers are becoming more sensitive to outage or degradation in service performance. In simple language, customers rely on networks for their day to day business. That brings an opportunity and responsibility on operators to assure that customers can rely on them. This assurance shall be reinforced with a tangible estimate and measure of the reliability metric.

Reliability heavily depends on the knowledge of Statistics, Physics, and Engineering. However, in order to systematically implement Reliability Engineering, the service operators have to evolve a mindset of viewing every aspect of the organization as contributor to the improvement of reliability.

This paper will discuss strategies and techniques to enhance network reliability for enterprise customers in the present state of network design and performance. This paper highlights one approach to reliability and many additional factors are involved in ensuring overall system reliability. These models can then be utilized to evaluate the impact of hardware, software, and machine learning components on reliability of network to the end customer. This paper will delve into the factors that drive optimized reliability goals such as cost, complexity, maturity, redundancy, and operational efficiency, and will illustrate the reliability of networks from conceptual, architectural, monitoring, and cost optimization perspectives.

2. General Terms and Concepts about Reliability

While reliability has been understood and interpreted from varying perspectives, the most widely accepted definition of reliability is stated by Electronics Industries Association (EIA) as follows:

The Reliability of an item (a component, a complex system, a computer program or a human being) is defined as the probability of performing its purpose adequately for the period of time intended under the operating and environmental conditions encountered.[1]

Study and analysis of reliability presents an opportunity to integrate Reliability, Availability, Maintainability and Safety (RAMS) at every stage in the product lifecycle to achieve excellent quality, optimal product reliability, and customer delight.

Reliability engineering is a mindset homogeneously internalized within an entire organization. It requires a collaborative team effort where contributors of diverse perspectives, skillsets, backgrounds, and functional departments synergize to produce superior reliability for the product.

It is accepted industry-wide that reliability of the product or services shall be examined and analyzed at the earliest stage of development. Every missed opportunity translates into a cost increase of a multiple of 10. If a team misses the opportunity to identify a reliability issue during the design stage, then it will cost 10 times more to remediate in the development stage. In essence, reliability shall be applied at every stage in the lifecycle of product.

2.1. Common Terms

2.1.1. Failure:

Failure is an event when the element/service is no longer available to perform as per SLO/SLA.

2.1.2. SLA (Service Level Agreement):

SLA is an agreement written between service provider and customer. This agreement clearly determines the measurable metrics of service quality, penalties, and remedies, along with the roles and responsibilities of both parties in maintaining the mentioned quality of service.

2.1.3. SLO (Service Level Objective):

SLO is a commitment where the service provider declares its intention of maintaining certain level of measurable metrics.

2.1.4. Failure Rate:

The frequency at which failures occur.

2.1.5. MTBF (Mean Time Between Failures):

Average time between the occurrence of failures. This can be calculated as following:

$$MTBF = N_s(t_i) [t_{i+1} - t_i] / (N_s(t_i) - N_s(t_{i+1})); t_i < t \leq t_{i+1}$$

$N_s(t_i)$: Number of Survivors at time t_i

2.1.6. MTTF (Mean Time To Failure):

This metric is similar to MTBF, measuring the average amount of time a non-repairable element operates before it fails.

2.1.7. Risk:

The estimate of likely loss due to failure influenced by the reliability of one or more components of the system

2.1.8. Maintainability:

The probability that an element/service can be retained in, or restored to, a specified operable condition within a specified interval of time when maintenance is performed in accordance with the prescribed procedure. Maintainability is the characteristic of design, installation, and operation.

2.1.9. Observability:

It is a capability of measuring/estimating the internal state of the system by measuring/monitoring the external outputs of the system.

2.1.10. MTTR (Mean Time To Repair / Restore):

This metric is applicable only to repairable element/service. It measures the average time it takes to repair/restore a failure. This metric is an indicator of operational efficiencies and maintainability of the element/service.

2.1.11. Availability:

A measure of time that a system is operating versus the time that the system is targeted to operate

2.1.12. Supportability:

The capability of provider to maintain inbuilt reliability and to perform scheduled and unscheduled maintenance according to the Network maintainability with minimum cost.

2.1.13. Minimal Path Set:

Minimal Path Set is a set whose elements are paths. The System is available if all components of any element (path) are available. Refer to Figure1.

2.1.14. Minimal Cut Set:

Minimal Cut Set is a set of set of nodes. The System is unavailable if all nodes within an element of the Cut Set are unavailable. Refer to Figure 1.

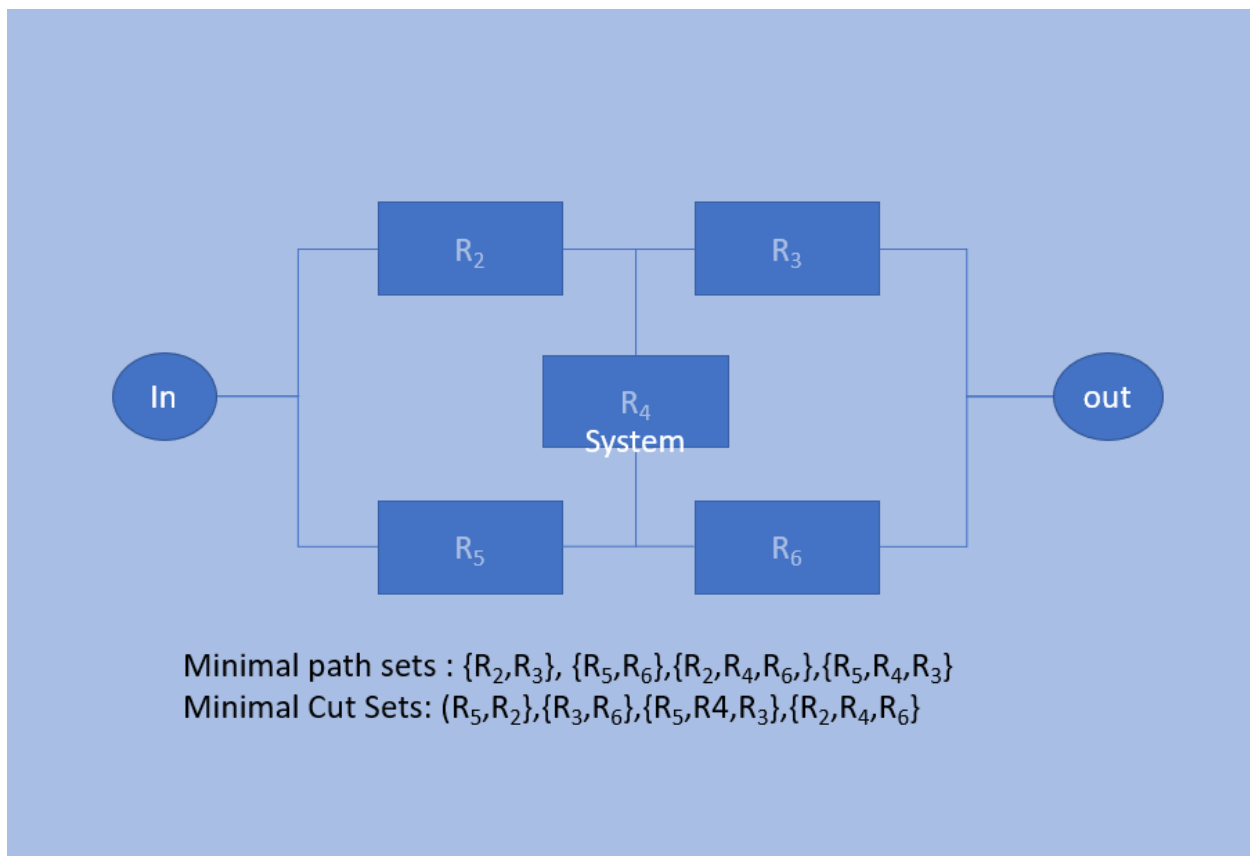

Figure 1: Minimal Pathset and Minimal CutSet

2.1.15. SDP (Sum of Disjoint Product):

The Joint Probability formula

$$\Pr(E1 \cup E2 \cup E3 \dots \cup En) = \Pr(E1) + \Pr(E2) + \Pr(E3) + \dots + \Pr(En)$$

is easy to calculate and valid only when Events E1, E2, E3,...En are mutually exclusive.

Referring to Figure 1, let P1 = R₂R₃, P2 = R₅R₆, P3 = R₂R₄R₆, P4 = R₅R₄R₆ be the Path Sets between Input and Output. Where R₂, R₃, R₄, R₅, R₆ are the components of the network (System).

In order to calculate the probability of success of the network a Boolean expression can be written such that all the terms of that expression are disjoint. This method of evaluating reliability is called Sum of Disjoint product. This disjoint form has one to one mapping with the probability expression.[7]

2.1.16. MVI (Multiple Variable Inversion):

MVI is a technique based on Boolean algebra used to generate a compact expression of SDP terms. In this technique a group of variables are inverted simultaneously. This results in generating a compact Boolean expression at very efficient processing time. The mentioned Lemmas in the illustrated table are used by MVI techniques to extract compact and disjoint form of Boolean expression.[8]

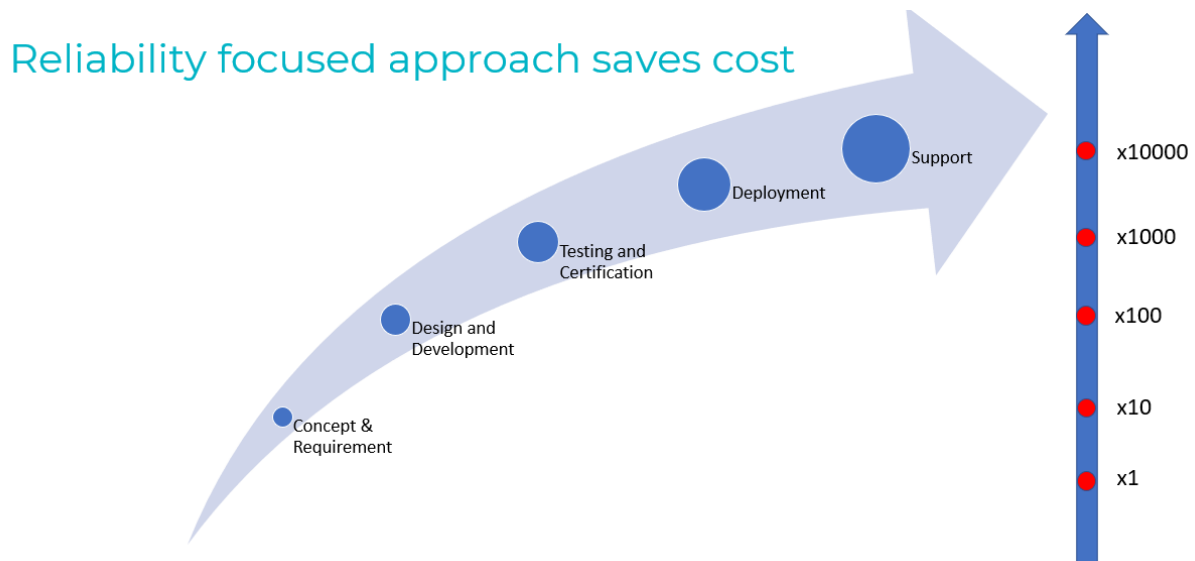

S. No	Lemma	Explanation
1.	$\overline{U}V.U \equiv \emptyset$	
2.	\overline{UV}	$\overline{UV} = \overline{U} + U.\overline{V}$
3.	$\overline{UV}.\overline{U} \equiv \overline{U}$	$(\overline{U} + U.\overline{V}) \overline{U} = \overline{U}$
4.	$\overline{UV}.U \equiv U\overline{V}$	$(\overline{U} + U.\overline{V}) U = U.\overline{V}$
5.	$\overline{UV}.\overline{UW} = \overline{U} + U.\overline{V}.\overline{W}$	$(\overline{U} + U.\overline{V})(\overline{U} + U.\overline{W}) = \overline{U} + \overline{U}.U.\overline{W} + U.\overline{V}.\overline{U} + U.\overline{V}.\overline{W}$
6.	$UV + UW = U.(\overline{U} + (V + W))$	$U.\overline{U} + U.(V + W) = U.(\overline{U} + (V + W))$

Figure 2: Boolean Lemmas

3. Reliability As A Mindset

It is common knowledge that Reliability is synergy of Statistics, Physics and Engineering. This concept of Reliability is absolutely true. However, besides the pure objective part of Reliability Engineering, there is also a subjective aspect. That subjectivity is associated with the mindset that any reliability-aware organization should have intentionally evolved. This mindset involves viewing every part of the organization as contributor to reliability.

This vision of reliability not only enhances the customer experience but also provides enormous cost savings. The following chart will give an idea:

4. Useful Life Of Components

There is a usual failure pattern in the lifetime of components when they are placed in service. These patterns are resultant of weaknesses in the components resulting in early-stage failures, normal random failures due to natural phenomenon of physics, and failures due to aging of the component. The following graph shows the three types of failures with their distributions and also the combined failure:

Figure 4: Example of Bathtub curve created by different life stages

If we take a large sample of components and operate them under constant conditions, a statistical pattern emerges with three regions. Each region providing its own interesting failure/ hazard behavior.

4.1.1. Early Failures:

This pattern of failures is also called burn-in, or debugging period. These failures are related to weakness in hardware, software, or design. Issues that arise during this period can be stabilized. These failures fit in a Weibull distribution. The **failure rate** in this region **decreases very rapidly**.

4.1.2. Chance Failures:

The useful life of the component starts after the burn-in period. This is the period where failure rates are at the minimum level. During this period the failure rate is constant which tells us that chance failures cannot be prevented by any replacement policy. Also, due to **constant failure rate**, these failures fit into exponential distribution.

4.1.3. Wear-out Failures:

The wear-out begins when the element has lived its life in terms of age, stress, or cycles of operation. **Failure rate starts increasing very rapidly** with the start of wear-out time. The simple indicator of wear-out time is a period during which approximately one-half of the total population will fail. These failures fit in Lognormal distribution.

The golden rule of reliability is to replace the component as it fails during the useful life and proactively replace them before the end of their useful life. The actual algorithms and optimization techniques of proactively replacing the component are not in the scope of this discussion but plenty of literature is available in this regard.

5. Failure Distribution

For an operating network it is important to understand the distribution of categories of failures. An example of a distribution is illustrated as follows:

Figure 5: Example distribution of categories of events causing outages

This distribution allows us to identify the opportunities to enhance the reliability of the network. This will provide a very good data point to teams to start with their Failure Mode and Effect Analysis, and Fault Tree analysis.

Few examples from above illustration produces these observations:

- Failure cause code 1531 – Power. This indicates that the failures are attributed to the failure of electrical power managed by the service provider. This opens the opportunity to prevent power failures either by providing redundancy, back up, or in some cases, simple routine preventive maintenance of a backup power generator.
- Failure cause code 150 – Scheduled Maintenance. This failure cause code is attributed to failures that occur during scheduled maintenance. The opportunities for improvement are multiple including the potential for enhancement of method of procedures, network impact analysis, customer impact analysis, and data integrity of the network inventory management systems to name a few.
- Provisioning Incomplete 119 – This failure cause code can be attributed to the process of provisioning all service attributes in the system. It opens a number of systemic and

communication opportunities. Many times, these scenarios bring into light the issues like flexibility of product or need for automation.

6. Reliability Evaluation of the Network

Reliability of the system is the sum of reliabilities of its components. The components themselves are dependent on the reliabilities of their elements. There are numerous techniques and algorithms to determine overall reliabilities of the system.

A system can be a small system with very few components in it, or the components may be connected in a simple manner such as a series. Any component failure will cause system failure.

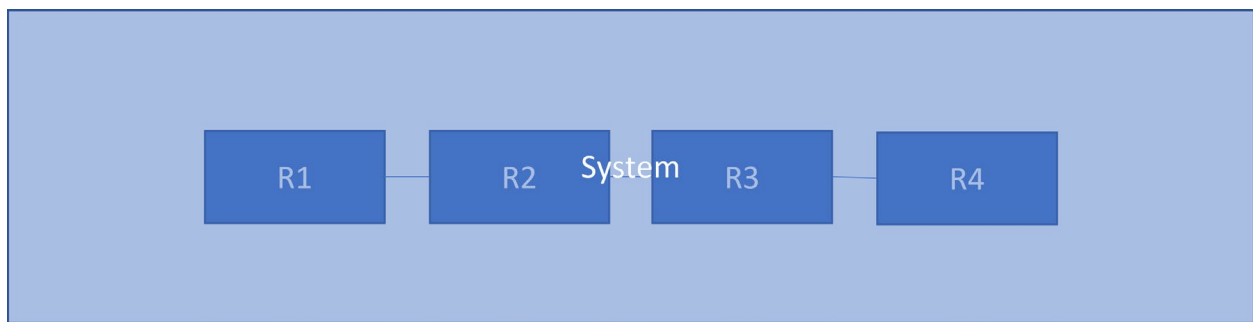

Figure 6:Series System

Another configuration could be that a few components are connected in parallel for the sake of redundancy. This system is termed as Series Parallel System.

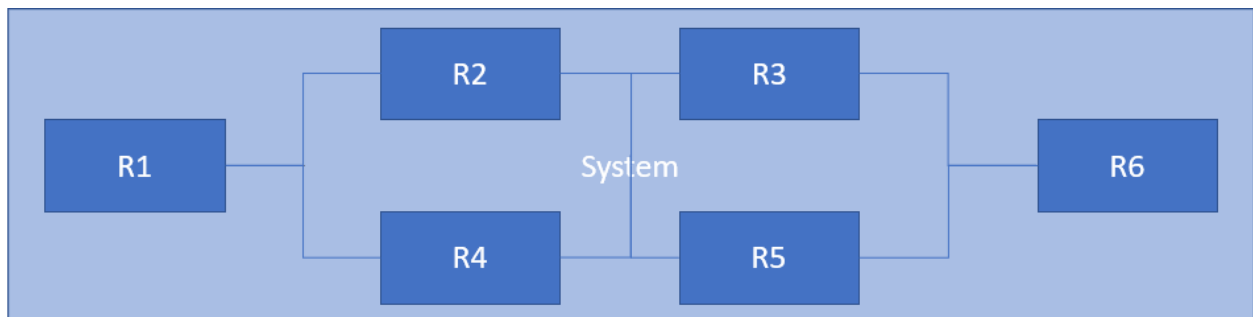

Figure 7:Series Parallel System

The next configuration is a Non-Series Parallel system (NSP). This is the configuration that presents us a reliability evaluation problem in most of our scenarios. The example is illustrated in the following picture.

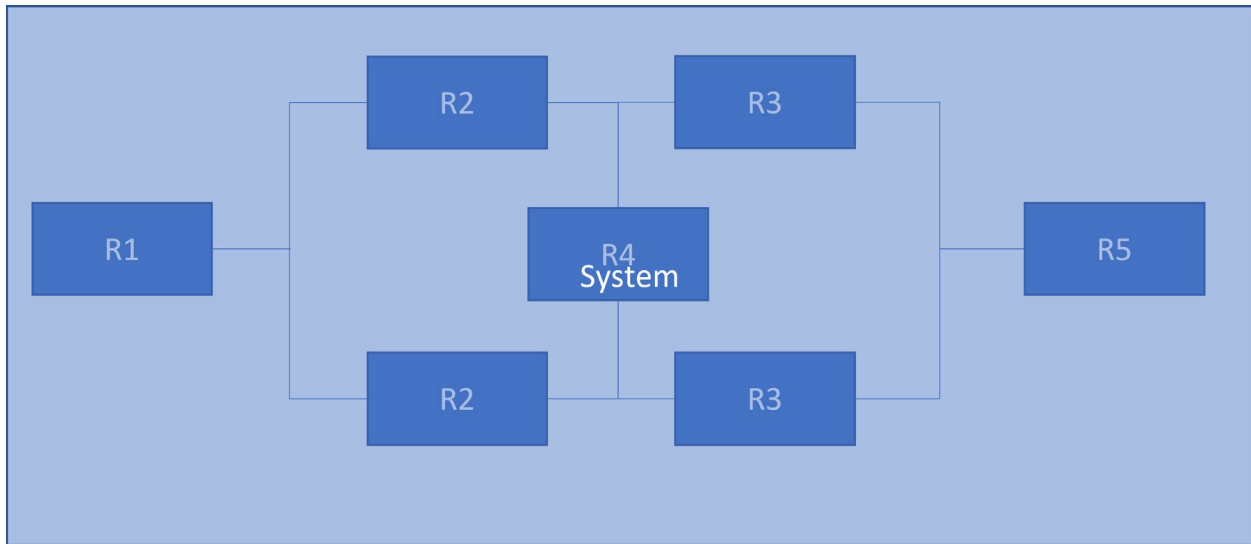

Figure 8: Non-Series Parallel System

6.1. Reliability Evaluation of a large Network

Figure 9: Small Sample NSP Network for Reliability evaluation

The above picture shows a network with n1, n2 as input and output nodes respectively. Nodes n3, n4 are intermediate nodes. A, B, C, D, and E are edges.

In order to evaluate the reliability of the above network following two assumptions are made in order to simplify the mathematics:

1. Edges failure (success) are statistically independent
2. Nodes are perfectly reliable

Let p_a, p_b, p_c, p_d, p_e be success Probabilities of Edges A, B, C, D, E respectively.

Also, q_a, q_b, q_c, q_d, q_e be failure Probabilities of Edges A, B, C, D, E respectively.

Using available reliability evaluation methods, the reliability of the system is calculated as follows:

$$R(z) = p_a p_b + p_a p_c q_b p_d$$

There are several algorithms and techniques for evaluation of reliability of large networks. They had their own advantages and disadvantages in terms of efficiency, scalability, and accuracy.

With the recent contributions and advancements, Graph Theory has been playing a very important role in the field of reliability evaluations of large networks.

In this paper we will evaluate the reliability of a very large network using Sum of Disjoint Product (SDP) and Multi Variable Inversion (MVI) techniques. This is a three-step process.

1. Create reduced network topology
2. Extract minimal path set or minimal cut set from the topology
3. Evaluate reliability from the path set or cut set extracted from step 2 using SDP and MVI

Step1.

For the current networks spanning large distances, operators are using the model of access network delivering to a full or nearly fully meshed core network as illustrated below:

Figure 10: Example Point 2 Point link between customer locations

From this illustrated network it is evident that there are potentially hundreds of millions of paths sets or cut sets. This makes any reliability evaluation algorithm reach its processing limits and accuracy suffers due to roundup errors.

In this paper we address this problem by reducing the size of this network into a focused network. We are aware of the situation where network boundaries are limited by the latency introduced by the links. If the total latency introduced is beyond the service level objective, then that path is a failed path (infinite horizon). Based on this philosophy we have extracted path sets belonging to k-shortest paths. Following table list the 8 shortest paths between node 1 and node 2011:

Table 1: k-Shortest Paths

Path	Latency(ms)
[1, 25, 62, 2011]	12.20812742
[1, 53, 62, 2011]	12.20812742
[1, 25, 37, 62, 2011]	12.22414687
[1, 53, 65, 62, 2011]	12.22414687
[1, 25, 65, 62, 2011]	12.22414687
[1, 53, 37, 62, 2011]	12.22414687
[1, 25, 34, 2011]	12.40271075
[1, 53, 34, 2011]	12.40271075

These paths are then merged into a new reduced subgraph as illustrated below.

Figure 11: Simplified network topology

Step2.

At this stage we must decide whether we should utilize a cut set or path set approach. It has been suggested by Aggarwal, Chopra, & Wajwa, (1982) that for a network of n nodes and l links, the number of cut sets between any pair of nodes would be of the order of 2^{n-2} , whereas the number of path sets is of the order of 2^{l-n+2} . From this recommendation the estimated cut set = 64 and path set = 256.

Hence, we have decided to use cut set approach.

The cut sets are enumerated as per algorithm described in Ahmad, (1990).

The following cut sets were returned by using the algorithm:

Table 2: Cut Sets for the reduced network graph

Cut Sets		
2 8	1 7 8 9 10 14	1 5 7 8 9 12 14
6 7	2 3 7 11 12 13	2 3 4 7 9 11 12
2 11 14	3 4 6 9 12 14	2 3 5 7 10 11 13
1 3 4 5 8	3 5 6 10 13 14	3 4 5 6 9 10 14
1 7 9 10 11	3 6 8 11 12 13	3 4 6 8 9 11 12
3 6 12 13 14	1 2 4 6 10 13 14	3 5 6 8 10 11 13
1 2 6 9 10 14	1 2 5 6 9 12 14	1 2 4 5 6 12 13 14
1 3 4 5 11 14	1 3 4 10 11 12 14	1 3 9 10 11 12 13 14
1 3 4 8 10 12	1 3 5 9 11 13 14	1 4 5 7 8 12 13 14
1 3 5 8 9 13	1 3 8 9 10 12 13	2 3 4 5 7 9 10 11
1 4 7 10 11 13	1 4 5 7 11 12 13	3 4 5 6 8 9 10 11
1 5 7 9 11 12	1 4 7 8 10 13 14	

We can visually verify that the links in each cut set is isolating network with node 1 (Source) with node 2001(Sink).

Step3.

Finally, we can now evaluate reliability of the network by using CAREL algorithm (Soh, S. & Rai, S., 1991 [7]). The input that mentioned algorithms needed are minimal cut sets and failure probability of the link. We assumed that all links fail with 0.1 probability.

After applying CAREL algorithm to the minimal cut sets derived in Step 2, the Reliability / Unreliability of the Mentioned P2P links is calculated as following:

System Unreliability = 0.02082693568

System Reliability = 0.979173064

With total disjoint paths = 76

7. Reliability Cost Optimization

Every organization aspires to achieve maximum profit while keeping customer satisfaction at an optimum level to sustain the profit margin. Reliability engineering is the scientific tool that management can use to keep balance between customer satisfaction and cost of the product or services.

The following picture is illustrated to enumerate important categories that contribute to the cost incurred by implementing Reliability enhancement methods.

Reliability Costs				
Internal Failures	Prevention Cost	Administrative Cost	Testing and Detection Cost	External Failure Cost
<ul style="list-style-type: none"> • Root Cause Analysis • Testing Cost • Fix , Upgrade cost 	<ul style="list-style-type: none"> • Vendor evaluation Cost • Device Certification Cost • Network Design certification Plan • Customer Impact Analysis • Data collection, storage and Analysis 	<ul style="list-style-type: none"> • Reviewing Contracts • Preparing Paring Budgets • Forecasting • Management 	<ul style="list-style-type: none"> • Cost of Monitoring and Detection(Operation Centers) • Cost of Testing Infrastructure 	<ul style="list-style-type: none"> • Cost of Customer care • Cost of customer credits • Cost of replacement and credits in leu of damage control • Cost of repair

Figure 12 :Reliability cost categories [7]

It is not always profitable to increase reliability to achieve perfection. There is always an optimum point where a balance should be made. That decision of balance shall be dictated by the facts emerging from reliability analysis as shown in this diagram.

Figure 13: Cost curves for the service/product [7]

There are several cost reliabilities functions in the literature. A few have been listed here:

- Misra et al Function
- Tillman et al Function
- Aggarwal et al Function
- Fratta et al's Function
- Majumdar et al's Function
- Llyod and Lipow's Function

A hypothetical study is illustrated here on a model trained on real failures from a very large network. Here the goal is to showcase an optimum time at which the preventive maintenance shall be done on the devices. In this example the cost of preventive maintenance is 5 and cost of corrective maintenance is 200.

Cost model assuming as good as new replacement ($q=0$):
The minimum cost per unit time is 0.0092
The optimal replacement time is 1095.22

Figure 14: Optimal preventive maintenance time

8. Conclusion:

As we discussed in this paper reliability of the network needs to be measured, monitored, tested, and investigated continuously. The reliability should be investigated for each product right from its inception. We have talked about different life stages of components. Reliability evaluation technique is demonstrated with an optimized approach for large networks.

Referring to Figure 14, the reliability studies can optimize the opex and capex by making optimally calculated decisions.

There is an enormous opportunity for improvement, development, and enhancement for telecom networks' reliability and availability.

1. Introduction

This qualitative study considers the relationship between an immersive Virtual Training Environment (VTE) and the post-training confidence of learners, through examining the perceptions of trainers. Study participants were selected from trainers in a large telecommunications organization who provide instruction on software and systems, including those both with and without a VTE. Six participants responded to an online survey containing closed- and open-ended questions that gathered their perceptions of post-training confidence for learners relative to use of a VTE during their training course, and responses were analyzed to identify key topical patterns. The findings indicate a perception that the presence of a VTE provides significant positive impact to the learner experience, and that the absence of one can be equally detrimental. Concepts from the literature, including exploratory and participatory learning, self-directed learning, learning transfer and others were found throughout the participant responses. The findings indicate a clear preference for VTEs and suggest an opportunity for future inquiry to establish the validity of this instructional method.

2. Overview

The use of computer software and applications has become intertwined with the work performed by most employees in both large and small organizations in the United States. A 2001 study by the US Department of Commerce estimated that 65 million adults use a computer in order to perform their job, and by 2003 that number had risen to 77 million, accounting for 55.5% of total employed persons (US Department of Labor, 2005). The ensuing years have only continued this upward trend. The transition to remote work as a result of COVID-19 further shifted the workforce to an online computer-supported work model, with many workers performing all job duties remotely via computer. Despite this clear reliance on software and applications in the workplace, many organizations still struggle to provide effective training to employees on software and applications that are necessary to perform their work.

Companies invest significant capital in proprietary software systems but still suffer implementation failures, some of which can be related to employees' inability to effectively use the systems (Marler et al., 2006). Participants often lack confidence and proficiency in the use of the software tools at the conclusion training programs, which contributes to errors and impacts both employee performance measures and the business overall. Why are some companies willing to fund the creation of new software and applications, yet hesitant to fund the corresponding training programs needed to ensure their success?

While we may consider this a modern problem, studies in the early 1990s clearly indicated a need to conduct further research to correlate failures of workplace technology to communication and training methods, and that workplace computer and software training should incorporate an understanding of learner needs in their design (Martocchio & Webster, 1992; Turnage, 1990). More recent works explore relationships between instructional methods such as video tutorials to post-training performance, learning transfer, and learner self-reported satisfaction (Van der Meij et al., 2018; Roumell, 2018; Lavendels et al., 2014).

Research has been conducted on the methods of instructional design to use in the creation of simulations or training videos (Van der Meij, 2013a, 2013b, 2014; Van der Meij et al., 2018), but minimal research has been performed relative to the concept of a virtual training environment (VTE), here defined as a full-function, separate instance of the software used to create an immersive learning experience. Virtual training tools do exist for complex procedures and systems in the medical field, and a 2017 study of a tool used to teach radiotherapy indicated that despite the availability of a virtual environment for training, many of the advanced features of the training system were unused and some organizational skepticism existed (Bridge et al., 2017). Further, current studies of adult learners in a workplace setting related to

use of VTEs for software and application training are extremely limited. The work of Van der Meij (2013a, 2013b, 2014) and Van der Meij et al. (2018) provides a fascinating and relevant starting point, but focuses on the experience of K-12 learners rather than workplace learners. Further inquiry into the experience of adult learners in the workplace could help expand the collective understanding of this important and timely topic.

Based on my own observations and anecdotal conversations with both instructors and learners during my eighteen years as an adult learning professional in a large technology organization, learner confidence and proficiency post-training may have a relationship to the methods used in the training program. Specifically, learners who are afforded an opportunity to use a VTE report greater confidence in its use after the completion of the program. Learners who have been presented only video simulations have struggled to effectively use new software and their self-reported confidence post-training is low. The continued increase of complex and proprietary software applications as an integral part of the modern workplace indicates that further research specifically targeting the efficacy of VTEs for software and application learning is warranted and necessary.

Exploring the relationship between the presence of VTEs and efficacy of training programs can help workplace learning professionals understand the need for the initial investment in a VTE through a consideration of post-training performance. Further, instructional designers can better customize the design of software training programs to include structured VTE activities that improve learner experience and provide greater learning transfer. Businesses may be hesitant to invest capital in VTEs without a clear relationship to a return on that investment, and closer examination of the impact of VTEs on post-training trainee confidence, proficiency and workplace effectiveness can help with that justification.

3. Literature Review

Data from the US Department of Labor (2005) indicate that workplace use of software and applications will only continue to trend upward in the future, and companies seeking to remain vital and retain a strong workforce should cast a critical eye to the training practices used for these systems. In reviewing current literature specifically relevant to the topic of VTEs and software training methods, we will consider two main areas. First, we will examine literature related to the core principles of adult learning theory and practice, including self-directed learning theory and learning transfer. Second, we will explore current literature specifically investigating practices and methods used for software and application training in both K-12 and workplace settings.

3.1. Adult Learning Theories and Practices

What specifically differentiates the concept of a Virtual Training Environment (VTE) from other methods of software and application instruction such as videos or e-learns? How might existing research help to differentiate a need for this instructional methodology? An answer may be found in early concepts of andragogy and adult learning theories first explored by Knowles, who presented a series of five foundational characteristics of the adult learner which have since been incorporated into the collective understanding of adult learning theory (Merriam & Bierema, 2014). Among these principles are that adults have “an independent self-concept. . . and can direct [their] own learning” and that they are “problem-centered and interested in an immediate application of knowledge” (Merriam, 2001, p. 5). These two foundational principles directly support the use of software VTEs in the workplace learning environment, since one of the differentiating factors of a VTE compared to other instructional methods is that the learner is afforded an opportunity to experience an immersive environment in which unstructured self-directed learning can occur, and practice can directly mimic very real and practical skills that can be immediately put into use back on the job.

3.1.1. Self-Directed Learning Theory

Self-Directed Learning (SDL) as a learning theory is a fundamental concept and has been extensively researched and practiced for over fifty years (Merriam & Bierema, 2014). Tough's 'Adult Learning Projects' during the 1970s provided an in-depth study of how adult learners work through the process of selecting the topic(s), resources, and materials needed to support a specific learning endeavor (Abdullah et al., 2008). A more recent piece by Hendriks et al. (2018) focuses specifically on the workplace learning experiences of customer-facing employees, as related to SDL and integration of technology. The study found a correlation between participant comfort with technology and a perspective that technology is integral to work and career development.

Caruso (2018) further explored the correlation between the effectiveness of learning outcomes and the use of technology-supported SDL methods during learning events. She found that the use of Web 2.0 technologies (defined in the scope of the paper as socially-driven resources or applications such as media sharing, discussion boards, search tools and the like) are effective in supporting both structured and informal learning events in the workplace if they are strategically and deliberately used and the guidelines around their use are clear to the learner. Learner affinity and comfort with technology also directly impact the effectiveness of technology-supported SDL and in order to remain nimble in a quickly changing marketplace, employees need to be afforded the technological tools to enable them to use SDL principles and informal learning to meet the needs of the organization (Fleming et al., 2014).

3.1.2. Learning Transfer

While the concepts of SDL instructional methods provide a compelling case for the use of VTEs from a participant experience perspective, an even stronger case can be made related to the concept of learning transfer, which is most simply explained as the ability to put the new skills learned in the classroom environment into practice (Roumell, 2019). Foley and Kaiser (2013) defined the different levels of learning transfer, including near and far, positive and negative, and high- and low-road transfer. The context of the VTE aligns closely with the concepts of near transfer, meaning the newly-experienced situation is similar to the original learning; and low-road transfer, where the technique or skill is practiced extensively in the learning environment so that its replication is nearly automatic in the new experience (Foley & Kaiser, 2013). Foley and Kaiser also noted that instructional practices can become barriers to learning transfer, specifically noting situations in which opportunities to practice transferable skills are lacking in the learning environment. To remediate this, the authors recommend several techniques, the most relevant of which to our current context is the concept of scaffolding, which affords learners structured tools to enable them to construct their learning. This aligns with the concept of a VTE, in that the learner is empowered to construct their own learning experience while still receiving support and guidance (scaffolding) of the learning process by the instructor.

Hardré (2013) explored the concept of learning transfer specifically in the context of technology training and proposed that the effectiveness of learning transfer is related to the concept of authenticity, defined as the realism of the training experience compared to the actual environment. Hardré further noted that effectiveness of software training videos or e-learning courses is limited when there is low authenticity to actual tasks or work environments. Relevant to the scope of this work is Hardré's concept of the authenticity of the learning environment, considering that often the learning environment holds less distractions, variables and errors than the "real world" and as a result, the learner may not be able to effectively transfer their skills outside of the classroom. The concepts of authenticity of representation and authenticity of interactivity are key to the potential value of a VTE, since they specifically indicate the need for the technology learning experiences to be as true-to-life as possible, affording the learner an experience that effectively mimics their ultimate experience.

3.2. Software Training for Adult Learners: Early Inquiries

Beyond the core adult learning theories and practices that support the concept of VTEs, research and inquiry into the nuances of software training for adult learners provides important insights. A need for research into the effectiveness of software training was recognized in the early 1990s, and researchers sought to explore how training methodologies and course design could be used to maximize learning outcomes (Martocchio & Webster, 1992; Turnage, 1990). Martocchio and Webster (1992) proposed that “cognitive playfulness” during the learning process is related to greater effectiveness, indicating that learners “exercise and develop skills through exploratory behaviors, resulting in enhanced task performance” (p. 557). They conducted a study with 68 individuals employed at a large public university who were enrolled in a training course on a word processing program, and their findings indicated a strong correlation between learners high in playfulness to positive outcomes both in test scores and post-training performance. They recommended further research on the topic, noting that outcomes may vary between students and those in a workplace learning setting. The early need for a customized and enhanced approach to workplace training to suit the computer-based work environment was also recognized by Turnage (1990) who somewhat presciently stated:

“Training will change as computer based training becomes more prevalent with new applications including embedded training, computer literacy, interactive video disc, and electronic lectures. Intelligent computer-assisted instruction (CAI), authoring systems, hand-held computers, speech processing, and new telecommunication technologies will also shape the future direction of automated instruction in the workplace.” (p. 176)

3.3. Technology for Adult Learning: Simulations and Learner-Centered Design

While these early works provide us important context, recent studies allow for more relevant and timely inquiry into the topic of software training methods for adult learners. Hardin et al. (2013) explored the effectiveness of computer simulated software training systems (CSSTS) and investigated the connection between software self-efficacy and post-training effectiveness. In this context, a CSSTS is defined as “a specific type of e-learning self-study system that has become immensely popular for facilitating software instruction” (Hardin et al., 2013, p. 4). Important to note here is the difference between the CSSTS and the VTE discussed within the scope of this inquiry - specifically, the CSSTS is a *simulation* of the software, which provides a more structured experience for the learner; whereas VTE is a fully immersive instance of the *actual* software that allows the learner greater self-direction and control of the learning activities. The research reviews user perceptions of a CSSTS that uses a model of “Teach Me, Show Me, Let Me Try” to guide learners through the steps of the learning process, moving from a verbal instruction, demonstration, and unaided practice. The findings of the study indicate that learners with a high self-reported software self-efficacy (SSE) score (in other words, those who indicated on a survey that they were confident in their ability to learn a new system) were less likely to utilize the “Teach Me” and “Show Me” portions of the CSSTS, but instead were more likely to proceed directly to the “Let Me Try” feature.

Lavendels et al. (2015) explored the use of an online learning methodology in the insurance industry for employees learning to use a complex software solution that contains sensitive customer data. The research proposes a remote training process in which the trainer and the trainee are in different locations, and the trainer utilizes a screen-share application to review the trainees’ work and provide feedback. Due to the intensive nature of the program discussed, Lavendels et al. specifically called out the need to have synchronous trainer oversight and coaching for the trainees as they learn, since their activities are performed within the production system rather than a VTE. The concerns raised about training in a

production environment align with the scope of this inquiry related to a VTE, although the remote instruction aspect will not be addressed here.

Bridge et al. (2017) studied user perceptions of the Virtual Environment for Radiotherapy Training (VERT), an immersive 3-D software solution designed to teach medical personnel skills and procedures needed for administration of radiation therapy to patients. Users of the VERT tool were surveyed, and while overall feedback on individuals' perceptions of the value of the tool was positive, the researchers found that 32% of those surveyed reported that their organizations had a perception that VERT was not actually useful. The researchers were not able to identify a clear reason for these organizational impressions, and greater inquiry into this type of impression of virtual training systems and software could be beneficial to helping identify why companies may be hesitant to invest in this type of learning solution.

The concept of participatory design (PD) in technology learning experiences was explored by Inguva et al. (2018), citing the value of including various self-directed and experiential learning methodologies to create a more learner-centered environment in a university engineering laboratory. Specifically, the researchers studied the use of a practical, hands-on learning model called the "Knowledge Laboratory" in which undergraduate students were provided an opportunity to work in small groups in a self-directed fashion through exploratory and experiential learning. The researchers surveyed students who participated in a more traditional instructor-centered course design, and those who participated in the PD model. Those in the instructor-centered model reported that they did not feel challenged by the delivery method, had less interest in the content, and struggled to find relevance in the content and topics. Conversely, students who were provided the opportunity to approach their learning in a more participatory, self-directed method with more realistic practice scenarios reported they were better able to understand the relevance of the work, and that their overall understanding of the processes being taught were greater.

Both Inguva et al. (2018) and Bridge et al. (2017) noted that an overarching benefit of their respective virtual environments was the ability for learners to gain confidence and skills through realistic simulations in the learning environment, rather than in a higher-stakes environment after the learning. This closely aligns with the concept of the VTE, where learners are provided an opportunity to practice in the safe learning environment of the classroom without fear of making mistakes that could impact customers or the business.

3.4. Software Video Tutorials in the K-12 Environment

Extensive and detailed research exists in the K-12 space on design and implementation of software training, although the research is centered around the creation of software videos rather than a VTE. In a 2013 work by van der Meij and van der Meij, the authors proposed a series of eight guidelines for the design of instructional videos for K-12 software training and provide a definition for the term "video tutorial" to mean a "set of videos that together form an instructional package" (p. 207). A notable difference between this paper's definition of a VTE and the definition from van der Meij and van der Meij is that the video tutorial is a guided, structured learning experience; whereas the VTE is an open-ended unstructured environment in which the learner is free to explore and self-direct the process of learning. Regardless, many of the design concepts and guidance discussed in the work are equally applicable to the concept of a VTE. Specifically, Guideline 2 from the work calls out the need to ensure that the video tutorial "gives the user the same image that he or she is likely to be facing when trying to execute the task" and Guideline 3 specifies the need to incorporate an element of user control of the video tutorial (van der Meij & van der Meij, 2013, p. 210). Additionally, the researchers note that their design principles align both with the concept of constructivism and with multimedia design principles from Mayer (2003). Both Guideline 2 and Guideline 3, and the constructivist and engagement theories are

aligned with the use of a VTE since it is an immersive instance of the software. A later work by van der Meij et al. (2017) elaborated on the guidance from the 2013 study and noted that video tutorials not adhering to these design principles failed to successfully prepare the learner to use the software, even when the steps were clearly and accurately portrayed in the video.

3.5. Conclusions

Existing research and inquiries provide critical insights into learner needs in the software and application training space. While adult learning theories and practices have a long history, recent works continue to support the needs identified by Knowles in regards to adult learner self-direction, exploratory or experiential methods, and the importance of learning transfer (Foley & Kaiser, 2013; Hardré, 2003; Roumell, 2019). Core andragogical theories such as self-directed learning theory and learning transfer provide overall conceptual support for the value of a VTE, relative to the need for authenticity of the training experience and appropriate learner involvement in constructing meaning. Beyond the theoretical considerations, current research describing training methods or practices provides additional perspective, but there is still a gap in the collective body of work. Specifically, most research has been done on the modality of e-learns, videos or other more guided/structured teaching methods, rather than the open-ended exploratory environment a VTE provides. In addition, a significant amount of the available research focuses on participants in a K-12 environment, rather than the workplace environment of adult learners.

The purpose of this qualitative study is to describe the impact of the presence or absence of a Virtual Training Environment (VTE) on the post-training confidence and proficiency of trainees, by exploring opinions of trainers at a large national telecommunications organization. To do so, we pose the following questions:

- What is the trainer perception of the post-training confidence level for telecommunications employees who are provided access to a Virtual Training Environment?
- What is the trainer perception of post-training confidence level for new telecommunications employees who are not provided access to a Virtual Training Environment?

4. Research Methods

As detailed in the literature review, there is a lack of current research that directly addresses the topic of Virtual Training Environments (VTEs) in workplace learning. Seeking to gain a better understanding of the impact of these tools through the perspective of trainers required an open-ended approach that did not begin with the end in mind, as traditional quantitative research typically does. Instead, a qualitative method allowed for a more curious and exploratory approach, which provided an opportunity to learn from the experiences and attitudes of the study participants. Qualitative study enables insight into the human experience and perspective, which is a foundational element of what this research sought to identify (Creswell, 2013). It allowed a level of detail that quantitative study would not provide by capturing the very personal perspective of the participants, to help broaden the understanding of the central phenomenon we are studying. Finally, since qualitative research begins with an open mindset, the findings of this research may help inform future study on this topic by identifying themes and patterns which warrant further inquiry (Creswell & Guetterman, 2019).

4.1. Participants

The participants in the study are Training professionals in a large telecommunications organization, who support the delivery of coursework to new and experienced employees within the Field Operations

business unit. In their roles, they provide training on software and systems, including some that currently have a virtual training environment (VTE) and others that do not. As a result, their perspectives and attitudes on trainee confidence post-training relative to VTEs provides valuable insight into this research.

These individuals are a diverse group of males and females in various locations across the 41 states in which the company operates, and range in age from mid 20s to early 60s. Since the study is being performed within a workplace setting, and age, gender, and race are considered protected data in this scope, participants were not asked to provide this specific demographic information as part of the study.

Table 1 – Population Data – Total Headcount by Job Title

Job Title	Total
Field Tech & Safety Trainer	73
Training Manager	11
Senior Field Tech & Safety Trainer	79
Training Supervisor	32
Technical Service Trainer	12
Total	207

The total population of participants within the organization was approximately 200 at the time of the study (see Table 1). Because the research was intended to explore the trainers' ideas on VTEs, the concept sampling method was selected. This method enables purposeful selection of participants, areas or sites in order to uncover information about the research topic (Creswell, 2003; Creswell & Guetterman, 2019). Three of the total eleven regions were selected to participate, targeting those that have trainers who were known to be actively teaching coursework on software and applications that have VTEs, including the Northwest Region, Northeast Region, and Great Lakes Region. The Training Managers and Human Resources leaders for each of the selected regions were notified via email that they could select up to five training professionals from their team to participate in the survey. The leadership were not provided any specific criteria for selection and were free to select any of their employees. One Manager indicated that their selection was based on those employees who frequently use training environments (J. Knapp, personal communication, April 6, 2021). Northeast and Great Lakes each provided five, and Northwest provided three, for a total of 13 participants. This represented 6.2% of the total training staff population, and represented 33% of Great Lakes training staff population, 23.8% of the Northeast training staff population, and 18.7% of the Northwest training staff population (see Table 2).

Table 2 – Sample Data – Total Headcount for Selected Regions

Region	Total	Number Selected	% of Regional Training Population
Field Ops Great Lakes	15	5	33.0%
Field Ops Northeast	21	5	23.8%
Field Ops Northwest	16	3	18.7%

In addition, the distribution of job titles was five Field Technical & Safety Trainers, (7% of the total population of this job title), five Senior Field Technical & Safety Trainers (6% of the total population) and three Technical Service Trainers (25% of the total population), as shown in Table 3.

Table 3 – Participant Data – Job Title Distribution

Job Title	Total	Number Selected	% of Total Population
Field Technical & Safety Trainer	73	5	7%
Senior Field Technical & Safety Trainer	79	5	6%
Technical Service Trainer	12	3	25%
Total	13	164	8%

4.2. Permission

The Senior Directors of Human Resources leadership within each Region were the gatekeepers who authorized access to the study participants detailed in the Participants section. They directly manage the training departments, and the recruiting and training process as a whole within their respective regions (see Figure 1). Their permission was necessary to gather data from the participants (indicated in green in Figure 1), since they are the senior leaders for that organization (indicated in orange in Figure 1). In addition, they are uniquely suited to provide this permission since their positions are responsible for effective training for new and existing employees. Permission from the leaders within the regions whose employees were surveyed was obtained via email using the format shown in Appendix A. Training Managers for each Region were included on the email requesting access to the study participants, but the final gatekeepers were the Human Resources Directors (see Figure 1). A side benefit of using these individuals for permission for the current study is that interest may be generated, which may open the door to future studies on the central phenomenon being explored.

Figure 1 - Example Reporting Structure

Note. Example of typical reporting structure including gatekeeper (orange) and study participants (green)

4.3. Data Collection

Respondents were sent a cover letter via email, which provided background on the importance and purpose of the study, as well as including language that fulfilled the need for informed consent and confidentiality considerations based on examples from Creswell & Guetterman (2019). Respondents were given 10 days to complete the survey, after which time the survey was closed and no new responses were accepted.

Data was collected via an online survey using SurveyMonkey™, which included a series of open- and closed-ended questions. An online survey method was selected to allow greater time for coding and analysis of responses in two significant ways. First, by removing the need to transcribe a recorded interview or notes, more time was available for review and analysis of the data. Second, an online survey allowed participants to respond asynchronously during a window of time, thereby avoiding scheduling challenges and lengthy phone or online interviews. Beyond reasons of efficiency, this method also improved the credibility of the research through greater number and diversity of responses, compared to fewer but lengthier one-on-one interviews often used in qualitative research. There is a notable challenge with qualitative methodology and gathering greater numbers of responses, since greater volumes of information require more time for analysis to identify and interpret themes (Creswell, 2003; Creswell & Guetterman, 2019).

The survey began with an open-ended question asking the participants to provide their own interpretation and definition of a training environment or VTE, which was designed to help identify whether a common understanding of this concept existed amongst the participants. As noted previously, the survey did not include demographic questions such as sex or age, since it was distributed within a workplace environment in which these data points are considered sensitive or protected. Instead, the survey contained a question on current job title and a question on tenure in a training role.

In addition to the modified demographic questions, the survey also contained questions that began with a closed-ended question, followed by an open-ended question to enable more exploration of the answer, as demonstrated in Creswell and Guetterman (2019). For example, participants were asked to read a statement (e.g. “Having a training environment for practice during class helps participants be more confident after they’re back on the job.”), then used a Likert scale to indicate their relative level of agreement or disagreement with the statement. The subsequent question asked the participants to explain their response to the prior question in more detail. This was designed to help with narrowing the focus to key categories that were anticipated to emerge during the data analysis.

4.4. Data Analysis

After the survey concluded, the data was exported into a spreadsheet from the survey system. Each respondent was assigned a number (e.g. “Respondent 1”), which was used throughout the rest of the study to notate and track that individual’s response. The closed-ended questions were coded using Likert scale responses (e.g. 5 - Strongly agree, 4 – Agree, 3 - Neither agree nor disagree, 2 – Disagree, 1 - Strongly disagree), see Appendix C for full question and answer details. The open-ended questions were coded through reviewing the actual response text to determine common words/phrases and develop categories of ideas (Creswell, 2003; Creswell & Guetterman, 2019). After determining the broad categories apparent in the open-ended responses, major themes were developed and linked back to the research questions.

5. Results

The average time to complete the survey was 23 minutes, 50 seconds; the longest response time was 57 minutes for Respondent 1 and the shortest response time was 12 minutes for Respondent 3. Of the 13 participants invited to participate in the survey, six responded, for overall response rate of 46%. By job title, the highest response rate of 67% was among the Technical Service Trainers, and the lowest response rate of 20% among the Senior Trainers, with only one of the five responding (see Table 4). Technical Service Trainers are the job title most likely to train frequently on software and applications, and many of the tools they provide training on have VTEs so the higher response rate in this job title was not unexpected.

Table 4 – Response Rate by Job Title

Job Title	Number of Recipients	Number of Respondents	% Response
Field Technical & Safety Trainer	5	3	60%
Senior Field Technical & Safety Trainer	5	1	20%
Technical Service Trainer	3	2	67%
Total	13	6	46%

Of the six respondents, only one indicated that they had been in a training role greater than eight years, and the other five respondents indicated they had between two and five years in a training role. Participants were also asked to indicate how frequently they teach any software or applications in their classes, using a Likert scale (5 – Very Frequently, 4 – Frequently, 3 – Sometimes, 2 – Infrequently, 1 – Never). The mean score across all participants was 4, with only one participant (Respondent 2) indicating anything other than “Frequently” or “Very Frequently.” The respondents were asked to indicate whether the software or applications they currently provide training on have a VTE available or not. Four indicated that they teach some programs that do include a VTE and some that do not (indicated by “Both” in the Use VTEs column of Table 5) while the other two indicated that none of the software/applications they teach currently have a VTE (indicated by “No” in the Use VTEs column of Table 5). Participants were asked to rate the frequency of post-class support provided to trainees using a Likert scale (3 – Frequently, 2 – Sometimes, 1 – Never) and the mean score was 2.3, with all participants responding with either “Frequently” or “Sometimes”.

Table 5 – Demographic Data

Name	Job Title	Years in Role	Frequency of Software Training	Use VTEs	Post-Class Support
Respondent 1	Technical Service Trainer	>8	Very frequently	Both	Frequently
Respondent 2	Field Technical & Safety Trainer	2-5	Infrequently	No	Sometimes
Respondent 3	Field Technical & Safety Trainer	2-5	Frequently	No	Sometimes
Respondent 4	Sr Field Technical & Safety Trainer	2-5	Frequently	Both	Sometimes
Respondent 5	Field Technical & Safety Trainer	2-5	Very frequently	Both	Sometimes
Respondent 6	Technical Service Trainer	2-5	Frequently	Both	Frequently

Participants were asked to read two statements and indicate the extent to which they agreed or disagreed, using a Likert scale (5 – Strongly agree, 4 – Agree, 3 – Neither agree nor disagree, 2 – Disagree, 1 – Strongly disagree). For the statement “Having a training environment for practice during class helps participants be more confident after they’re back on the job” the mean response was 4.8, with only one participant responding “Agree” and all others responding “Strongly Agree” (see Figure 2).

Figure 2 - Question Responses – Trainee Confidence Related to Presence of VTEs

The same results were found for the statement “Having a training environment for practice during class helps participants be more proficient using the software after they’re back on the job,” with a mean of 4.8 and the same participant (Respondent 1) responding “Agree” and all others responding “Strongly Agree” (see Figure 3).

Figure 3 - Question Responses – Trainee Proficiency Related to Presence of VTE

5.1. Categories

While the closed-ended questions provided a clear foundation of the survey participants' perspectives on the efficacy of VTEs, significant information supporting the research questions was also found in the open-ended responses from the survey. In reviewing the text of these responses, four main categories were identified. These categories closely relate to the research questions and will be discussed here.

5.1.1. *Safe Environment*

The clearest and most common theme across the responses to the open-ended questions was the concept of safety within the learning experience. The first question in the survey asked the participants to provide their own definition of a VTE. Respondent 1, who is the most tenured trainer of those surveyed, defined a VTE as "a safe, controlled environment." Respondent 5 also included the phrase "safe environment" in their definition. Respondent 3 noted that a VTE provides the participant an opportunity to learn without the "consequences of a live environment," and Respondent 4 stated that having a VTE means that the participants do not have to be "scared" or "worry about blowing things up." Respondent 6 noted that a VTE provides an opportunity to "comfortably learn."

The theme of safety in the learning space emerged again in the responses to the open-ended question related to post-training confidence of the learner. Respondent 2 characterized a VTE as a "safe controlled environment" in their response, echoing Respondent 1. Respondent 3 indicated that having an opportunity to use a VTE helps alleviate the "fear of repercussions or breaking something." Respondent 4 noted that having a VTE provides a setting where learners have "little fear of ruining things or screwing up."

5.1.2. Learning from Mistakes

The value of making mistakes during the learning process was another clear pattern that emerged in the participant responses. Respondent 5 included this in their definition, stating that a VTE is an environment where learners can “play with and learn to control said program and make mistakes.” Respondent 2 noted that the positive impact to learner confidence comes from “making mistakes and learn[ing] from them rather than [sic] affecting a real account.” Regarding the concept of building proficiency through use of the VTE, Respondent 2 stated that the “inability to make mistakes in a controlled environment will hinder the learning experience because people tend to learn more from mistakes than [sic] successes.” Respondent 5 also indicated the value not only of being afforded an opportunity to make mistakes during the learning, but also that a VTE can allow the opportunity to learn how to correct mistakes, as follows:

“They also need to know how to fix what’s wrong. Especially if the mistake was their fault. Having a place to show them those errors and how to fix them will allow us to teach how to not only how to do that, but make them good at it before they reach the live application.”

5.1.3. Business Impact

Another category identified in the analysis of the open-ended responses relates to the topic of impact to the business. Respondent 6 noted in their definition that a VTE allows learners to practice navigation in the software “without impact to the business unit,” and Respondent 1 specifically called out that use of a VTE avoids “negative customer impact” by better preparing the learners for their job. Three of the respondents included statements related to minimizing the effect on the live environment/production environment in their response to participant confidence back on the job.

5.1.4. Confidence

The category of confidence with use of the tool was a major element found in many of the open-ended responses. The respondents noted that the ability for trainees to practice in a realistic simulation of the live environment and have repetitive activities was key to building their confidence and skills during training (Respondent 4 characterized it as “muscle memory”), with the word “comfort” or “comfortable” being used six times across multiple respondents and “confident” or “confidence” used four times. Respondent 5 noted that “operating one of our programs requires confidence. Having a training platform to build that confidence and make mistakes will allow the employee to become familiar and comfortable in that program.” Respondent 6 summed it up succinctly:

“For programs that we currently have a training environment for, I’ve noticed that my trainees are more confident going into their job duties. They are more comfortable with navigation and more willing to attempt job tasks that they may not be as familiar with. For programs that we do not have a training environment to use, the trainees are typically less comfortable heading into their job duties. I usually do not see them interacting with the tool as comfortably, nor using it unless they are specifically directed to and someone is there to work with them as they execute the task.”

6. Discussion

The overwhelming pattern that emerged from the responses of the survey participants to both the closed- and open-ended questions was a consensus on the value and benefit of the use of VTEs in software and application training. Even those survey participants who indicated that they teach software less frequently, or do not teach software that currently offers a VTE for training were clear on this point. The research questions related to the post-training confidence level of trainees as observed by the trainers, and

the responses to the closed-ended questions showed a clear preference for the presence of a VTE, with a mean score of 4.8 on both proficiency and confidence. Beyond just a close match to the research questions, responses to the open-ended questions contained the same concepts and ideas as those found in the literature, including the concepts of scaffolding, authenticity of the learning environment, and self-direction or exploration.

6.1. Authenticity of Learning Environment and Learning Transfer

Hardré (2003) noted that the authenticity of the learning environment vis-à-vis the actual tasks or work impacts the effectiveness of software training videos or e-learning, and several respondents alluded to this in their responses. Respondent 4 stated that by using a VTE “it’ll look familiar to them in the real world when they get out there . . . they won’t be completely lost when they see a screen that looks nothing like the old material pictures that were shown in training.” Respondent 6, who is one of the more frequent users of VTEs also noted that the VTE must be as close to the real world as possible, and that “if the training environment is too different from the live system, it can create more confusion than good.” This aligns closely with Hardré’s findings that authenticity of representation and authenticity of interactivity are critical to the ultimate success of the learning experience.

Foley and Kaiser (2013) highlighted the importance that extensive practice of skills in the learning environment ensures that replication is nearly automatic in the new experience, and the survey participants noted this in their responses as well. Respondent 4 noted “the more they practice with something, the better they will be,” and Respondent 6 stated “they are more willing to utilize the skills and translate them into live functions” if they have access to a VTE. The concept of scaffolding as described by Foley and Kaiser (2013) is also present in the responses to how the trainers teach the software today, with several respondents providing detailed descriptions of processes by which they build a series of practice exercises and scenarios whereby the learner is presented with increasingly complex tasks while receiving support and coaching from the instructor.

6.2. Learning from Mistakes and Safe Learning through Self-Direction

In much of the literature, the concepts of self-directed learning and the ability for learners to gain confidence and skills through an open-ended, exploratory environment in which they can safely make mistakes was key to success (Bridget et al., 2017, Hardin et al., 2013, Inguva et al., 2018, Merriam & Bierema, 2014, Martocchio & Webster, 1992). This concept was found throughout the open-ended responses and was one of the main categories identified in the data analysis. The consensus of the survey respondents was that without an opportunity for learners to explore, try things, and fail in a safe environment, they are not as effective or confident with the program after class. A key component of the safety of the learning environment as noted by the respondents was that the learners were able to practice skills without the risk or fear of negatively impacting customers or the business in a production environment of the program.

6.3. Study Limitations

There are at least two potential limitations related to the scope of this research. A first limitation relates to the number of respondents to the survey, which represents only a small sample of the overall population of trainers at the specific organization. While the purposeful selection of this group allowed us to gain a greater understanding of the phenomenon at the center of our inquiry, seeking insights from a larger group could increase the diversity of perspectives and create a deeper understanding of the impact of VTEs on workplace learning. A second potential limitation concerns the selection of exclusively trainers for this survey. By using the concept of triangulation and gaining perspectives from different

sources (e.g. supervisors and/or the trainees themselves) the validity of the data analysis could be improved.

Despite these limitations, the results suggest a clear connection between the presence of a VTE and trainee performance. The implication to organizations that are engaged in workplace software and application training is that the presence of a VTE can be the differentiating factor between confident, correct use of the software post-training, or potential business- or customer-impacting mistakes and errors.

6.4. Future Research

Although the findings of this particular study support the value of VTEs in workplace learning, the most important contribution may be that it raises awareness of this instructional method and creates an opportunity for further inquiry. If, as this study suggests, the presence of a VTE significantly improves both the learning experience itself and the learner performance post-training, organizations seeking to improve accuracy in software usage would be wise to continue the line of inquiry begun in this research. A recommendation would be to consider a quantitative study to better understand the actual performance measures of trainees who are afforded access to VTEs during training, and compare these to the performance of those who do not have a VTE. Alternatively, mixed-method research combining both the personal feedback of individuals and focus groups combined with quantitative performance measures may provide more robust insight into the topic. As noted earlier, organizations will require a clearly-articulated business case to justify the potential investment needed to design and deploy VTEs for their software solutions; and further research by learning professionals will be critical to help shape the future of software instruction in the workplace.

7. Conclusion

The findings of this research show a pattern of trainer perception that the presence of a VTE during software and application training provides significant positive impact to the learners' experience, and that the absence of one can be equally detrimental. Concepts from the literature, including exploratory and participatory learning, self-directed learning, learning transfer and others were found throughout the participant responses, indicating that respondents have a strong sense of what works (or doesn't work) in the learning environment based on their own experience as professional educators of adults. Although future study will be needed to further explore this topic, the present study has enhanced the understanding of the relationship between virtual training environments for software training and trainee confidence and provided clear support for the value of this instructional method.

Test Environments and Methods for Validation of DOCSIS 4 Devices

Jon-En Wang

Sr. Director, Physical & Environmental Product Evaluations
Comcast

Jon-en_wang@comcast.com

Introduction

The Comcast Physical and Environmental team is responsible for hardware evaluation for deployment into Comcast.

Our main functions are

- Research
- Product evaluation and change management
- Root cause analysis
- Standards development (CMD)
- Quality verification assurance

Our technology environments

**ELECTROMAGNETIC
COMPATIBILITY**

MECHANICAL

**MATERIAL
ANALYSIS**

**END-TO-END
ENVIRONMENTAL**

DOCSIS 4.0 implementations

Extended spectrum DOCSIS

- Downstream spectrum extended to 1.8 GHz
- Attenuation increases with frequency

Full duplex DOCSIS

- Upstream spectrum extended to 684 MHz
- Echo cancellation mitigates interference between transmission and reception

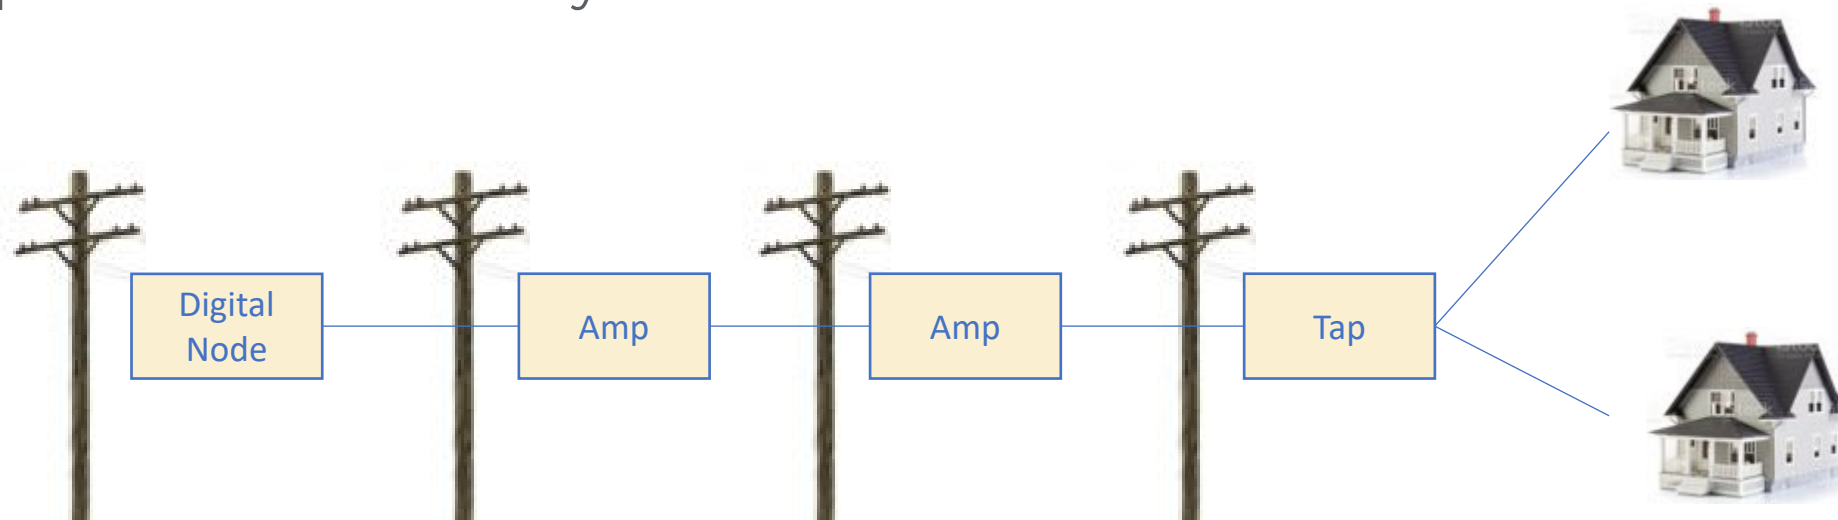

Figure 25 - Configurable FDD Upstream Allocated Spectrum Bandwidths

Source: CableLabs Data-Over-Cable Service Interface Specifications DOCSIS® 4.0

Our Environment

- Variety of networks due to geography, power, and density
- Cascade of plant components (nodes, amplifiers, taps, cables, connectors) contribute to RF performance
- Impairments from craftsmanship or other causes
- Temperature and humidity

Dense MDU - high density

Dense MDU

Frequency Domain - Single Tap

Frequency domain measurement shows return loss degrades as taps are added

Time element needs to be measured differently

Dense MDU

Time Domain – Individual Taps

Time domain measurement shows 2 reflections from each tap, corresponding to the interface between the connector and the input and output ports of the tap

Each tap was the same body style, resulting in the same travel time for the reflected signal from each interface

Dense MDU

Time Domain –Cluster of 4 Taps

Time domain measurement shows additional reflections at longer times as taps are added.

The added reflection times correlate to the extra path lengths for the reflected signal to travel.

Dense MDU

Frequency Domain - Multiple Tap Clusters

Frequency domain measurement shows return loss degrades as taps are added

Time element needs to be measured differently

Dense MDU

Time Domain – Multiple Tap Clusters

Second cluster of taps added with ~80 feet of hardline cable in between tap clusters.

Calculated round trip delay based on RF signal propagation over 80 feet of cable is 187 nanoseconds.

Return loss of the second cluster of taps is attenuated by coaxial cable as well as tap's through port loss.

Summary

Most contribution to reflection amplitude is from the closest tap cluster

Time domain analysis shows that reflections from multiple taps in a cluster, and from multiple clusters are important and must be recreated

Complete plant models can be recreated in environmental chambers for testing to outside plant conditions

Creating Infinite Possibilities.

Thank You!

1. Abstract

Subscriber satisfaction is increasingly about delivering services with the right latency and throughput characteristics. So, how does Orthogonal Frequency-Division Multiple Access (OFDMA) technology deliver this in the home? This paper analyzes empirical testing within a home using typical Wi-Fi clients, focusing on latency and throughput with real-world traffic patterns.

OFDMA in Wi-Fi 6 and Wi-Fi 6E allows for simultaneous transmissions on all spatial streams for each device and subsequently results in lower latency and less contention of airtime. When using both Wi-Fi 6 clients and legacy clients with OFDMA enabled, the latency and jitter improvements are still seen. Wi-Fi 6E access points and clients fully realize OFDMA latency reduction with 6 GHz greenfield spectrum.

The results of testing empirically focus on latency, throughput, and application performance for each Wi-Fi standard and OFDMA setting and showcase use cases of traffic patterns in a house with different client utilizations. By showing latency for a given client while changing only the access point mode and OFDMA settings, a latency reduction is realized in homogeneous client environments as well as mixed client environments. This paper will explain a method for evaluating OFDMA without expensive test equipment or ideal lab setups while providing decision points for when to invest in Wi-Fi 6 or Wi-Fi 6E access points and when to expect an improvement from enabling OFDMA.

2. Introduction

Subscribers are increasingly dissatisfied with their quality of experience (QoE), using programs and applications that have sufficient bandwidth in the home yet are plagued by a problem they do not fully understand: too much latency. Multiple System Operators (MSOs) traditionally sell speed or bandwidth tiers but not latency tiers. Much of the latency conversation is traditionally regarding the wide area network (WAN) access layer to the internet, whether this is fiber, Data Over Cable Service Interface Specifications (DOCSIS), digital subscriber line (DSL), or Satellite. However, the Wi-Fi connection from a gateway/access point (AP) is a common medium by which users access the internet regardless of the WAN link being used.

Using a Wi-Fi 6 or Wi-Fi 6E AP, with OFDMA support, along with devices that also support Wi-Fi 6 or Wi-Fi 6E, allow for a lower latency access to the shared Wi-Fi medium for a more responsive experience during congested or multi-client situations. Improving one layer of the larger network can have a dramatic increase in the QoE of the end-user. All latency values reported in this paper were tested without a contribution from WAN latency [3] referred to in Table 1, which should be considered in addition to values reported in the test results of this paper.

Table 1 – RTT Latency Added from WAN

Last Mile Connection	Latency Contribution
Fiber	10-20 ms
DOCSIS	15-40 ms
DSL	30-65 ms
Satellite	45-500 ms

OFDMA can be used between an AP and client that both support OFDMA. Improvements in latency are possible in mixed legacy client populations by allowing OFDMA capable clients to have some improved latency while less capable clients are still using legacy Wi-Fi standards and continue to tie up access to the whole channel for part of the time. OFDMA is not a feature that is meant to increase throughput and, in many scenarios, can decrease speeds in the current generation of chipsets and software. Decisions on

grouping OFDMA capable clients and other scheduler decisions to prioritize speed or latency over one another, as well as serving legacy clients, can change the total throughput seen with OFDMA enabled, negatively impact latency, or cause variation in test results from run to run. In some cases, the data will demonstrate latency is improved, while in other cases it is about the same or worse.

A real house with OFDMA capable clients using a common Wi-Fi client chipset was used to run a few APs through tests to show the relative difference for the same channel but with different OFDMA settings and AP modes used. While changing the wireless mode between Wi-Fi 5, Wi-Fi 6, and Wi-Fi 6E, several variables were tested. This included OFDMA enabled and disabled, different traffic patterns to a client under test, different channel utilizations from other clients, different packet sizes, and different protocols in the downstream and upstream directions while measuring RTT latency on the client under test. Total throughput was also observed, and although Wi-Fi 6 and 6E increased the MCS data rates to support 1024 QAM, as well as allowed better usage of the spectrum with smaller subcarrier width and more efficient use of the spectrum for data subcarriers, throughput was not a focus of the paper.

Results in this paper will show that as you increase the channel utilization or the throughput needs of the client under test, both conditions are more conducive to showing a decrease in latency if OFDMA is enabled. The reduction in average round trip time (RTT) latency is sometimes seen but more often a dramatic decrease in the maximum RTT latency measured is observed with OFDMA enabled. This is also accompanied with a lower median deviation of RTT or variance of the latency known as jitter. This means that even in cases where the average RTT is about the same, the maximum and median deviation RTT are often meaningfully lower providing a smoother QoE for the end-user with applications less likely to encounter latency spikes that cause issues with the QoE.

3. Latency Overview

Much effort is put into emphasizing network throughput achieved or bandwidth available, but latency is also one of the most important and often overlooked metrics. A consistent and good QoE reduces churn for MSOs, and latency is a main contributor to QoE. A user may be able to achieve the same throughput, that is data over time, on different networks, but one network could have less latency and be more responsive and pleasant to use.

When discussing latency, it's important to define terminology. This paper will discuss round trip time (RTT) vs. one-way delay (OWD), as well as the difference between idle pings and pings under load, and lastly a consideration for RTT of each transmission control protocol (TCP) stream or session vs. RTT of a ping to and from the source and destination.

Latency means different things to different people even in the networking industry. End-users outside the networking industry are that much further removed from knowing what is good or bad and may blame the wrong metric for a poor user experience. Latency can be defined simply as the amount of time for information or a packet to arrive from a source to a destination and is comprised of components such as: propagation delay (time required for the signal to travel over the medium), transmission delay (time required to push the bits into the link), processing delay (time required to process packet headers), and queuing delay (amount of time a packet is waiting in queue to be processed and gain access to the physical medium) [1]. This can be defined over a subset of network segments or a full network delay of a packet going to the destination over multiple hops locally or through the internet. This delay is also different under a working load vs. while idle. Latency observed in an idle network or idle Wi-Fi channel does not correlate with the user experience on the same network under a different load. On the wireless medium, latency is an especially fluid number changing constantly based on traffic passed, the number of clients accessing the shared medium, un-coordinated channel collisions, distance, and retransmissions.

Latency can be defined by the time it takes for a packet to be sent from a source and received at a destination; this is referred to as OWD. OWD measurements are usually accomplished with user datagram protocol (UDP) and require clock synchronization between source and destination to measure the elapsed time without having feedback to the source's clock. A timestamp is added in the data of the outgoing packet which is measured against the destination's clock when it is received. For this method of OWD measurements to be accurate, the same synchronized time must be used on source and destination devices. One such tool that uses this approach is an application called NUTTCP when used with UDP.

Latency can also be defined by timing how long it takes for a packet to go from source to destination and back to source with a response. This method is useful as well because most packets in networks are going to a destination to solicit a response back to where it came from. This may not be latency in its purest sense, but it is a total latency that most users would experience with a real application. This full elapsed time is measured and referred to as round trip time (RTT). Internet control message protocol (ICMP) pings and TCP RTT are common ways of measuring RTT. Pings over long multi-hop connections are not necessarily a true reflection of the latency in a loaded network, because network equipment could choose to prioritize or de-prioritize handling ICMP pings or cached information in routers could speed up subsequent pings. However, on a local network with a single hop, pings are still an essential tool to measure RTT delay. Iperf3, a networking throughput testing tool, can also report RTT per TCP flow while data is being sent if sourcing from a Linux Ethernet port.

3.1. Latency Values and Test Techniques

Considering only the instantaneous or just the average latency measured is not enough to characterize QoE of the end-user in a real wireless network. In addition to the average values of RTT or OWD, consideration of the minimum, maximum, and jitter, or a measure of the variability of the latency reading during a measurement period, is necessary. Sometimes, the average or minimum latencies won't change much in test scenarios, but the maximum latency observed can be far higher than the average and responsible for problems in user experience [1]. Many applications can handle a higher consistent latency, but if a packet suddenly has a much higher delay than average, this can cause extremely noticeable problems depending on the application being used. If an application can buffer without the user noticing, such as video playback, the end-user may not notice high jitter or higher latencies as easily.

Consider the difference in effect of high latency packets while watching a movie that buffers a significant amount, a voice call or video call that buffers very little, a virtual reality headset tracking a person's movements, or online game play that experiences a sudden skip in graphics displayed or a delayed reception of an action of a player. General expectations for good and bad latency values per application type are found in Table 2 below [4,5,6]. This includes full network round trip time latency including WAN, while the values in this paper are the latencies inside the house with Wi-Fi and do not include a WAN component.

Table 2 - Common Application Latency Expectations for RTT Latency

Application	Excellent	Good	Fair	Bad	Recommended
Gaming (FPS)	<20 ms	20-50 ms	50-150 ms	150+ ms	x
Gaming (MMO)	<20 ms	20-100 ms	100-250 ms	250+ ms	x
Gaming (RTS)	<20 ms	20-100 ms	100-200 ms	200+ ms	x
Cloud Gaming *	<20 ms	20-30 ms	30-40 ms	40+ ms	x
Voice Call	x	x	x	x	<100 ms
Video Call	x	x	x	x	<100 ms
Video Stream	x	x	x	x	<100 ms

* Latency requirements for cloud gaming are more stringent due to control input

A loaded network, especially in wireless networking, will have increased delays when traffic is being sent and while serving multiple wireless clients on the shared medium. Enhanced distributed channel access (EDCA) provides the mechanism for how backoffs are observed between different APs and clients trying to access the same channel. The more clients attempting to use the channel the greater the chance for one of them to need to backoff and wait even longer before winning an opportunity to transmit on the channel.

A network with traffic during tests or pings is referred to as experiencing load or being loaded. For example, a Wi-Fi 5 network with just 4 clients and very low utilization on the channel of 10% can still achieve 2 to 5 ms RTT pings with a very low 0.5 Mbps iperf3 data flow in the downstream direction. However, the same very low 0.5 Mbps TCP data flow to a Wi-Fi 5 client while the channel is 90% loaded, causes the same flow to incur an average of 19 to 24 ms RTT pings, up to a max of 187 to 198 ms possibly. A loaded network's delay is a more accurate view of the worst-case latency experienced by an end-user and is a preferred situation to characterize latency improvements. Loaded networks have more delay in queues/buffers, from backoff timers for fair access of other clients, and from retransmissions. Without load, it is more difficult to make discernable differences in outcome or QoE with different technology or settings when later used in a real environment.

In Wi-Fi channels, for this paper, the load refers to channel utilization which does not refer to Mbps. Channel utilization could be very high, even for a very low Mbps being transferred, if a slower, more robust MCS rate is being used for a client that is far away. Referring to load as airtime utilization abstracts away problems in test setups that specify loads as Mbps which are not the same anywhere else. Scheduler algorithms in AP chipsets are proprietary and have thresholds for considering usage of OFDMA to begin with, and idle or low usage clients are often not allocated any resource units (RUs). In this paper, many channel utilizations and throughput levels to a client under test were characterized.

The above methods for determining latency are simplifying what can be complicated. The absolute RTT or absolute OWD may change with a different number of TCP flows or different TCP window sizes, better time synchronized clocks, and with special treatment of ICMP pings by each operating system. In addition, if separate Ethernet links were used to source to each client, further differences may be observed. However, the relative differences between AP Wi-Fi modes and OFDMA settings, while keeping test methods and conditions the same accompanied with automation of test execution, allows for compelling comparisons.

4. OFDMA Overview

The primary feature being tested empirically in this paper is OFDMA. This technology first available for 802.11 networks in the Wi-Fi 6 standard allows for simultaneous transmissions to and from clients in the same channels on different subcarriers. This contrasts with previous generations of Wi-Fi standards,

which are for the most part round robin transmissions. Multi-user multiple input multiple output (MU-MIMO) in Wi-Fi 5 was able to achieve simultaneous transmissions, but it was not able to predictably realize gain in many real environments and often causes too much self-degradation and overhead to be beneficial especially with more than 3 clients. It did however improve latency in many cases even with increased retransmissions or lower throughput as client counts increased. To isolate contributions of OFDMA to latency, MU-MIMO was disabled for very high throughput (VHT) and high-efficiency (HE) modes in downlink and uplink directions.

OFDMA is often presented in settings of the web user interface of an AP with control separated to enable downlink OFDMA, that is AP to client, as well as uplink OFDMA, that is client to AP. For this paper both downlink and uplink OFDMA will be enabled or disabled together. The AP scheduler, proprietary in each chipset's firmware, is responsible for determining what technology should be used or which groups to form for simultaneous transmissions. For each transmit opportunity (TXOP), the AP will choose if the transmission will be single user (SU) legacy orthogonal frequency-division multiplexing (OFDM) traffic, synchronized multi-user OFDMA uplink traffic or synchronized multi-user OFDMA downlink traffic. The OFDMA modes are referred to as high-efficiency multiple user (HE-MU). This is because of the synchronized aspect of OFDMA transmissions, which drives efficiency, instead of legacy carrier sense multiple access with collision avoidance (CSMA/CA). Each OFDMA capable device is assigned a subset of subcarriers, or tones, by the AP for that device to simultaneously transmit on at the same time as others do on different subcarriers in the same channel.

With OFDM in Wi-Fi standards prior to Wi-Fi 6, the subcarrier spacing is 312.5 KHz, however, with Wi-Fi 6 and OFDMA the subcarrier spacing is 78.125 KHz. The subcarriers are 4 times closer together in OFDMA, and the symbol time is increased to be 4 times longer from 3.2 microseconds to 12.8 microseconds. The reduction in size of each subcarrier also results in efficiency gains in the channel itself because of less spectrum being used for pilot subcarriers and null guard carriers. The trigger frame from the AP to the clients specifies which RUs are allocated for simultaneous uplink transmission. In Wi-Fi 6 on 2.4 GHz and 5 GHz bands, the data exchanges can occur with OFDMA, however, many control and management frames must still use legacy OFDM to hold off and notify legacy clients about the channel being used [2]. The exception is for HE specific control frames such as buffer status report (BSR), clear-to-send (CTS), and block acknowledgements (ACK) which can occur simultaneously on RUs that are assigned.

4.1. OFDMA: Resource Units

Resource units (RUs) are groups of OFDM subcarriers, referred to as tones, and are predefined in these allocations: 26, 52, 106, 242, 484, 996, or 2x996 tones. The location of the RU within the channel is further defined by an RU index contained in a trigger frame that lets the client know what part of the spectrum is set aside for it in the single TXOP. Most current generation APs use a 242 tone RU as the smallest RU allocation in the 5 GHz and 6 GHz bands when 80 MHz channels are in use. A total of four 242 tone RU assignments can exist in a single group if the channel is 80 MHz. The 2.4 GHz band was not considered in this paper, but naturally uses smaller than 242 tone RUs to achieve multi-client OFDMA transmissions in 20 MHz and 40 MHz channels.

The AP can create additional groups to simultaneously transmit or receive from different sets of clients using the same RUs but in different groups, and therefore at different times. Multiple groups using OFDMA within each group are still advantageous to a certain point, but it does reduce the benefits of OFDMA and a study on multiple groups and its effect on latency reduction is left for further study. There would be a certain point when clients have unequal bandwidth needs in a specific TXOP that warrant scheduling a single group with lower RU designations than 242 tones. However, currently 242 tone RUs

are preferred most often in simultaneous 4 client scenarios as the AP doesn't have to allocate extra null guard carriers or pilots in the spectrum as it does with smaller 106 tone RU assignments. When 106 tone RUs are assigned to be used in an 80 MHz channel, there are 8 to 13 total clients supported in the group if the AP allocates 26 tone RUs to 5 of the clients. Some APs are not allocating smaller RUs with larger RUs in the same group and would leave gaps in the spectrum unused. However, using RU assignments of less than 242 tones is more advantageous for latency reduction with many clients at the same time. In Figure 1 below, the difference between single-user and multi-user OFDMA is shown with respect to time; one or more clients will be allocated tones across an 80 MHz channel. This example shows 996, 484, and 242 tones being used over time.

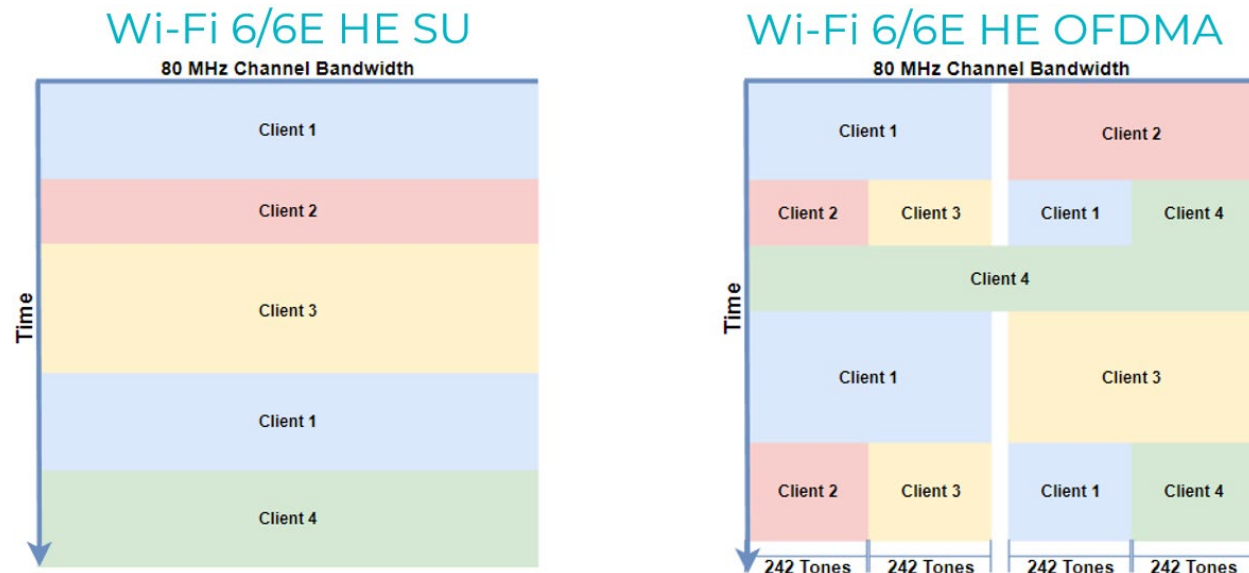

Figure 1 – Example OFDMA Tone Allocation with HE SU vs. HE OFDMA

The AP's scheduler is constantly managing if it prefers two clients at 484 tone RUs each in two separate groups to alternate between, or if it prefers to have four clients in a single group of 242 tone RUs each. This was observed to constantly change and is unknown exactly what proprietary reasons, other than the amount of traffic needing to be sent, that the AP is using to make decisions to use 2 groups of 484 tone RUs each or a single group of 242 tone RUs each. Receive power differences per client is one such reason for an AP to prefer to group certain clients together. However, when seeing spontaneous and rapid changes in RU assignments while clients are physically static and traffic is at a set limit, the rapid RU assignment changes and group changes are something that should be improved upon and will as AP schedulers are matured.

4.2. OFDMA: Process

For downlink OFDMA, non-Wi-Fi 6 clients are aware of the time they must be silent because after the AP has won a TXOP, it will send a multi-user request-to-send (MU-RTS) frame to clear the channel for the length of time of the full OFDMA exchange. The physical header and mac layer will contain the RU assignments, but they can also be specified in other trigger frames, or buffer status report frames. Other Wi-Fi 6 clients receive this frame and respond with their own CTS on their designated RUs at the same time. Next, the AP will send simultaneous data or multi-user downlink physical layer convergence procedure (PLCP) protocol data units (MU DL-PPDU) on each client's RUs. Clients will auto block ACK or wait for a block ACK request (BAR) from the AP and send upstream a block ACK at that time [2].

For uplink OFDMA, the AP still must win a TXOP, and only then can it schedule simultaneous uplink transmissions with uplink OFDMA on the clients that support it. A buffer status report poll (BSRP) is sent from the AP to the clients and solicits a BSR from each client. The BSRP contains the RU designations to be used for each client to respond with its own BSR which contains information about how much and what quality of service (QoS) of data needs to be sent upstream. This BSR information can also be unsolicited and indicated to the AP using a QoS control field in a data frame. A MU-RTS trigger frame may be sent from the AP and assigns RUs to each station as well as serves to notify the legacy clients of the upcoming transmission. The AP then waits for a CTS to return on each clients' assigned RUs. The MU-RTS is optional and can be skipped; the AP can go straight to a basic trigger frame which contains information about which RUs each client can use, the power each should try to use, as well as spatial streams and MCS rates to send their data upstream simultaneously. Next, the uplink PLCP protocol data unit (UL-PPDU) from each station is received for the same amount of time and each client will pad data if there is empty time. Finally, a multi-STA block ACK is broadcast so all clients can discover which frames need to be resent and the AP may optionally choose to send individual block ACKs to each client [2].

The goal of any network is to maintain high enough throughput and low, consistent latency, and low packet loss to provide a smooth, responsive, and predictable user experience. OFDMA technology in Wi-Fi 6/6E provides a mechanism to realize decreased maximum and average latencies in the Wi-Fi layer, as well as decreasing the variance or range of latencies experienced in more heavily utilized Wi-Fi channels.

5. Test House Setup

The Wi-Fi test house used for this testing is over 4500 square feet and consists of 3 stories including the finished basement and typical build materials such as wood floors, carpeted floors, sheetrock walls, and furniture throughout; it also has clean channels available with 0% utilized airtime because of the distance to neighbors. Microsoft Windows test clients were used to represent a more typical use case and good control of clients. The AP location was in a front corner of the house.

In contrast to normal lab testing techniques that seek to setup ideal conditions including precise location of clients, angles that present equal power to and from each client, and intricate test instrumentation, this paper was meant to determine if improvements can be realized in normal and non-curated test conditions with easy-to-use test applications. The locations of clients for this test were also chosen to represent a normal use case of clients in simultaneous use in the following locations: a client on the 2nd floor above the AP, a client in the basement below the AP, and a client in the same room as the AP.

A fourth client, the client under test (CUT), was located 26 ft away on the same floor and was the farthest client in this test on purpose as end-users are not usually right next to the AP. This client was used to ping and monitor more closely to investigate when the client was able to see better latency or not. The client was also used to play the game on for the test case involving playing an online game. This client under test would represent an end user's experience while other clients are using the same Wi-Fi network at various loads. The AP was not rotated to find ideal angles since comparison tests were planned, and therefore relative differences only were being considered.

6. Test Tools

Many test tools and scripts were evaluated including subscription-based tools we routinely use in our lab environments that are not freely available. However, there is value in being able to show improvements with tools that are freely available, such as iperf3. Another free tool NUTTCP was considered, but we had problems with ensuring time synchronized clocks with a LAN NTP server in the Wi-Fi test house.

This negated the advantage to using NUTTCP with UDP to measure OWD as this tool can do with well synchronized clocks. Also, because NUTTCP did not show the RTT of each TCP stream and instead only found RTT before the test started, it would have necessitated more complexity by using a second tool to get TCP RTT results. IxChariot was also considered but it proved harder to allow the type of automation required to test and then send back certain values into the next test automatically.

When using a source computer running Ubuntu Linux combined with iperf3, we were able to get RTT per TCP flow in the downstream direction, AP to Client, and this proved valuable enough to combine with ping data to select iperf3 as a tool. In the upstream direction, since the clients in use for this paper were Microsoft Windows to show applicability to real world use cases, we were missing the ability to get per TCP stream RTT. However, we still had the ability to run data in the upstream direction and use pings to evaluate the channel.

Another appealing reason to select iperf3 was the easy-to-use javascript object notation (JSON) output for aiding use in automation. The large number of test iterations planned called for creating some automation to organize and execute tests and remove any possibility for user error in setup of test parameters. Python3 was used to automatically setup certain iperf3 settings and rates, get data, and calculate different rates based on the data from a prior baseline run. Python3 also allowed for easy parsing of JSON output and presenting data in an easy to consume format, even the exact format needed to organize data in Excel. Using a Linux Ubuntu 20.04 operating system source Ethernet on LAN allowed for more precise timing control of pings used at a rate of 10 per second and was started just after traffic began and terminated just before traffic ended. The following network config parameters were changed on the linux machine to allow a larger TCP window size: *net.core.optmem_max = 524287; net.ipv4.udp_rmem_min = 8192; net.ipv4.udp_wmem_min = 8192; net.core.rmem_max = 16777216; net.core.wmem_max = 16777216; net.core.rmem_default = 2097152; net.core.wmem_default = 2097152; net.ipv4.tcp_rmem = 4096 87380 16777216; net.ipv4.tcp_wmem = 4096 87380 16777216; net.ipv4.tcp_mem = 1638400 1638400 1638400*. Using python3 allowed precise control of iperf3 sessions to all clients while simultaneously saving the TCP RTT data and using controlled pings to gather RTT information and throughput information for each controlled test cases.

The version of iperf used was 3.9. An example of the iperf3 commands that the custom written python3 scripts would launch with 'Popen' simultaneously and receive JSON output from is seen below. The rate-limited bitrate is per flow, and in this example, it was 4 flows per client at the bitrate listed in -b. The first 4 seconds of each run were always discarded with the -O omit flag. -J command was used to specify to receive results in JSON format. -R --get-server-output was used for an upstream direction test to specify receiving data at the Ethernet source from the clients.

- */usr/bin/iperf3 -c 192.168.0.238 -i4 -P4 -w2M -M1460 -b12.5M -t60 -O4 -J -T cut*
- */usr/bin/iperf3 -c 192.168.0.2 -i4 -P4 -w2M -M1460 -b62.13M -t60 -O4 -J -T client2*
- */usr/bin/iperf3 -c 192.168.0.3 -i4 -P4 -w2M -M1460 -b62.205M -t60 -O4 -J -T client3*
- */usr/bin/iperf3 -c 192.168.0.4 -i4 -P4 -w2M -M1460 -b62.3625M -t60 -O4 -J -T client4*

The JSON output received back per client was converted to a simple python3 dictionary object for parsing. The data for each stream to a client was then processed to take the average RTT of the streams, the maximum of the max RTT, and the minimum of the min RTT to represent that client's data in the test. An example of the data contained, per stream is seen in Figure 2.

Figure 2 – Example iperf3 JSON to python3 Dictionary for a Single Flow on One Client

An example ping command, launched one second after the simultaneous iperf3 flows started is: *ping 192.168.0.238 -i.1 -c570 -w57 -D*. The pings were sent at a rate of 10 times per second and were set to end at 57 seconds with -w flag regardless of being able to complete the 570 pings specified by -c flag. This was necessary to make sure any delays or loss did not result in pings being measured after iperf3 flows had ended. The total time of traffic being sent from iperf3 to clients was 64 seconds, with the first 4 seconds being discarded.

Below in Figure 3 is an example at the end of the ping data received during a test; this allowed for parsing and graphing per ping sample.

Figure 3 – Example Ping Data Received During a Test

A particular online game was chosen as well, Counter Strike Global Offensive (CS:GO), because it was hosted easily on the Ethernet LAN connected Linux server that also sourced iperf3 traffic, and it was able to be played without interaction with the WAN internet at all. This game also has a developer mode that overlays latency and variance on the screen during play. This game is also not graphic intensive and was used only for the networking measurement aspect to show any relevant differences experienced in a real application under different channel load conditions and AP settings.

Figure 4 – Counter Strike Global Offensive Screen Overlay with RTT Latency

Figure 4 above shows an example of the overlay used to get the game's measurement on the RTT of data which changes during a given 60 second run. Its value was recorded every 3 seconds for analysis during traffic for the given game play test scenarios. This information along with iperf3 RTT data and ping data was used to characterize latency in this real application while the channel was set to various utilization levels and the AP under test was used in different modes.

7. Test Methodology

7.1. Test Constants

This paper sought to identify which scenarios can show lower latency, lower max latencies, or a more consistent delay with much lower variation in latency. This setup was specifically not in a lab or in a heavily curated test with equal power clients and equal traffic to each client. 2.4 GHz was not considered for this paper. For 5 GHz testing, channel 100 was used as it was a completely clear channel in the test house which allowed for repeatability. For Wi-Fi 6E tests channel 37 was chosen. A channel bandwidth of 80 MHz was used because this paper was about evaluating AP modes, OFDMA, and latency, not throughput. Increasing the bandwidth of the channel to 160 MHz would inflate the total throughput required on each test case to max out the channel and leads to less deterministic or repeatable results. However, some chipsets and firmware today can aggregate even more clients on 242 tone RUs in a single group with 160 MHz. This will be left to one of many additional tests for a later date.

Another test constant decided for this paper was to completely disable MU-MIMO including VHT MU-MIMO as well as HE MU-MIMO. MU-MIMO contributions to latency or throughput was not the focus of this paper and would have only served to confuse the contributions of OFDMA in various test scenarios including when baselining the ability of a channel with three clients, vs. adding in one more client under test in the same channel. The additional client under test added to a scenario would change the interference experienced and grouping of the other clients negating the baseline if MU-MIMO was enabled beforehand. The various non-repeatable conditions and baselining issues in addition to the overhead of null data packet announcement frames and beamforming report poll frames made disabling MU-MIMO for this paper an easy decision.

Default QoS was used by not setting QoS at all, to not intermix this layer of prioritization in with the evaluation of the OFDMA feature in these test conditions and iterations already defined. Other constants included the fixed physical positioning of the AP and clients between representative loads and setting changes. A certain AP was used to ensure coverage of Wi-Fi 6E data, however, the maturity of firmware on the Wi-Fi 6E AP is still lagging APs with just 5 GHz Wi-Fi 6. Two other APs for a good sampling of today's AP abilities were used to test in 5 GHz.

7.2. AP Settings for Comparison

The AP under test was controlled and tested against the following modes, settings, and client modes:

- Wi-Fi 5
- Wi-Fi 6 with OFDMA DL & UL disabled
- Wi-Fi 6 with OFDMA DL & UL enabled
- Wi-Fi 6 with OFDMA DL & UL disabled and two clients set to Wi-Fi 5 (802.11AC) only
- Wi-Fi 6 with OFDMA DL & UL enabled and two clients set to Wi-Fi 5 (802.11AC) only
- Wi-Fi 6E with OFDMA DL & UL disabled (if available)
- Wi-Fi 6E with OFDMA DL & UL enabled (if available)

At the beginning of a test with the AP set to a particular mode and OFDMA setting, a set of baseline tests were executed. The baseline tests determined what the max average rate was for each of the three control clients running traffic together. This was baselined separately for each AP mode and OFDMA setting and directly preceded each set of test iterations listed in the client conditions for comparison section.

The baselining served a couple purposes. Each client was in a different location which represented a more typical use case and therefore each client's capability to achieve a certain Mbps throughput was different. For example, the same throughput achieved in Wi-Fi 6 was more than what was achievable in Wi-Fi 5; it would not be a fair comparison of channel utilization to set the Wi-Fi 6 speeds at the same rate limits used in the Wi-Fi 5 testing, because the channel would be at a different airtime utilization in the comparison. A better approach was to determine what speeds the clients could achieve during each set of AP settings, then discount the rates of those clients to achieve an approximate percentage of channel utilization; this would be a different bitrate for each client and each AP mode, packet size, OFDMA settings, traffic direction, and client mode settings. Another reason for doing this is certain settings in use would cause different schedulers to be employed and different technology or decisions to be used. For example, in UL OFDMA the AP is instructing the clients which MCS to use amongst other parameters, however, with OFDMA disabled, the clients are choosing their own rates.

For these and other reasons it was decided to not rate limit other clients based on Mbps blindly for all test cases, but instead to rate limit based on percentages of max achieved average rates when the other three clients were used simultaneously without rate limits. After determining the throughput on average achieved by each of the 3 clients with no rate limits, this allowed a known discounted rate to approximate channel utilization to a given percentage for subsequent tests. This method should also allow extrapolation of findings to similar test scenarios with clients that are far away and not able to do high rates, but they could of course use up certain percentages of the channel's airtime just the same.

7.3. Client Conditions for Comparison

During the test iterations for all the AP settings defined above, different parameters for the other clients and the CUT were then tested over the following test parameter iterations:

- Downlink and uplink traffic direction
- TCP and UDP
- Client under test rate limits of 500 Mbps, 50 Mbps, 5 Mbps, and 1 Mbps while also playing a low bandwidth LAN Ethernet hosted game.
- Other three clients rate limited to 10%, 50%, and 90% of their capability determined in prior baseline tests with just the three clients running traffic without rate limits
- 536 byte and 1460 byte size payloads (Used for both TCP and UDP tests)

The different rate limits chosen were to represent high, medium, low, and very low rates for the CUT. The rate of 500 Mbps was specifically chosen to be below the full channel capacity for most test conditions, but also higher than what could be achieved in a 242 tone RU assignment for a 2x2:2 client at the client locations chosen. This was to expose some areas where OFDMA can reduce throughput as schedulers struggle to figure out how to divvy up tones and groups for multiclient scenarios with high data rates for some clients but not all clients. The scheduler must decide how to handle a highly utilized client in the face of lower utilized clients. There is not a right or wrong answer here, and we believe it is a source of some unknown expectations and ongoing improvement.

The highly utilized client could be transmitted to using the entire channel and then rotated between the other OFDMA transmissions of the 3 other clients using their RU designations for short periods of time. However, the highly utilized client could also be put in a smaller than needed RU designation for the sake of preserving low latency access to others and put in the same group as the lower RU designated clients; this would cause throughput degradation in the name of reducing total latency for all clients. Finally, it could decide to only briefly use a smaller RU combined in the same group with other lower utilized clients for part of the time, and then switch back to full usage of the channel causing higher latency on the other clients.

The channel utilization percentages chosen included 10% for the other clients to represent low utilization either in the house or to an extent, overlapping neighboring networks on the same primary or secondary channels of a similar percentage. Utilizations of 50% and 90% would represent busy and very busy channels which will uncover at what points of channel utilization OFDMA starts to help with latency reduction. The same testing re-executed while creating controlled amounts of out-of-network traffic on the same primary and secondary channels are left to future testing. This would be to characterize the difference in results with uncorrelated utilization and EDCA backoffs being observed between different APs in other houses or even multi-AP mesh systems sharing channels within a house.

The different packet sizes represent a range of payloads, small and large, to determine if benefits are only seen based on the size of packets sent in the channel. The same payload was chosen for UDP payload and TCP max segment size (MSS) tests for parity's sake even though the UDP data could have been smaller than the lowest TCP MSS and 12 bytes larger than the largest TCP MSS. The packet size for a test scenario is used to all 4 clients for the test case, not just the CUT. iperf3 TCP flows were set with 4 flows except for the CUT at 1 Mbps and 5 Mbps where multi-flow was not beneficial; in this case just 1 flow was used. iperf3 TCP window size was set to 2 MB in all cases. UDP was also tested to isolate much of the other direction's traffic except for MAC layer 2 acknowledgments (control frames) to see if behavior is much different without the constant interruptions to send and receive TCP acknowledgments as data frames in the opposite direction. Lab test scenarios often start with UDP for more exact control, but it is not indicative of real-life application flows this paper sought to primarily evaluate.

8. Test Results

Different AP chipsets were used to do this testing and to investigate what amount of channel utilization or amount of client under test utilization can show improved latency with the OFDMA feature in current generation firmware. The test environment was not overly curated to create ideal lab test conditions in a chamber or test cases that included every client receiving the same low to medium throughput with UDP and equal power as many lab test cases and vendors would and should execute. This paper evaluated a non-lab test scenario in an actual house of four clients of controlled and different throughput with TCP and UDP while at varying AP receive power, AP transmit power, and distance. This simulated a real situation but with repeatable, controlled utilization of clients to facilitate finding relative differences between OFDMA settings and AP modes in a real environment.

The relative comparisons and charts were made on the same chipset for direct comparison and consideration of OFDMA's contributions to latency. There were extreme differences in chipset abilities, algorithms, and scheduler decisions, but comparisons were made on the same AP. 260 to 364 tests created approximately 5,000 to 6,000 data points per AP and protocol. This was executed on three APs with both protocols creating total data points of well over 30,000 between the modes and different APs tested. Each test also had additional raw data saved that represented the per sample data making up the averages, min, and max; some of the per sample data was also analyzed and graphed. The data was examined to find generalizations to illustrate improvements that could be expected in certain scenarios.

There is much data created from this type of exhaustive testing, as well as what would be created from the myriad of proposed follow-up testing scenarios. Many of the scenarios tested were not expected to show a latency RTT improvement. Executing each scenario, however, was the only way to find at what amount of channel usage and traffic level the client under test would start to realize a latency improvement in today's chipsets and firmware. Improvements and more testing will be continuously sought, while drawing more conclusions to the data already collected.

The most compelling RTT latency reduction improvements included the scenarios with high channel utilization, including maxed out, non-rate limited iperf3 flows for each client as well as many of the 90% channel utilization test cases. Also, the higher usage of the client under test provided the highest improvement in latency RTT for that client. The other generalized improvement was when using a larger MSS of 1460 bytes compared to smaller MSS of 536 bytes. Many test results did not show favorable results and in many scenarios, this was expected. For example, in a low utilized channel the airtime is not causing contention and clients already get access to the channel without the need of OFDMA. Test results selected to be shown in this paper are just a very small subset chosen to represent a mix of UDP and TCP, large and small packets, downstream and upstream, different rates to the CUT, and different channel utilizations.

For each chart consider the following way to look at the chart. The categories on the X axis are used to group test results for a given AP mode and client mode scenario including OFDMA enabled or not. Each test result for that given test mode is then listed front to back, starting with latency values as indicated and labeled per parameter as a category to the right, and ends with total throughput for reference in the back of the chart. The Y axis is being use for both Mbps for the last category per group and serving as a millisecond reading for all the other categories with latency.

8.1. Non-Rate Limited Test Scenarios

The tests with no iperf3 rate limits to all four clients were sourced from or destined to a single Ethernet 1 Gbps port on the LAN of the AP. Non-rate limited scenarios are perhaps where many test efforts start and is worthwhile to characterize, but it is not a likely scenario to occur in a house. However, since this test case is craved by many, it was also evaluated. In general, when comparing unidirectional UDP vs. TCP results, the ping RTT is lower for the same test case using UDP due to most of the data being in one direction.

When testing in the upstream with TCP, as previously discussed, the only indication we have of RTT, because of using Microsoft Windows clients with iperf3, is the ping RTT statistics. When testing the same non-rate limited scenario in the upstream direction, we do see improvements with OFDMA enabled on TCP and UDP.

Shown in Figure 5 is UDP in the upstream direction at UDP Payload of 1460 bytes, the average RTT of a ping is reduced by more than half for OFDMA enabled scenarios in the maxed-out channel test. For example, with all Wi-Fi 6 clients used and OFDMA disabled, the average RTT of a ping was 14.41 ms to the client under test (CUT). With OFDMA enabled on the AP for the same four Wi-Fi 6 client test, the average ping to the CUT was reduced to 6.76 ms. Even better results are seen with UDP payloads of 536 bytes in this same test scenario, however, the throughput is better with the UDP payload of 1460 bytes.

Figure 5 – UDP Upstream No Rate Limits

In this completely saturated airtime scenario, the per ping sample to the CUT was graphed in Figure 6; it is quite revealing in the OFDMA disabled to OFDMA enabled comparison for upstream traffic in a completely used airtime scenario. The AP scheduling upstream transmissions allows for very quick and continuous access to the channel. In Figure 6 below, a much tighter and lower latency can be seen with the blue line with OFDMA enabled and is a visual representation of the median deviation of RTT latency changing from 15 ms to 3 ms which was revealed in the previous Figure 5 as well as the max RTT recorded reducing 3 fold.

Figure 6 – Per Ping Sample OFDMA Disabled vs. Enabled

In Figure 7 below, the same scenario of UDP and maxed out upstream traffic is compared between AP set to Wi-Fi 5 (gray line) vs. OFDMA enabled (blue line) and disabled (orange line) while half the clients are set to Wi-Fi 5 only mode. This test mode was tried in all scenarios to evaluate if benefits to Wi-Fi 6 clients can be realized in multi-client scenarios that include previous generation Wi-Fi 5 clients. The latency reduction benefit is still seen to the Wi-Fi 6 client under test with half the clients being unable to use OFDMA but still sending traffic upstream.

Figure 7 – Per Ping Sample Wi-Fi 5 vs. OFDMA Disabled/Enabled with half Wi-Fi 5 Clients

Next is an example of downstream TCP traffic while maxing out the utilization of the channel with no rate limits being used. There was a particular improvement seen in the mixed client population test scenario where half of the network's clients, are set to Wi-Fi 5 mode only. The other two clients, including the CUT, are left to support Wi-Fi 6 and OFDMA. In the following scenario TCP was used in the downlink direction at 1460 byte MSS with no rate limit set on iperf3 while measuring the client under test's RTT latency. This scenario again shows a benefit can still be seen on a Wi-Fi 6 client under test while half the clients in the test are Wi-Fi 5 clients and don't have an ability to use OFDMA. The AP can schedule the OFDMA clients together, in this case 484 RU each in a group while Wi-Fi 5 clients are served in alternating fashion with the OFDMA group of size 2 as transmit opportunities are won.

Shown in Figure 8, the maximum RTT latency (orange bars) recorded during a 60 second test showed a latency reduction of about 50% with OFDMA enabled and was seen in both max ping RTT as well as max data RTT (blue bars) to the Wi-Fi 6 client under test. The average RTT (gray bars) only showed slight improvements in OFDMA enabled case, however the max RTT recorded was meaningfully lower. This reduction in the max RTT recorded is very likely to improve the QoE for the end user in the most demanding maxed out scenarios of fully used channel airtime from mostly downstream traffic. The mean deviation of the latency (green bars) or jitter as reported from the approximately 567 pings in the 1 minute test time showed a reduction to just 8.42 ms with OFDMA enabled while OFDMA disable was at 22.26 ms and legacy Wi-Fi 5 was at 50.98 ms.

Figure 8 – TCP Downstream No Rate Limits

The same scenario of the AP at Wi-Fi 6 but half the clients being set to Wi-Fi 5 is graphed below in Figure 9 on a per ping basis to the CUT and shows a good improvement in reduction of frequency of RTT latency spikes with OFDMA enabled (blue line) vs. OFDMA disabled (orange line). The AP set to Wi-Fi 5 mode (gray line) is shown as well to show how variable Wi-Fi 5 networks can be when loaded.

Figure 9 – Per Ping Sample Wi-Fi 5 vs. OFDMA Disabled/Enabled with half Wi-Fi 5 Clients

In summary, for the non-rate limited scenarios with heavy in-network channel utilization, the OFDMA enabled tests showed improvements in average RTT and max RTT as well as mean deviation of RTT latency. For upstream traffic utilization UDP traffic tests were the easiest to see drastic improvements while for the TCP traffic tests the most latency reduction was seen in downstream direction test cases. In most non-rate limited test scenarios there was an improvement for Wi-Fi 6 client latency even when half the clients receiving background traffic were Wi-Fi 5 clients.

8.2. Rate-Limited Test Scenarios with Channel Utilization Set to 90%

In this section's test scenarios, the bitrate limits for each of the other 3 clients were set to a limit of 90% of what each had achieved without rate-limits in baseline testing, per AP mode. This caused approximately 90% channel utilization as compared to the baseline unlimited test case. Two of this scenario's results were selected to discuss below.

In the following scenario with results shown in Figure 10, the client under test was set to send 50 Mbps upstream with the channel utilization at approximately 90% with upstream traffic from the other clients. This scenario represents a very highly utilized channel from the other clients while a moderate throughput demand in the upstream is created from the CUT. The OFDMA enabled test, shows a reduction in the max RTT ping (orange bars) from 313 ms to 121 ms to the CUT with an average RTT ping (gray bars) that reduced from 50 ms to 37 ms. The median deviation or jitter (green bars), also decreased from 44 ms to 21 ms for the same OFDMA enabled vs. disabled comparison to the CUT. Additionally, the data in Figure 10 records a decrease in the max RTT ping seen when OFDMA is enabled with half the clients set to Wi-Fi 5 mode; this shows some improvement can still be realized in mixed client populations of Wi-Fi 5 and Wi-Fi 6 clients.

Figure 10 – TCP Upstream, 90% Limit Others, CUT Limit 50 Mbps

In Figure 11 below, the per ping sample between OFDMA disabled (orange line) and enabled (blue line) is graphed for the same scenario depicted in Figure 10 and shows visually the drastic improvement in the max RTT latency observed with much lower spikes in latency and a much tighter jitter or median deviation of the latency. The median deviation was shown previously to have reduced from 44 to 21 ms from OFDMA disabled to enabled and is seen below with a smaller range of values during the test, meaning the blue line's spikes in latency were much lower with OFDMA enabled.

Figure 11 – Per Ping Sample OFDMA Disabled vs. Enabled

The next scenario, for an approximately 90% utilized channel, was with downstream TCP traffic at a smaller 536 byte MSS and was more compelling on a different AP shown below in Figure 12. Other clients were limited to approximately 90% and the rate-limit of the CUT was set to 500 Mbps. This test scenario is like the maxed-out scenario in that the total allowed rates are well over the ability of the channel to support but serves as a test to see if the CUT can get more throughput in the channel with less latency on that data when OFDMA is enabled. Indeed, in addition to improving the throughput achieved, latency was also reduced for the CUT. The CUT throughput (dark blue bars) seen in this scenario for each AP mode included Wi-Fi 5 achieving 69 Mbps, Wi-Fi 6 with OFDMA disabled achieving 153 Mbps, and Wi-Fi 6 with OFDMA enabled achieving 173 Mbps. The scheduler preferred to give more equal access to the channel preserving lower latencies for all clients while still allowing more traffic through on average to the CUT in the OFDMA enabled test. This contrasts with assigning a higher number of tones for this client and others in two groups or just 996 tones to the CUT to try to allow the higher TCP limit of 500 Mbps, however it did not do this. In Figure 12 below, both the iperf3 data max RTT (light blue solid bar) and iperf3 average RTT (orange bars) have reduced by about 30 - 40%.

Figure 12 – TCP Downstream, 90% Limit Others, CUT Limit 500 Mbps – AP 2

In summary, the approximately 90% utilized channel scenarios showed most improvements in TCP upstream and UDP upstream scenarios. With UDP downstream scenarios the results were usually worse at all CUT bitrates tested and may allude to the fact that the scheduling overhead is just too much to see a benefit over OFDMA disabled test cases. In UDP downstream tests, low latency is already able to be achieved to begin with since the AP is already in control of scheduling traffic one at a time to each client without much interruption in the other direction since only layer 2 acknowledgements need to be received. With downstream TCP scenarios the lower utilization tests of the CUT were not able to realize much of an improvement, however, with slightly higher bitrates to the CUT such as 50 Mbps or 500 Mbps, some moderate improvements were measured.

8.3. Rate-Limited Test Scenarios with Channel Utilization Set to 50%

In this section's test scenarios, the bitrate limits for each of the other 3 clients were set to a limit of 50% of what each had achieved without rate-limits in baseline testing, per AP mode. This caused approximately 50% channel utilization as compared to the baseline unlimited test case. Two of this scenario's results were selected to discuss. As channel utilization is reduced from 90% to 50% the RTT latency benefits are seen to less of an extent but are still noticed if the CUT has a high bitrate.

In the following scenario, the CUT is set to receive at a 500 Mbps limit while the other clients are set to a limit of 50% to represent approximately 50% channel utilization before the CUT's traffic. The 500 Mbps rate limit set on the CUT is a higher demand or throughput limit than available unused channel airtime and higher than what can be achieved in only a 242 tone RU alone. This tests if the scheduler will give higher RU allocation, such as 484 tones, to this client under test to achieve its higher throughput needs. Or, if the scheduler would cause throughput degradation to the CUT by assigning a smaller than required RU allocation such as 242 tone to maintain a single group of all 242 tone RUs to each of the four Wi-Fi 6 clients, in the OFDMA enabled test case.

Since the client throughput (dark blue bars) can achieve a rate over time that is higher than the rate possible in just a 242 tone RU, this scheduler sacrificed some latency reduction potential that could have been obtained for all clients, at the expense of creating multiple groups with higher number of tones for each client. In this way, a higher throughput on a client demanding more than the others was accommodated. Therefore, the latency reductions shown in Figure 13 are more muted, and a great example of scenarios that are not expected to show a big RTT latency reduction because of the test conditions and scheduler deciding to allow as much of the CUT's higher throughput traffic as possible.

Figure 13 – TCP Downstream, 50% Limit Others, CUT Limit 500 Mbps

In another scenario of approximately 50% channel utilization allowed on other clients, downstream UDP traffic is used with a moderate limit of 50 Mbps to the CUT. The average RTT latency (gray bars) on the CUT is about 1 to 2 ms higher with OFDMA enabled. However, the max RTT latency (orange bars) did fall from 104 ms to 39 ms with OFDMA enabled, and from 86 ms to 54 ms in the mixed Wi-Fi 5 client tests with OFDMA enabled. This is an example of a scenario that may not show great average latency reduction on the Wi-Fi 6 CUT but does show a lower max RTT latency and would result in a better QoE for the end user. These results are shown below in Figure 14.

Figure 14 – UDP Downstream, 50% Limit Others, CUT Limit 50 Mbps

To illustrate the moderate benefit of a lower max RTT for this scenario, a per ping sample graph in Figure 15 is shown below. The spikes in latency are still seen but not as high, and the slight increase in average RTT ping is also able to be seen.

Figure 15 – Per Ping Sample OFDMA Disabled vs. Enabled

In summary, the approximately 50% utilized channel scenarios showed most improvements with OFDMA enabled when the CUT was set to a higher throughput limit such as 500 Mbps. This was certainly the case with UDP in the upstream direction, but not as convincingly seen in the downstream direction. UDP upstream isn't really a use case seen at this high bitrate in real-life and therefore focus was to show UDP and TCP downstream scenarios described above. UDP downstream showed a small improvement in RTT latency with the CUT receiving 50 Mbps. For TCP traffic tests, the only cases improving with approximately 50% channel utilization were in the downstream direction and at 500 Mbps to the CUT. The TCP upstream tests, for the 50% channel utilization scenarios, for the most part showed slightly worse latency.

8.4. Rate-Limited Test Scenarios with Channel Utilization Set to 10%

In this section's test scenarios, the bitrate limits for each of the other 3 clients were set to a limit of 10% of what each had achieved without rate-limits in baseline testing, per AP mode. This caused approximately 10% channel utilization as compared to the baseline unlimited test case. Two of this scenario's results were selected to discuss including one to show the difference between two different AP's in the same scenario.

In the least utilized channel test scenario with other clients set to 10% rate limits, there were less situations found with meaningful improvements in latency for the CUT. One of the only scenarios that showed a compelling difference for a low utilized channel and highly utilized client was in the mixed client mode test with and without OFDMA enabled. In the scenario shown in Figure 16, TCP is used with a 1460 byte MSS and a 10% utilization limit for the other clients while the client under test is set to a rate limited 500 Mbps in the upstream direction. This represents a very high throughput demand in the upstream while the channel utilization is quite low in the same direction on the other clients. The mixed client mode cases of half Wi-Fi 5 clients and half Wi-Fi 6 clients showed a compelling difference in the latency experienced on the CUT during this high throughput of a lightly utilized channel in the upstream. The CUT was able to achieve the 500 Mbps upstream in both cases, yet the RTT max latency (orange bars) as well as the RTT average latency (gray bars) both were reduced approximately 3-fold.

Figure 16 – TCP Upstream, 10% Limit Others, CUT Limit 500 Mbps

The same scenario is graphed with per ping RTT latency data in Figure 17 below and really illustrates the 5 times lower RTT median deviation in the ping data to the CUT with OFDMA enabled (blue line) in the mixed half Wi-Fi 5 client test. The data set to flow upstream from the CUT was able to achieve 500 Mbps in both scenarios, but the OFDMA enabled case did it with a much lower average RTT latency as well as considerably less jitter.

Figure 17 – Per Ping Sample OFDMA Disabled vs. Enabled with half Wi-Fi 5 Clients

As mentioned before, not all scenarios showed reduced latency and many also show increased latency, especially with lower utilized channels or lower rates to the CUT. Most notably, differences between different APs are very easily seen when compared in the same test conditions and scenarios. The same scenario with two different APs will illustrate this extreme difference that can be seen.

The scenario compared here was TCP 1460 byte MSS with 10% traffic in the downstream direction with the CUT receiving a rate-limited 5 Mbps. So, this represents lightly used channel conditions and a low throughput on the CUT. This is actually a very common scenario and may represent the most often situation experienced in the home.

The first AP's results, in Figure 18, show that with OFDMA enabled or disabled the same average RTT latency (solid light blue bars) for the iperf3 data flows is seen at 4 ms. The max RTT latency with OFDMA enabled increased from 5 ms to 7 ms and reduced max RTT latency from 7 ms to 5 ms in the mixed Wi-Fi 5 client mode case. All these latency values, both average and max RTT are acceptably low for the local LAN segment for most applications but are shown here to illustrate the improvements are not usually seen in low to medium use cases with 4 clients. Also, this simple result is given as a contrast to the result with the same scenario on a different AP.

Figure 18 – TCP Downstream, 10% Limit Others, CUT Limit 5 Mbps – AP 1

In Figure 19, the same scenario is tested using a different AP and revealed some issue with increased latency for the OFDMA enabled test cases with all Wi-Fi 6 clients and again in the mixed half Wi-Fi 5 client mode test as well. This is likely from scheduler problems with deciding if the clients should be in a group or not and the overhead associated with creating and tearing down groups when low bitrates are used. The scheduler in this AP should be improved to create groups early, even with low bitrates, to receive upstream TCP acknowledgements coming back as data frames in OFDMA transmissions.

Figure 19 – TCP Downstream, 10% Limit Others, CUT Limit 5 Mbps – AP 2

An area of further testing to be completed is to investigate at what bitrate threshold AP schedulers are considering adding clients to OFDMA groups. A client at distance could be achieving a low bitrate but are using a lower MCS rate and airtime usage would still be high; these low bitrate and high airtime clients should not be denied scheduling into OFDMA groups. A threshold based on predicted airtime usage would be a better approach for such situations when clients are not close to the AP and low MCS rates with high airtime usage are being used. The data shows that highly utilized channels can benefit greatly by OFDMA and highly utilized refers to airtime usage, not bitrates. Therefore, it is likely beneficial that chipsets use thresholds that are airtime based, not throughput based if the scheduler requires such thresholds.

In summary, the approximately 10% utilized channel scenarios showed some small improvements with OFDMA enabled when the CUT was set to 5 Mbps and TCP was used with half Wi-Fi 5 clients in either direction. It was also an easy result to showcase differences in implementation of OFDMA in different chipsets. In other TCP tests, with the bitrate to the CUT set to 50 Mbps or 500 Mbps, latency generally was slightly worse with OFDMA enabled with either direction of traffic. However, an exception was the mixed client scenario with upstream traffic of 500 Mbps to CUT and 10% utilization with other clients, a large reduction in latency was seen with OFDMA enabled and was shown in Figure 16. UDP traffic scenarios with CUT limits of 1 Mbps, 50 Mbps, and 500 Mbps showed slight improvements in the

downstream direction tests while the upstream direction only showed an improvement with 500 Mbps from the CUT.

8.5. Rate-Limited Test Scenarios with LAN Hosted Gaming

Online gaming requires quick and responsive connections to have a good QoE. As explained in more detail earlier, a LAN Ethernet hosted CS:GO game was played within the LAN on the CUT while monitoring the RTT Latency reported on the game screen in real-time. Simultaneous to that game play is iperf3 data of 1 Mbps flowing to or from the same CUT and pings just as in prior scenarios. This provides information about the responsiveness from the CUT in the traditional RTT iperf3 data and ping data, in addition to the CS:GO RTT latency reported on the screen overlay.

The 10%, 50%, and 90% usage levels of the other clients as well as iterating over the two packets sizes and AP modes showed similar results to testing without the game play. The scenario that showed an obvious improvement in game play was the heavily utilized 90% TCP upstream traffic scenario, the results are shown in Figure 20. A real-life example of this scenario might include one or more clients in the house backing up data or uploading videos to the cloud while another client is trying to play an online game. Notice the max RTT ping (orange bars) reductions from 212 ms to 69 ms with OFDMA enabled and from 196 ms to 74 ms with half the clients being Wi-Fi 5 clients. The RTT median deviation ping (green bars) also shows a reduction of approximately 50% which alludes to more consistent and lower pings achieved in this scenario to the CUT with OFDMA enabled regardless of half the clients being Wi-Fi 5 clients. The average RTT ping (gray bars) was cut in half when OFDMA was enabled with all Wi-Fi 6 clients.

Figure 20 – TCP Upstream, 90% Limit Others, CUT Limit 1 Mbps + Game Play

Consistent with the above measured max and average RTT ping times improving with OFDMA enabled in the heavily utilized channel in the upstream with TCP, the CS:GO game play itself on the CUT also showed improved latency in both OFDMA enabled modes. The average ping recorded during the same sample period of the game play was very close to the RTT Latency reported on the screen overlay during the CS:GO game play itself. This sampling of the CS:GO RTT latency over the 60 seconds is graphed below in Figure 21 and shows the two OFDMA enabled cases performing much better with all Wi-Fi 6 clients (blue line), as well as the mixed half Wi-Fi 5 clients (green line). Both OFDMA enabled tests show an obvious consistent latency or low jitter to the CUT during game play while the channel has very low available airtime with heavy upstream traffic. This was also evident by the reduction in median deviation of RTT pings shown in Figure 20 above.

Figure 21 – CS:GO Reported RTT Latency Over 1 Minute of Game Play

In Figure 22 below, the same game play scenario is graphed per ping RTT latency for OFDMA enabled (blue line) vs. OFDMA disabled (orange line). The per ping data shows the same increasing latency for OFDMA disabled at the same points on the graph as were reported by the overlay on screen of CS:GO and depicted in Figure 21 above. In Figure 21 at 36 seconds into the OFDMA disabled test scenario (orange line) latency begins to rise; this correlates with the ping data in Figure 22 for the OFDMA disabled test (orange line) at around the 360th sample which also starts to have more spikes in latency. The ping data samples over time in Figure 22 below show that pings are a good representation of what is also occurring to the actual game flow's latency even if the absolute values are different.

Figure 22 – Per Ping Sample OFDMA Disabled vs. Enabled During CS:GO Game Play

In summary, during online game play via Wi-Fi, OFDMA enabled really improved the variance of latency, or jitter, in highly utilized channels in the upstream for both TCP and UDP. This improvement was measured solely on the LAN as game play was limited to within the LAN. The improvement on the CUT playing the game was realized even with half the clients in the network being Wi-Fi 5 clients. The consistency of RTT latency is much improved with OFDMA enabled in this scenario that represents several other devices uploading data and using approximately 90% of the channel airtime at the same time as a CUT is playing an online game.

8.6. Wi-Fi 6E Testing with Rate-Limited Test Scenarios

Wi-Fi 6E testing revealed some throughput degradation perhaps from range degradation at 6 GHz or from immaturity of firmware on AP or client for 6 GHz. The specific AP used for this testing showed some unexpected degradation in the upstream with OFDMA enabled even in 5 GHz. However, relative differences are still able to be seen by rate-limiting to certain percentages and comparing relative latency during the same approximate channel utilization across AP modes and scenarios.

Like other findings with APs in 5 GHz band, the highly utilized channel of 90% showed the most improvement to the CUT when enabling OFDMA in the 6 GHz band. Figure 23 shows 6 GHz testing with 90% utilization on control clients during TCP 1460 byte MSS testing in the upstream direction with 50 Mbps from the CUT. All stats improved with pings for OFDMA enabled cases, including the median deviation RTT (green bars), average RTT (gray bars), and max RTT (orange bars).

Figure 23 – TCP Upstream, 90% Limit Others, CUT Limit 50 Mbps – AP 3 with Wi-Fi 6E

The same scenario's per ping RTT latency is graphed in Figure 24 below to show Wi-Fi 6E OFDMA disabled (orange line) vs. OFDMA enabled (blue line). The reduction in median deviation of RTT pings as well as the reduction of the max RTT ping recorded is evident with a more consistent and lower average latency for the OFDMA enabled test.

Figure 24 – Per Ping Sample OFDMA Disabled vs. Enabled – AP 3 with Wi-Fi 6E

8.7. Wi-Fi 6E Rate-Limited Test Scenarios with LAN Hosted Gaming

While playing CS:GO on the CUT during the Wi-Fi 6E test scenario, the RTT latency improved the most during upstream 90% channel utilization scenarios while the downstream version of the same test showed about 50% worse RTT latency. Shown below in Figure 25 is the 1460 byte MSS scenario and shows results from a 90% utilized channel in 6 GHz before and after enabling OFDMA. The 536 byte MSS results were similar. This chart is the CS:GO reported RTT latency during a 60 second test while approximately 90% utilization is occurring in the downstream or upstream as labeled by a different colored line. Improvements in latency on a CUT playing a game are not always seen based on if the channel is heavily utilized with downstream traffic or if it is the same percent utilization with upstream traffic. It is also likely something this AP would improve upon with later firmware over time.

In Figure 25, the blue line shows game play latency improved while heavy traffic was flowing in the upstream direction using 90% of the channel. This is to be compared to the orange line showing the same test with OFDMA disabled.

However, the 90% utilization set in the downstream with OFDMA disabled produced a lower average RTT latency shown as the green line in contrast to the OFDMA enabled case shown as the red line, where RTT latency was consistently higher. These results further underscore the point that improvements in latency are not necessarily the same based on the direction of the traffic that is loading the channel. During this game play the downstream traffic load produced lower RTT latency with OFDMA disabled, while the upstream traffic load test produced lower RTT latency with OFDMA enabled.

Figure 25 – CS:GO Reported RTT Latency Over 1 Minute of Game Play – Wi-Fi 6E

9. Additional Tests to Consider

There are many opportunities to extend this work and help chipset vendors to improve schedulers for real world scenarios and expectations. A list of additional tests to explore include:

- Create approximate defined percentages of out-of-network traffic on the same primary and secondary channels
- Create approximate defined percentages of out-of-network traffic on only the second half of an 80 MHz channel in the non-primary channels
- Traffic load set on the channel in the opposite direction of the direction of traffic to/from a client under test
- The same test conditions in this paper but with 5, 8, 9, and 13 clients at 80 MHz and 160 MHz to test grouping and usage of mixed RU allocations
- The same test conditions in this paper but with Linux operating system on the clients to get RTT of each TCP data flow in iperf3 in the upstream as well
- 20 clients with 12 clients doing constant 0.1 Mbps traffic to stay utilized while testing other 8 clients with various traffic and channel utilizations
- Characterize how a scheduler allocates RUs as you gradually increase bitrates or airtime percent in use
- Locating clients at near and far locations for 2 groups of power ranges
- Locating clients at near, mid, and far locations for 3 groups of power ranges
- Creating varied but defined traffic load percentages for the other clients to represent low usage and medium usage on many clients in addition to a client under test usage
- Send high data rate to a client while alternating low data rates to another and then vice versa to see if groups are too sticky or if RU allocations are not changed fast enough
- Enable VHT MU-MIMO for evaluation against OFDMA benefits with clients in various locations where VHT MU-MIMO can operate ideally
- Enable HE MU-MIMO for evaluation of scenarios that should use HE MU-MIMO instead of or at the same time as OFDMA – run each separately to determine if schedulers are picking the right mode when both are enabled
- Set up a reliable NTP for better time synchronization between source and clients to get reliable one-way-delay UDP measurements with NUTTCP
- Evaluate the same test case repeatedly to evaluate consistency of results with schedulers for a given test method and given scheduler implementation – is it doing the same thing each time?
- Statically/manually set OFDMA groups and RU number of tones per client to evaluate best case 100% OFDMA performance and compare to results of automatic scheduler operation in throughput and latency
- Use a separate physical Ethernet port for each of the four client's iperf3 traffic
- Use a different Wi-Fi 6/6E client chipset for all the above
- Use one of the many other test tools to evaluate all the above

10. Upgrading to Wi-Fi 6E and enabling OFDMA for Wi-Fi 6

Considering the testing described in this paper, when is the best time to enable OFDMA or deploy Wi-Fi 6E? The answer depends on the needs of the end-user. If the end-user is in a crowded RF environment with a lot of out-of-band Wi-Fi traffic and neighboring APs, upgrading to Wi-Fi 6E now is appropriate. OFDMA alone may not be enough to help overcome persistently crowded channels especially if it is out-

of-network traffic on the same channels in use. There are more than enough Wi-Fi 6E devices and laptops available now to take advantage of the extra channels and clean airtime if the end-user needs to solve a problem with airtime availability and can change to a Wi-Fi 6E client or Wi-Fi 6E client adaptor. The clients using Wi-Fi 6E have endured some growing pains with sparse driver update availability and security differences in how clients connect, but these are temporary issues and have already improved greatly over the last year. OFDMA enabled in 6 GHz will continue to improve as chipsets and firmware mature and much of the development and progress on-going in 5 GHz will directly carry over to 6 GHz without much delay.

In environments not overly crowded from out-of-band overlapping 5 GHz traffic, enabling OFDMA on a Wi-Fi 6 AP is a great way to allow what appears to the end user as a more responsive channel while serving the same clients and bandwidth needs in the home. This appears to be the case from the testing completed in this paper, especially if the channel is crowded from in-network traffic. Even mixed client populations of Wi-Fi 5 and Wi-Fi 6 can achieve latency improvements with OFDMA enabled if the Wi-Fi 6 clients are served quicker and simultaneously. Most of the traffic on the internet is TCP, and with TCP traffic the number of situations where latency worsened with OFDMA enabled were about the same as the situations that improved. The situations that didn't improve weren't necessarily situations that needed to improve to have a better QoE to begin with. AP chipset scheduler improvements over time should alleviate many of the issues encountered, because the channel is not contentious in many of the situations in which latency worsened instead of improving. It is yet to be determined if the same benefits observed and described in this paper are also seen with the additional test conditions listed in the Additional Tests to Consider section.

11. Conclusion

This paper sought to define a wide range of test cases to determine which scenarios with today's AP chipsets can achieve reduced latency when OFDMA is enabled. The results showed highly utilized channels stand to benefit the most from enabling OFDMA. Furthermore, higher utilization of the client in use improves the chance of realizing a latency reduction. The upstream tests with OFDMA enabled tended to show more impressive reductions in latency because the clients were not fighting each other for TXOPs in the upstream. The downstream tests did not show the same extent of improvements as were seen in the upstream. In the downstream with OFDMA disabled, the AP is already scheduling transmissions individually as the queues demanded and was less contentious as the AP was in charge in the downstream. VHT and HE MU-MIMO may be more advantageous for latency reductions in the downstream for the environments and schedulers that can use it effectively. The lower bitrates sent to or from the CUT also didn't improve latency as much as the higher bitrates tested and sometimes incurred even higher RTT latency, indicating some chipset thresholds to cause OFDMA scheduling of the CUT were not met.

Test scenarios with 10% utilization from other clients didn't have major problems with latency to begin with and didn't usually improve the latency to the CUT when OFDMA was enabled. When the airtime is highly congested, or a lot of frames are being sent to or received from many clients, the ability to win a TXOP becomes harder, and it delays the information being sent. In this setup, greatest improvements in latency were realized in high airtime usage scenarios. The greatest improvements in reduction are naturally seen when comparing to situations that have the highest latency to begin with.

In conclusion, the charts below in Figure 26 and Figure 27 summarize when an end-user may expect to see improved latency with OFDMA enabled in a house with four clients. This summary was created while generalizing the AP chipset used, ignoring differences in packet size outcomes, and generalizing results from pure Wi-Fi 6 client tests and mixed half Wi-Fi 5 client tests to provide a simpler summary

with just a couple variables. The jitter or mean deviation of RTT latency and max RTT latency were heavily considered in addition to the average RTT latency to indicate if latency was seen improving or worsening. This is because the changes were often more dramatic in max RTT and jitter of RTT samples even if the average RTT didn't change meaningfully.

The color of the bars represents the CUT throughput while the four clusters of bars in each chart represent each channel utilization scenario, indicated at the bottom of each chart. The taller the bars the larger the difference in RTT latency, one way or another. If the bar, starting from the middle, is going upward, a general improvement in latency was seen. If the bar is going downward from the middle, a general degradation in latency was seen. The middle represents about the same latency observed and would be a missing bar in this set of charts, to indicate it generally was not better or worse.

Figure 26 – Latency Change Observed with OFDMA and Downstream Traffic

Figure 27 – Latency Change Observed with OFDMA and Upstream Traffic

The test iterations were large in number and defined many scenarios and settings, but was rigid in location of clients, number of clients, type of clients, and measurement methods. The rigid test constraints served the purpose of allowing for repeatable testing as well as allowing for relative testing so results of each mode could be compared to each other. There may be some results that are only realized in a setup like this paper assumed, and other results and improvements that were not seen from perhaps moving a client five feet in another direction, using a different client, or using 20 clients.

This paper sought to identify scenarios that improve with OFDMA enabled with the setup described herein, but it is not the only setup there is. In fact, there is not another house with the same layout, furniture, clients, AP or client positioning, or any number of many other factors which could lead to different results. There is included in this paper an extensive list of follow-up testing to consider, in order to investigate the many other ways and scenarios OFDMA can help reduce latency. In this paper, a given static setup and careful adherence to keep many things constant while iterating certain chosen parameters only, allowed for relative comparisons to be made and conclusions drawn.

1. Executive summary

Telecom for Wellness (T4W) is a multi-trillion-dollar opportunity for cable operators. This opportunity begins with the connectivity and device base that is already in place and expands simply to move into new high-value revenue opportunities in the wellness, telemedicine, and aging-in-place markets. In this paper, we analyze different in-home networking architectures that can be added to the existing Broadband and Wireless networks in the home to support T4W services such as Aging in Place (AIP) and Telehealth. To minimize CapEx investment for this new service evolution we will show how the existing infrastructure can support sensor-based networks, audio networks, video networks, and IoT for medical device networks in a simple incremental architecture from today's quad-play services. The paper will provide an analysis of the home networking components needed for the AIP and Telehealth applications to overlay into existing backend services, processes, and even technician in-home support. This paper will leverage the work done within SCTE Working Groups to derive an outline of the standardization of cable industry premises devices with wellness capabilities used for T4W services. It will highlight the interfaces for wellness solutions to be added to Broadband Gateways, STBs to provide access to resources like BLE and Wi-Fi, such as simple secure onboarding, messages and notifications on the TV / Video and Audio networks. It will also look at the cloud-to-cloud interfaces that can be standardized to allow partnerships between Service Providers and Cloud wellness partners to create inter-industry opportunities.

2. Introduction

The Wellness industry is going through a major transformation to modernize the infrastructure, reduce the cost and increase the quality of care. In a series of articles, we have suggested how the Telecom industry can assist the Wellness industry (Refer to [1], [2], [3], [4], [5], [6], [7]). We call this inter-industry collaboration Telecom for Wellness (T4W). Even though the T4W opportunity is not limited to these two major intersection points ([13]), we focus on Aging in Place (AIP) and Telehealth use cases to illustrate our thoughts on the end-to-end T4W architecture in [8]. (Refer to [9] for six different opportunities that a Telecom operator can address through the T4W architecture covered in this paper.) The SCTE Data Standards Subcommittee, of which the authors are members, is actively working on T4W solutions for the AIP and Telehealth areas in working groups three [10] and four [11].

[1], [2] provides a quick summary of the T4W opportunity and challenges from AIP and Telehealth points of view. Many of the needs, challenges, and Telecom opportunities of both markets are similar (refer to the SCTE working group analysis at [10], [11]). Some of the high-level use cases that need to be supported for these two markets include:

- A. Providing basic communication between the users and the providers/caregivers
- B. Providing seamless communication between the users and the stakeholders
- C. Monitoring the users for health, mobility, fall detection, etc.
- D. Analyzing the data collected from the users and properly notifying the stakeholders
- E. Assisting the T4W service providers with claims by documenting accountability
- F. Offering managed services to support installations, product support, and other services to improve adoption and retain customers

	 Aging in Place	 Telehealth
Users	Older adults (65+), caregivers	Individuals, providers
Stakeholders	Family members, care givers, doctors, service personnel etc.	All family members, providers, (payers)
Needs	Communicating, monitoring, service, support, integration	Communicating, monitoring, integrating with provider systems
Challenges	Ease of use, provider network integration, problem solving	Ease of use, device and EMR integration, remote monitoring,
Telecom opportunity	End to end solution, managed services, provider integration	End to end solution, managed services, provider integration

Figure 1 Telecom for Healthcare opportunity and challenges summary

Many of these use cases are elaborated on in [9]. In the use cases paper, we presented AIP, independent living, and hospital at-home use cases (the extreme ends of the T4W) with the consideration on what are the opportunities for the cable operators.

In the next sections, we summarize the T4W architectural needs, provide a framework, discuss individual components, and start discussing the **sensor network gateway** concept.

3. End-to-end high-level T4W architecture

Figure 2 provides a high-level end-to-end architecture proposed by Duke Tech Solutions (DTS) in their market analysis [13] based on different T4W market opportunities. The framework is elaborated in [8].

To understand the end-to-end T4W architecture, first, we need to understand the users, the service providers, and the other stakeholders as shown in Figure 1. We adopt the architectural framework provided in [8], DTS's Telecom for Wellness Environment Framework (DTEF), to evaluate the in-home components proposed in this paper. We will use AIP and Telehealth use cases (as provided in section 2) to do this.

1. In-home healthcare/wellness aware gateway: From use cases A, B, and C, it is clear that there needs to be a gateway in the T4W home. This gateway, as shown in Figure 2, acts as an integration point for monitoring the sensor devices (e.g., motion sensors, remote patient

monitoring equipment) and integrating with the interactive services endpoints (such as unified communication services). This **Sensor Network Gateway (SNG)** can be a standalone device or integrated with other vendor equipment such as the set-top box or residential gateway. In this paper, we treat it as a logically separate device.

2. **T4W aware network infrastructure:** Again from the use cases A, B, and C it is clear that the T4W requires connections between the users, the providers, and the other stakeholders. This requires not only reusing the existing telecom infrastructure but will also need to meet reliability, security, and privacy requirements specified by the T4W architecture. The communications infrastructure will have to meet the needs of the sensor network traffic, unified communications traffic, and notifications to the different stakeholders. To differentiate (or to keep the focus on) the T4W needs, we call this the **T4W Sensor Network Infrastructure**.

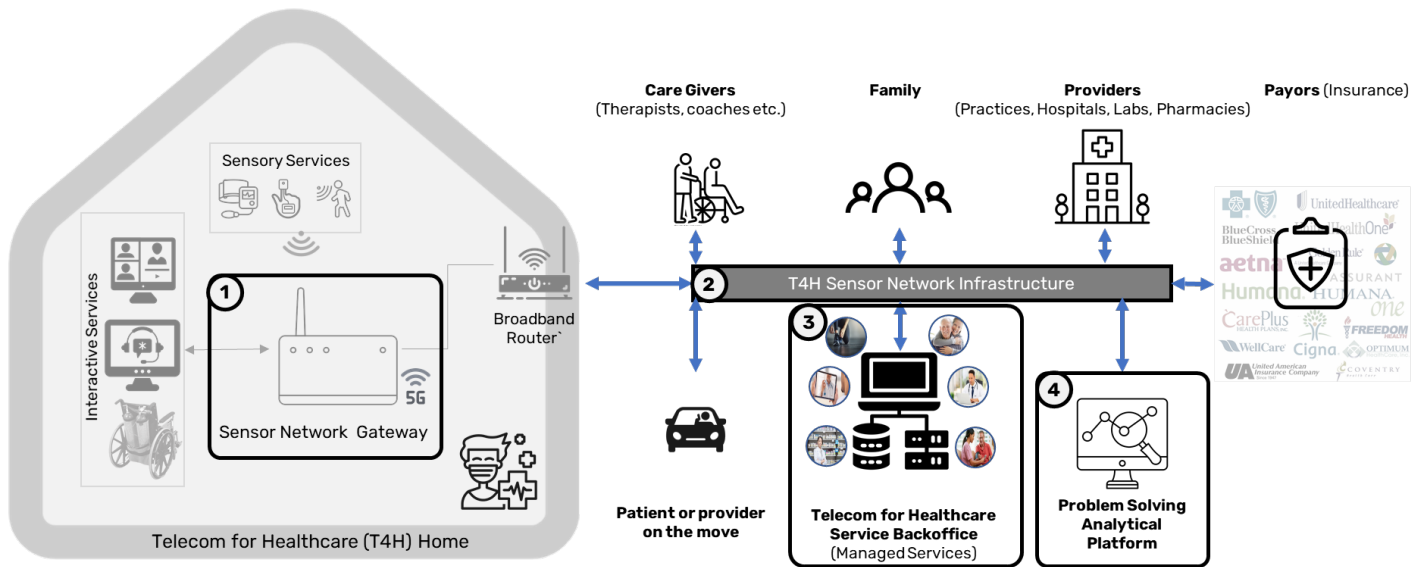

Figure 2 DTS's Telecom for Wellness Environment Framework (DTEF) based components

3. **T4W aware service back office:** The cable operators have all the required infrastructure for managing end-to-end services. As mentioned in use case F, it is essential to turn the fragmented, gadget-oriented point solutions into a well-oiled managed service. This can only be accomplished by Telecom operators who have access to such infrastructure and have been managing communications infrastructure for 90+% of the households in the US. We call such infrastructure as **T4W Service Backoffice**.
4. **T4W aware problem solving analytical platform:** Finally, as mentioned in use cases D and E, this infrastructure attempts to solve the problems stakeholders are facing. These problems and related algorithms may be unique to the healthcare/wellness industry, but the infrastructure is similar to the infrastructure the telecom operators use today. We call this repurposed analytical platform the **T4W Problem Solving Analytical Platform**.

In the following sections, we highlight the sensor network gateway's hardware, software, and cloud interface needs to enable inter-industry opportunities.

4. Sensor network gateway components

Figure 3 shows different tasks that need to be done in a T4W capable home, as briefly discussed below:

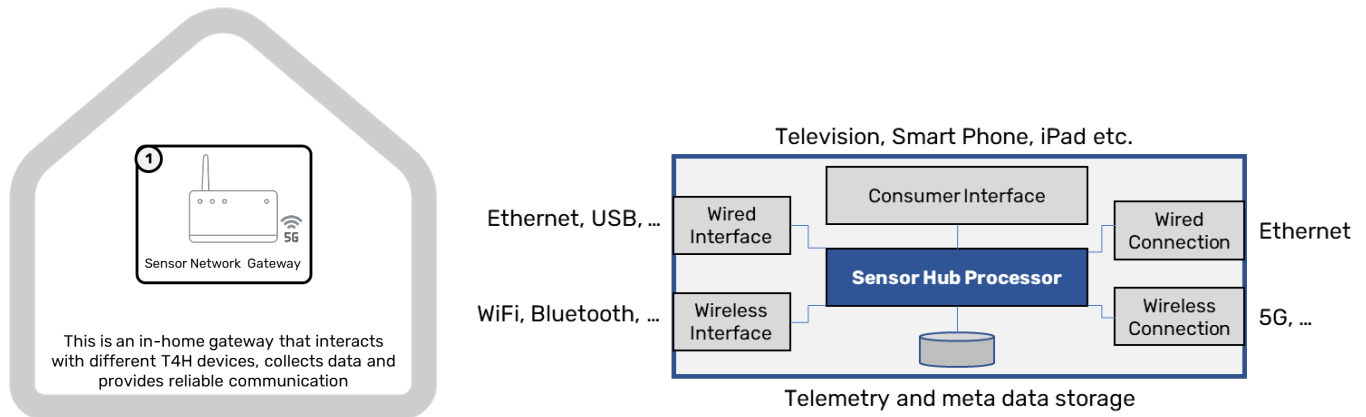

Figure 3 Sensor Network Gateway architecture

- Support for different data streams: The AIP and Telehealth infrastructure needs to support typical data streams generated in a T4W home. These include sensor and actuator data streams, streams to record events, and real-time streams such as video and audio communication between T4W stakeholders.
- Communication with existing in-home broadband devices: These might include consumer consoles (such as TVs or smart speakers), and smart home devices (such as smart locks, lights, or video doorbells). To increase the adoption of T4W solutions and for ease of use, the T4W in-home components need to be on the same logical network.
 - The T4W physical networking can be dependent upon the use case for any particular device. Most components are likely best connected with an in-home broadband network, but certain devices (such as a locator device) may need to be connected even if the user is beyond the limits of the in-home network. The important thing is that the networked devices can communicate with each other on a secure logical network. Critical components may require a secondary backup network connection in case the primary network fails. Cloud-based services also protect against exclusive dependency on the in-home network.
 - The in-home solutions shall integrate remote patient monitoring devices, sensor devices (such as fall detection, motion sensors, etc.), and other IoT devices that are used for wellness needs.
 - Additionally (to increase the utility and ease of use of the system), the T4W solutions shall be integrated with the frequently used consumer consoles (such as Television for the elderly), smartphones, and other handheld devices. Again, a cloud-based solution simplifies an experience that can be duplicated on whatever console is convenient.
- Provide installation and support services: The operator shall also streamline the installation and support services to improve the ease of use of the integrated solution.

4.1. Hardware and software components

As shown in Figure 4, the cable operators already have been deploying many standardized protocols, interfaces, and devices for different in-home solutions. Extending them to T4W solutions will be a natural extension for them. But they have to offer many subtle features to be adopted by the wellness industry. These extensions are elaborated on in the following section. The required tasks of the solution are broken into the device-facing interface, network connectivity interface, in-home controller interface, internal

capabilities, and inter-industry collaboration interfaces (represented by the Cloud2Cloud interface in the figure).

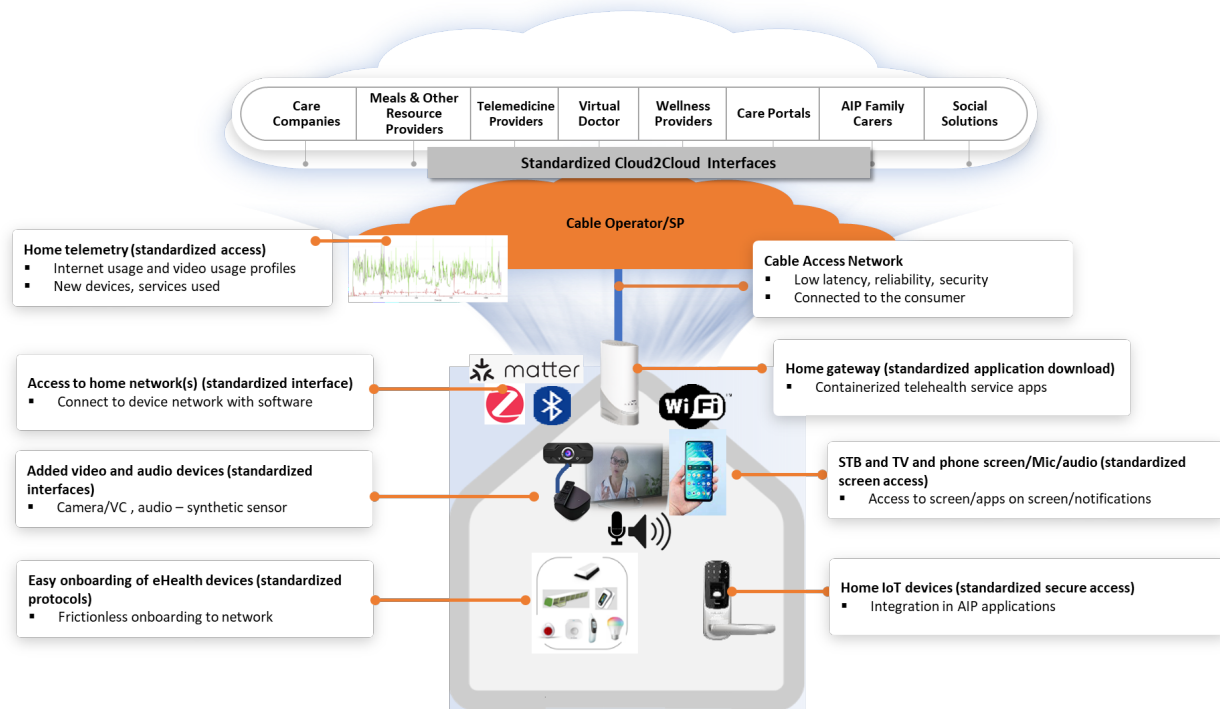

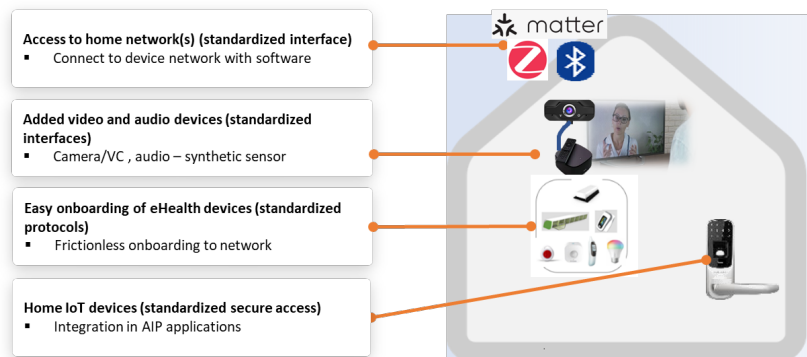

Figure 4 Unifying the wellness resources with the in-home and access networks

4.1.1. Device facing interface

Based on the above high-level needs, we propose that a Sensor Network Gateway (SNG) functionality be developed for supporting T4W solutions. The block diagram of such a gateway is presented in Figure 3 with a bit more details and how it interacts with other devices visually in Figure 4. This gateway will have wired (Ethernet, USB, etc.) and wireless (Wi-Fi, Bluetooth, BLE, etc.) interfaces to integrate the T4W devices and other IoT devices (such as turning on a light, placing a phone call to a family member). Note that if the SNG functionality is integrated with the residential gateway these requirements apply to the residential gateway.

Functionalities

At a broad level, there will be two types of southbound facing devices to the SNG. These are the two-way communication devices such as the devices used for Telehealth and the one-way communication devices such as sensor devices used typically for monitoring. The following discussion applies to both such categories.

The SNG should have the device-facing capabilities to:

- **Register** a new device and **onboard** with proper credentials before letting it use the network
- Learn the **capabilities** of the device as part of the device registration
- **Authenticate** a device against the registered credentials
- **Detect** the wired and wireless devices when they either come alive or connected
- **Securely** communicate with the device for different information exchanges for status gathering, data collection, etc.
- Identify the **status** and different levels of availability of the device during the communication.
- **Collect** on-demand and continuous **data** from the device

Types of interfaces

The SNG will act as a gateway to the T4W applications. This requires the SNG to support some of the following interfaces. Note that only some of the interfaces are required depending on the positioning of the SNG. It is not in the scope of this document to provide the number of such interfaces.

The SNG should support the device-facing (Note that it is not in the scope of this paper to recommend one protocol or the other):

- **Wired** interfaces such as Ethernet or USB connection with potential hub functionality
- **Wireless** interfaces such as Wi-Fi, Bluetooth, BLE, Matter, etc. with potential hub functionality

Serviceability

The serviceability of the SNG and its subtended devices are essential for making the T4W services more sustainable. In this section, we highlight the serviceability needs of the subtended devices.

The SNG should support different protocol serviceability constructs such as:

- **Monitoring the reachability/connectivity** status of different wired and wireless devices
- **Debugging the connectivity** and other **serviceability** issues for the subtending devices

Other requirements

Other requirements from the SNG towards the device interface include:

- **Charging** the connected devices where possible for high-priority devices, and

4.1.2. Network connectivity interface

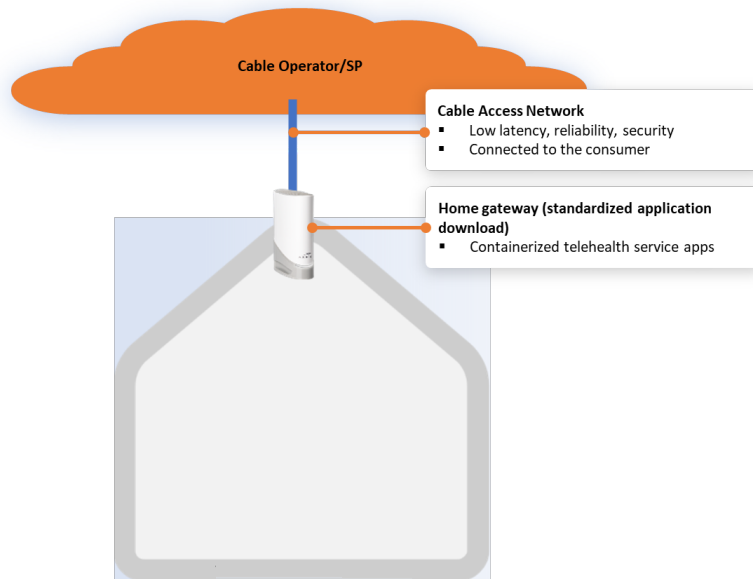

The gateway shall provide high-quality redundant Internet connectivity such as with an Ethernet interface to wired broadband and a 5G or other wireless connection as a backup.

Functionalities

The SNG will have northbound facing internet connectivity for providing access to the network or for in-home devices. The following discussion applies to both such categories of connectivity.

The SNG should have the network-facing capabilities to:

- Provide **high-quality differentiated communication** based on the priority of the application
- Offer differentiated services to both for **one way and two-way communications**
- Provide **high availability connectivity** based on the importance of the communication (for example, backup the cable connectivity with the 5G connectivity for some of the sensor devices as opposed to the Telehealth video communication solutions)
- Provide per **session-based secure communications** at the device level (Note that there may be multiple stakeholders for every session)

Types of interfaces

The SNG should support Quality of Service (QoS) supported redundant interfaces for high availability connectivity, such as:

- A **wired primary interface** for high QoS enabled interface (for example, Ethernet, DOCSIS, PON based)
- A **wireless secondary interface** (for example, 5G interface) for high-priority traffic communication during primary interface failure
- A **failover mechanism** that provides the service continuity protection for high-priority traffic during primary interface failures

Serviceability

The SNG should support different techniques to monitor and test service continuity, such as

- Remote access loopbacks (e.g., using 802.1x)
- Service level network connectivity polling

Interaction with other northbound interfaces

In addition, the SNG should interface with different in-home components, such as

- The **wiring closet**, as discussed in [14]
- The **broadband router**, if SNG is not integrated into the router, and

- An external or internal device that provides a failover redundant communication

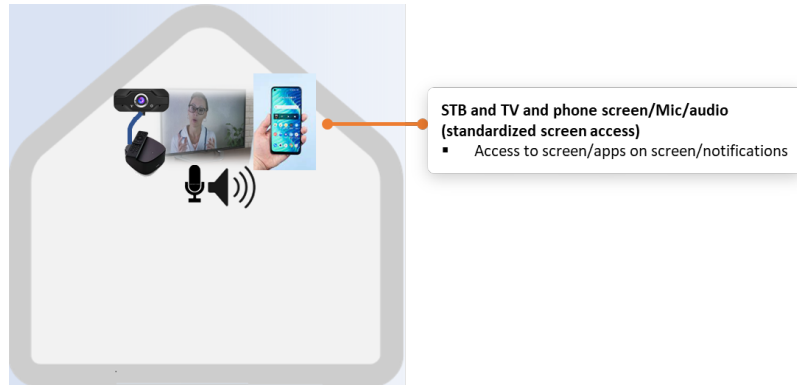

Other requirements

The SNG and its downstream applications may also require an accurate time of day and date. This can only be achieved if the SNG has access to the

- Network timing information through the timing protocols as a pass-through from the router

4.1.3. In-home controller interface

The SNG will also need to integrate the consumer access interfaces (TVs, smartphones, iPads, etc.) to increase the adoption of the T4W applications.

Functionalities

The SNG functionality and many other T4W solutions require some of the following functionalities for ease of use. The SNG should

- Provide **video console** (such as TVs, iPads, etc.) **integration** to offer as a console to the management of the T4W services.
 - This includes all the unified communication aspects of the interactions such as the notifications, two-way conversations, and certain process flows such as interrupting the activity that is being performed on the video console.
- Interact with an **easy-to-use remote controller** to manage the on-screen process flows
- Offer, where possible, **voice-enabled interactions** with the SNG
- Be able to **split the feeds among the stakeholders, on-demand** basis, based on the stakeholder privileges

Types of interfaces

The SNG shall offer different interfaces to communicate with the in-home controller device. It should

- Provide a **wired interface** to connect with the video console (such as USB, Ethernet, etc.)
- Provide a **wireless interface** to connect with the video console (such as discovering and connecting to the Smart TV over Wi-Fi)

Serviceability and debugging

The SNG should extend the service continuity evaluation to the in-home controller interface for ease of service assurance.

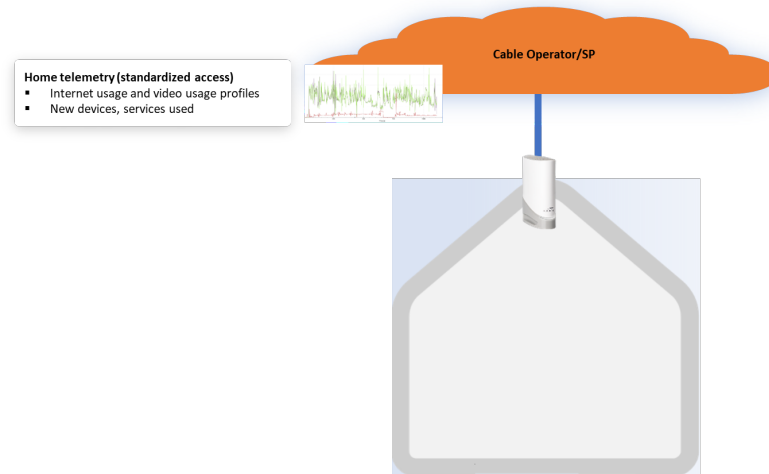

4.1.4. Internal functionalities

The SNG will need limited internal storage for the temporary storage of sensor data and to perform local analytics on time-critical events. The gateway shall offer an easy installation process and support self-install where possible.

Functionalities

The SNG should

- **Register** the gateway device with the T4W platform for different service capabilities that it can enable and is allowed to perform
- Provide support for the **unique addressability of the device** (IP address, etc.)
- Be capable of providing different **QoS** marking, prioritization, and fulfillment capabilities
- Be capable of **self-installing** during initial bootstrapping and later during the upgrading
- Provide a **management interface** to configure and manage different features of the device
- Provide **extensive stats collection** capabilities as highlighted in [12]
- Support some **basic analytics** to perform local analysis and notification capabilities
- **Store and provide access** to the information collected for at least **one day** in case of loss of internet connectivity

Types of interfaces

The SNG should

- Support **service** (a physical or a logical) **interface** to access the management interface
- Support a local **interface** for the field technician if the device is not reachable through the internet
- Allow **access to different debugging tools and statistics** that are collected on the gateway

Other requirements

The SNG should support

- AC and DC power with potential for battery backup based on the scope of the product

4.2. Inter-industry collaboration interfaces

The SNG is the customer-facing part of the end-to-end Telecom for Wellness solutions as shown in Figure 2. A cable operator or someone working along with the operator can create a platform with these components. Once the platform is created, it can be used to enable different stakeholders and solve their problems, and also can be used as a conduit for different services from other value-added wellness-related service providers.

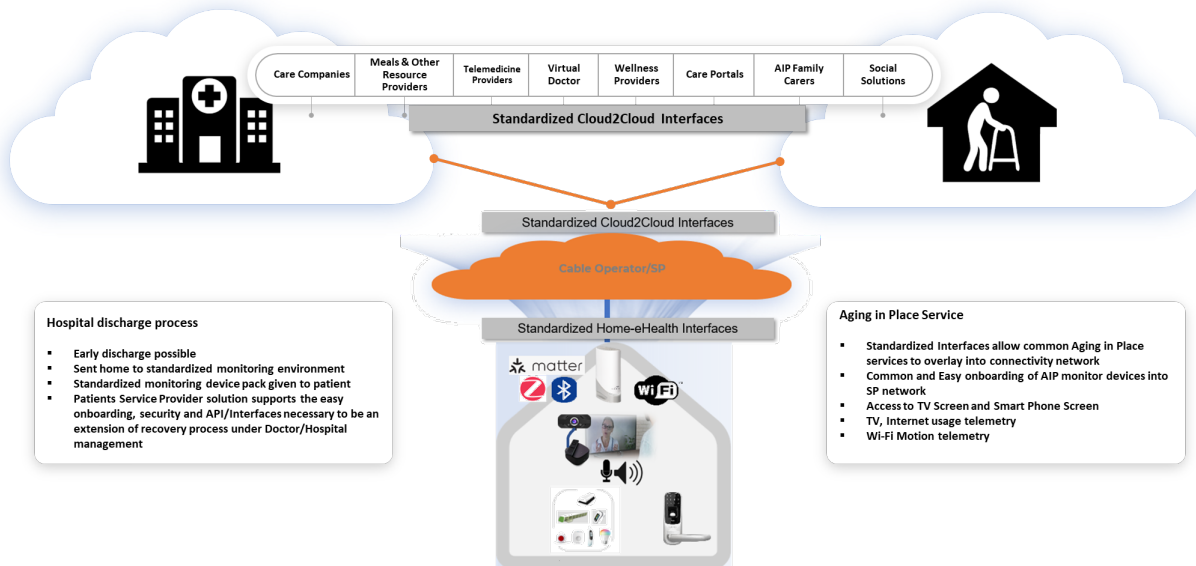

Figure 5 Making a home an extension of Telehealth services through standardized interfaces

The T4W provider can offer this platform for internal use and to the marketplace of the service providers through a set of services. Figure 5 provides two such use cases that can be enabled using an inter-industry collaboration. More information on these use cases and the opportunity for the cable operators are detailed in [9]. The SNG will in this case work as the subtended device in the house for the set of newer services. In this case, the SNG and the cloud platform shall support the following functionality through different service enablement constructs:

- Faster service enablement
 - **Onboarding** newer service providers
 - Establishing the service capabilities with the **same look and feel**
 - Creating constructs for **single billing** capabilities
 - **Extending** the proposed **serviceability interface** to the external service providers
- Knowledge sharing
 - Enabling **access to different monitoring** points based on the registration
 - Creating different status monitoring and **data collection points per service** (or provider)
 - Setting threshold crossing alarms and providing **access to those notifications**
- Giving access to the T4W platform's problem-solving infrastructure based on the service agreements
- Enable cloud-to-cloud interface between service providers through standardized interfaces

5. Conclusions and recommendations

As presented in the previous papers, T4W is a multi-trillion dollar opportunity for cable operators. In this paper, we extended the details of the DTEF framework's in-home component, namely the SNG, requirements to enable T4W. These requirements highlighted can be implemented in a standalone device or the functionalities can be integrated with one of the intelligent in-home devices (such as a residential gateway or a Set Top Box). The cable industry and partners are uniquely positioned to standardize and

implement such solutions with their ubiquitous presence, in-home deployments, service management workforce, and end-to-end infrastructure. To bring this opportunity to life, we recommend developing standardized SNG solutions that

- Enables different one-way and two-way communicating devices,
- Offers standardized, redundant north-bound interface,
- Provides an in-home customer (and their service) management interface,
- Offers constructs to different data collection, problem-solving, and management of the device
- Provides standardized cloud-to-cloud interfaces to enable inter-industry collaborations

We would like the cable operator ecosystem to actively engage with us at the SCTE working groups, implement these solutions and enable the Telecom for Wellness opportunities.

1. Introduction

The coming convergence of broadband, energy, and transportation has the potential to transform all three industries in unexpected and powerful ways – with significant impact on CAPEX, OPEX, and value creation opportunities. However, the potential of this transformation cannot be fully realized without successful collaboration across these three industries. The purpose of this technical paper is to raise awareness of this coming convergence and to stimulate conversations across these industries to take advantage of what, to this point, may be nonobvious synergies.

In the United States, the Infrastructure Investment and Jobs Act (IIJA) represents a once in a generation investment in infrastructure for these three sectors and a unique opportunity to speed this convergence by creating an opportunity to completely reimagine the country's underlying infrastructure. Historically, each industry has developed its infrastructure independently. However, as broadband has been a key driver in the transformation of many industries, as they digitize and move to the cloud, rethinking shared infrastructure can change the capabilities that the three industries can bring to market. It is the increased connectivity, reliability, bandwidth, and security of broadband that is enabling innovation at scale across virtually all sectors, not only in the U.S., but globally. Most importantly, the Energy and Transportation sectors are already poised for massive disruption and transformation and, as we will show, broadband is and will be a key enabler for this.

This technical paper will identify the key drivers of this cross-industry convergence and explore how it will come about by focusing on the three most important contexts for this convergence:

- Home: How will convergence impact services and behaviors in the home?
- Urban: How will cities and suburbs change and develop?
- Rural: How will rural areas adapt and thrive?

This technical paper serves as a call for cross-industry collaboration on the opportunities of this cross-industry convergence. As the Broadband Industry's innovation engine, CableLabs has decades of experience in bringing industry-transforming innovation to market through collaboration within and across industries and looks forward to uncovering and collaborating on nonobvious synergies across the industries.

One obvious area where cross-industry collaboration could stimulate innovation are the common expectations of communications capabilities that are limited to the “lowest common denominator”, as opposed to envisioning the possibilities and needs of the future. The cable industry is in the midst of its 10G [10 Gbps] industry initiative¹, addressing not only speed, but reliability, security, and latency. What applications and services could be developed for the transportation and power industries if they were not constrained by the limits of today's broadband technology?

This technical paper identifies several possible synergies and opportunities. We are certain that you will envision many more. 2. Background

Perhaps the most important insight into this coming convergence is from an understanding of how broadband access network technology (both fixed and wireless) intersects with the power grid and the shared opportunities that exist. Today, energy companies have a lack of visibility into the performance in the last mile of their power distribution grid. On the contrary, while less well known, broadband access network providers are consumers of energy from the grid, particularly in the last mile, which provides great insight into the last mile of the grid. To deliver broadband services to consumers and businesses, broadband access networks have active network elements that are powered by the grid. To provide broadband services in periods where there may be a power outage, broadband network operators integrate resilient, battery-backed power systems to keep these network elements operational (see figure below). These points of connection between the broadband network and the power grid provide unique insight into the performance of the power grid where power companies lack visibility. As an example of what is possible from these points of connection, Gridmetrics, Inc.² leverages them to provide visibility into the status and performance of the power grid at a geographical and temporal resolution not previously available.

The figure below provides an example of the convergence of broadband and energy utilized by Gridmetrics. It shows the power distribution grid along with a Hybrid Fiber-Coax (HFC) network and mobile small cell. It also shows their connection to the home with an EV charging station and potentially distributed energy sources. The HFC node and the mobile small cell are among the active elements in the fixed and mobile networks. The HFC network can act as a backhaul network for the mobile small cell and provide broadband services to the home. A backup power system monitors the power grid and provides backup power to both the HFC node and mobile small cell in case of power outages. These backup power systems are connected to the broadband network to report on their operational status. The backup power system can not only monitor the availability of power from the grid but can also monitor the quality of the power signal and more. Because this is part of the broadband access network, it can harness this broadband connectivity to aggregate information where it can be analyzed. This aggregated power measurement data provides high quality, fine grain insight into the health of the power grid. With the growth in distributed energy resources (DERS) this insight will be critical for the management of the power grid. It should be noted that the EV charging station at the home or the distributed energy resources (e.g., battery, solar, wind) shown in this figure can serve a similar function for monitoring the grid if they are connected to the broadband network and have some form of backup power.

² See *Gridmetrics White Paper* by CableLabs[®] and Gridmetrics[™] and <https://gridmetrics.io/>

Figure 1 - Point of convergence of broadband and energy at the home

In subsequent sections we will show how this point of convergence between broadband and energy is extended to include transportation and how it fits into the Urban/Suburban and Rural contexts. First, we will cover the key drivers of this coming convergence of broadband, energy, and transportation.

3. Key Drivers of Convergence

There are multiple drivers of the convergence of broadband, energy, and transportation, including:

1. Two-Way Flow - Grid Modernization, the digital transformation to enabling the bi-directional flow of electrons along the distribution power grid
2. Distributed Energy - The shift from centralized to distributed energy resources (e.g., solar, wind, battery, etc.)
3. Charging Infrastructure - The electrification of vehicles and the deployment of the supporting EV charging infrastructure, both at home and through commercial EV charging networks
4. Energy Transactions - The evolving EV charging requirements for connectivity to support “reservations and payments”
5. Transactive Energy - The evolving Transactive Energy Ecosystem that is tightly coupled to a modernized grid and EV needs
6. Electrification - The shift from natural gas to electric for traditional uses of natural gas (e.g., heating, hot water, cooking, etc.)
7. Autonomous Vehicles - The evolution of autonomous vehicles with the resulting transformation of public transit and shipping
8. Cyber Threats - The need to address cyber threats to critical infrastructure
9. Broadband Demand - Increasing demand for ubiquitous broadband connectivity with the pressing need to address the digital divide and rural broadband
10. Investment - Substantial investment resulting from the Infrastructure Investment and Jobs Act (IIJA)

Any number of these drivers could be sufficient to stimulate convergence, the combination of them all makes it essential that we envision this convergence now and take the appropriate steps to realize it in the coming years. Any investment in infrastructure should anticipate the future vision for these industries.

4. The Point of Convergence Across Contexts

It is important to understand where the physical point of convergence occurs across these three industry segments within the identified contexts. The insight here is that the power grid and the broadband network physically come together at those points where a broadband network connection is made that draws power from the grid, e.g.:

- At the home with the broadband modem/gateway, home EV charging stations, and/or distributed energy resources, such as solar and/or battery
- At public, commercial or fleet managed EV charging stations
- At the access points for commercial and MDU buildings
- Along roads and highways where Vehicle to Infrastructure (V2I) small cells are placed

It is these points of connection that enable the convergence of the broadband, energy, and transportation industries. To further illuminate the convergence, consider the deployment of an EV charger, either for use at home, commercially or publicly. Along with supplying power to the charging station, implicit is a communications link. Communications is essentially required to monitor and manage the EV charging (scheduling, notifications, troubleshooting, payments, etc.) The communications component is understood to be part of the delivered power charging solution, and with forethought and collaboration, the opportunity exists to create a more secure, robust, and efficient charging solution as well as a comprehensive data exchange capability. There is a natural, symbiotic interdependence among the industries. Consider:

- Real time monitoring of the quality of the power available and delivered to a vehicle
- Manage the sources of power available to the charging stations
- Scheduling charge times, particularly to optimize costs of power
- Reserving charging stations (public or commercial)
- Payments for on-demand charging
- Securing the charging stations, including video observations
- Providing data uploads to vehicles (including manufacturer specific updates, on-board entertainment, current navigation data, etc.)
- Providing data downloads from vehicles (telemetry data to manufacturer, insurance companies, fleet operators, etc)

Underlying each of these considerations is the communications network. Considering the protocols, security, resilience, and reliability of the communications networks as a key component of the complete solution benefits the entire EV charging ecosystem. In essence, addressing the complete solution with a holistic view can prevent the creation of inherent silos that fail to provide the optimal power delivery, reduce the costs, improve the software interfaces for the EV manufacturers and their consumers, ensure the security of the charging stations and its users and secure the power transactions. Minus an intentional desire to collaborate, the likely outcome is fractured solutions designed by the EV charger suppliers, car manufacturers, state/local specific solutions. The loser is the consumer who must manage the various interfaces with inconsistent outcomes.

4.1. Convergence at the Home

A primary point of convergence and one that is taking on increased importance with the changes in where and how people work, is the home. Figure 1 shows the diversity of assets that convergence at the home and we can expect these to grow.

The convergence of vehicle charging and distributed energy sources at home enable:

- Grid monitoring at the home
- Grid management for home-based energy sources (solar, battery, etc.)
- Automated Demand Response (ADR) for the home
- Secure broadband services for both consumer, grid monitoring/management, and autonomous EV connectivity (stationary)
- Consumer & commercial visibility into energy consumption & contribution
- Two-way power transactions between grid and EVs

It should be noted that there are also potential construction synergies (dig once for resiliency) in green field and new housing developments or in areas where investment is being made to upgrade or harden the grid and broadband infrastructures.

4.1. Convergence in Urban Areas

Moving outside the home, there are significant opportunities for convergence in urban areas across private, public, and fleet assets. The figure below shows the points of convergence across Urban areas.

Figure 2 - Point of convergence of broadband and energy in urban areas

In this context, V2I communication enables:

- Addressing traffic safety, congestion issues, and traffic signal management
- Parking and fleet management

- Transformation of public transit
- Transformation of package delivery
- Broadband connectivity to autonomous vehicles (in motion)
- Grid monitoring at the transportation V2I small cell location

Urban EV charging infrastructure enables:

- Grid monitoring at the charging station
- Security monitoring at the charging station (safety concern)
- Secure broadband services for autonomous EV connectivity (stationary)
- Two-way power transactions between grid and EVs

Vehicle charging and distributed energy sources at the commercial building or MDU enables

- Grid monitoring at the enterprise
- Grid management for enterprise-based energy sources (solar, battery, EV, etc.)
- Automated Demand Response (ADR) for the enterprise
- Secure broadband services for enterprise
- Secure broadband services for grid monitoring/management and autonomous EV connectivity (stationary)
- Commercial visibility into energy consumption & contribution

Similarly, there are construction synergies (dig once for resiliency) during construction or maintenance of transportation infrastructure.

4.1. Convergence in Rural Areas

Lastly, there will be convergence in rural locations that will be driving by engagement with devices while in transit and shifting population with a reimagining of the future of work with recent technology and behavior shifts. The figure below shows the points of convergence across Rural areas.

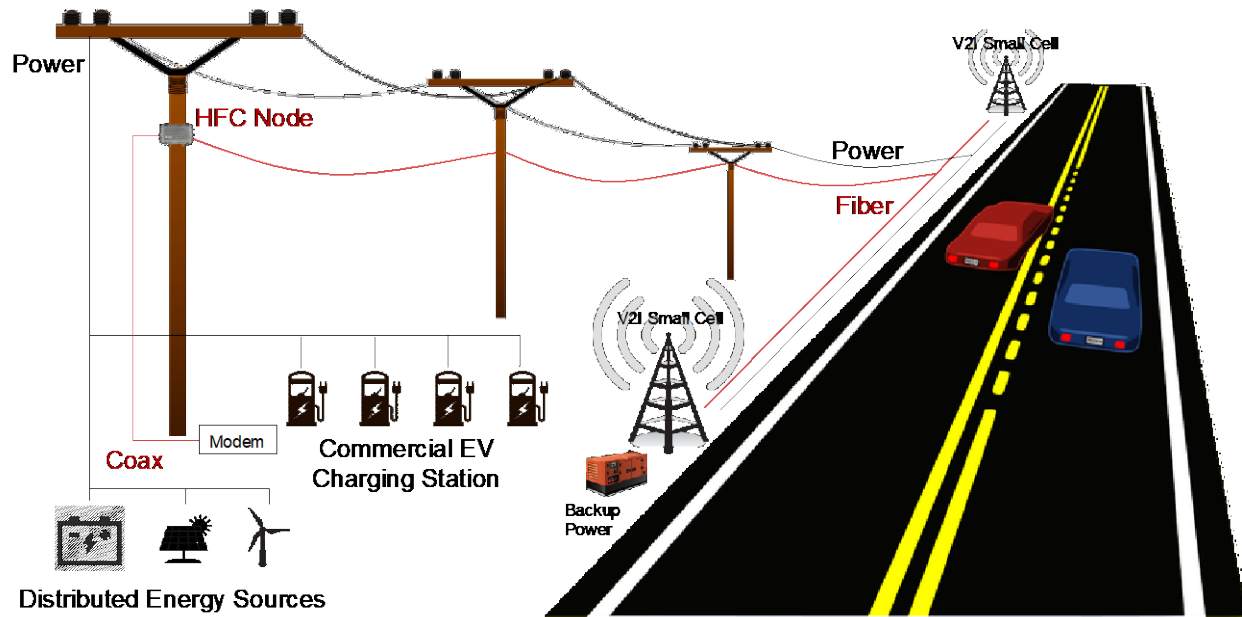

Figure 3 - Point of convergence of broadband and energy in rural areas

Like the Urban and Suburban contexts, V2I Vehicle to infrastructure communication enables:

- Addressing traffic safety and congestion issues
- Transformation of long-distance public transit
- Transformation of long-haul shipping
- Broadband connectivity to autonomous vehicles (in motion)
- Capability to identify and reserve charging stations (in motion)
- Grid monitoring at the transportation V2I small cell location
- Middle mile broadband connectivity for rural communities

As in the previous context, there are construction synergies (dig once for resiliency) during construction or maintenance of transportation infrastructure.

5. Conclusion

As noted in the Introduction, we are at a unique point in time to maximize the impact of investment into smart infrastructure across three major industries. This impact can only be fully realized through cross-industry collaboration. While we do not minimize the challenges of this kind of cross-industry collaboration, we do know that collaboration cannot occur unless the lines of communication are opened, both literally and figuratively.

CableLabs has a long history of creating standards and specifications to leverage communications infrastructure across broad markets. As the electrification of the transportation markets evolves, CableLabs is an ideal point of interface to ensure the communications networks are prepared to deliver the underlying protocols, transport, security, reliability, and resilience of this critical infrastructure.

1. Introduction

For the past decade, and within the halls of this very event (Cable-Tec Expo), technologists, researchers and experts across the compute and communications industries have been discussing and analyzing the “Edge”. Even though this term is not complex in and of itself, it, nevertheless, is fairly fluid. As much as the edge is about compute, it’s about communications, and even more about fusion of compute and communications for distribution of intelligence. Hence, the edge must be solved collectively by the communications providers (traditionally the cablecos and telcos) and the compute providers (the cloud), with a laser focus on consumption, treating the underlying tech merely as tools that can be swapped in and out.

Edge adoption will ultimately be driven by business value. Many organizations want their familiar cloud services brought to the edge where the data they want to process is created, on their choice of infrastructure — and with the flexibility of cloud consumption models. They want the cloud experience for the ever evolving workloads that are best suited to be at the edge. This “cloud edge” infrastructure might be in on-premises data centers, more of it will be in new edge data centers, embedded in edge devices, or even built right into the telecom infrastructure. Regardless of where it is, however, users will be able to consume services on cloud edge infrastructure the same way they consume services on traditional cloud infrastructure. For that reason, tremendous infrastructure investments are needed to support the growing device and infrastructure edge demand. Based on estimates, between 2019 and 2028, cumulative capital expenditures of up to \$800 billion USD will be spent on new and replacement IT server equipment and edge computing facilities [1]. These expenditures will be relatively evenly split between equipment for the device and infrastructure edges.

Many revenue-generating applications such as gaming, healthcare, IoT, AR/VR require low-latency networks with compute resources close to end users, leading to improved user experience and service quality. This brings multiple challenges regarding where to locate edge data centers, how to scale capacity and services within space- and power-limited environments, and how to provision and operate an increasing number of data centers and resources at scale. The answer is a cloud-like, virtualized, shared infrastructure combining compute and networking resources and supporting multiple container-based applications.

In this paper, we will analyze the evolution of the edge, emerging use cases that will accelerate and drive innovation, and key players in the ecosystem. We will touch upon the infrastructure ecosystem for the edge cloud and deep dive into the Network Cloud that will enable operators to utilize network functions on a shared pool of resources.

2. What is the Edge?

There is a biased view that edge and cloud are competing solutions. Actually, they’re part of the same continuum of putting colocation, compute, networking and storage in the most effective place, done in the most efficient way. Edge computing is comprised of combinations of systems that span a wide range of locations and conditions and support a diverse set of use cases. Certain use case might demand high-powered Graphics Processing Units (GPU) for AI (Artificial Intelligence), another one might demand low power consumption to lengthen battery life.

There's not just one answer to the question of the definition of "edge cloud". Each definition points out a unique and important concept in the world's computing infrastructure. For example, edge data centers are small data centers that are located close to the edge of a network. They provide the same hardware found

in traditional data centers, but are contained in a smaller footprint, closer to end users and devices. Distributed edge of 5G where a decentralized cell network made of edge data centers can help provide low latency for use cases with high device density, is another form of edge cloud. Cable operators, also, aim to leverage the edge and in this paper we will deep dive into multiple approaches in which this can be accomplished.

2.1. Evolution of the Edge

Historically, all the data and applications that enterprises needed was stored and processed locally in their on-premises data centers. Due to these resources being available locally, the latency and bandwidth was typically not a concern. These issues became apparent when users connected to the corporate network via a Remote Access VPN. Then, as the cloud computing paradigm took off, some of these applications moved to the cloud compute environment while the rest remained on-premises. This hybrid cloud model certainly has its benefits, but as digital transformation is driving enterprise applications and processes to the cloud, and particularly to public clouds the value of having data centers on site diminishes. Therefore, cloud infrastructure needs to become more distributed and ubiquitous to meet future enterprise needs as demand for cloud-based compute and storage grows. The first generation of distributed edge clouds is being deployed in metro data centers to provide enterprises with a greater choice of compute locations, both within and between countries. Such clouds are serving the needs of enterprises that want to process certain types of data at the edge for regulatory compliance reasons and/or that do not want to incur the cost of backhauling large amounts of data to centralized clouds. The proximity of the cloud infrastructure to the residential customers is, also, of high importance as the "work from home" shift is here to stay and there is a plethora of emerging uses cases like online gaming/streaming, AR/VR that are picking up the pace.

However, beyond this first wave of 'edge clouds', enterprises will require a more distributed, edge-native compute fabric that is available in every conceivable location, not just in a few hundred distributed cloud data centers worldwide, in order to support emerging software applications and software architecture. A new generation of data- and event-driven edge-native services will depend on the existence of a seamless fabric of edge-native clouds that can process their data very close to where it is needed. These edge-native services include but not limited to AI/ML, computer vision, autonomous mobility and applications that support collaboration across multiple contexts and devices, such as multi-player, AR gaming. Such edge-native services are being developed using a very different architectural approach to that used for today's web applications that run in the public cloud, and they have in common the need to be deployed to specific edge cloud locations to execute with the right level of security, latency and compliance.

The new class of edge-native services will serve an increasingly hyperconnected web of devices that is producing and consuming more and more data. AI/ML applications will turn this wealth of data into intelligence far more quickly than humans could and will replace manual steps that introduce friction into processes and experiences. At the end of this decade, industry visionaries expect an 'AI of Things' [2] (Figure-1) to have emerged, whereby everything in our lives will be able to exchange data with everything else, thereby enabling 'magical' and unprecedented levels of automation. The net effect of more data, and the application of AI/ML to it, will be the better optimization of business processes and user experience.

Figure 1 - AI of Things

Edge clouds enable enterprises to run semi-autonomous, latency-sensitive operations locally, to integrate applications into site-based processes more easily and to use server resources more efficiently at individual branches or sites. Cablecos and Telcos have driven early infrastructure edge demand as they virtualize and cloudify their networks. Initially core and transport networks are being transformed with disaggregated distributed networking solutions to enable massive scale and reduction of cost per bit. On top of that, ISPs are uniquely positioned with geographically distributed network infrastructure, which is well suited for infrastructure edge cloud implementations.

2.2. Key Players

There are three primary infrastructure service providers that play a significant role in the buildout of the edge cloud: data center operators, last mile operators, and cloud and edge computing service providers.

Virtualized networking services (NFV, VNF) have also had an early start in edge computing. However, they did not deliver on their promise due to multiple concerns which we will touch upon later. A vast majority of the computing service providers have allocated significant capital into the development of advanced software management platforms. This enables edge computing services to be delivered on-demand and remotely just like with cloud computing. Computing service providers are the most common tenants in early generation edge deployments, which is not an accidental event: they are the ones working directly with end user customers and ultimately hosting and managing the workloads and applications that are being placed at the edge.

Also, the Content Delivery Networks (CDNs) that already have substantial data center footprint predate the modern edge cloud. When CDNs were conceived in the 1990's, it was to enable video on demand and save peering and transport costs and thereby host storage closer to users. This was one of the first applications of edge computing. Now, there is a significant demand for plethora of other applications at the edge.

The CSPs/ISPs can themselves become providers of cloud infrastructure because they will be placing edge-native clouds across geographic locations in order to effect end-to-end, cloud-based transformations of their access and transport networks. Operators can then expose such edge-native clouds to support third-party application pipelines in an infrastructure-as-a-service model (IaaS). Operators are actively partnering with the vendors of disaggregated cloud-native networking solutions to provide a more

extensive edge Network-as-a-Service (NaaS) solution leveraging open hardware that can support use cases that need a high degree of mobility across geographies and can enable them to spin up network functions within a pool of shared resources [3]. We will dive deep into this partnership in a later section.

2.3. Use Cases

There is plenty of demand today for enhanced connectivity and edge computing in multitude of geographical locations. Here are some of the use cases that edge computing will enable and optimize. It is, however, paramount to understand that use cases are different than business cases, as edge cloud ROIs are still a hotly contested item that we are in many cases looking for.

2.3.1. Remote Work

The Work-from-Home (WFH) trend is here to stay. The latest global health concerns have only underlined the importance of minimizing the need for onsite expertise in data centers of any type, from core to edge, and this has hastened the development of tools for remote monitoring, provisioning, repair and management, which could greatly reduce the cost of edge computing. Our solution allows to spin network functions remotely without having anyone on site thereby easing the requirements for on-premises presence.

Also, enterprises have to assure the security of the teleworkers' workstations and secure connectivity to the corporate digital assets. Due to the fact that majority of the resources employees need to access and work on are hosted in the cloud, and depending on the location of the workers, the latency might cause inadequate application response. The necessary workloads have to move closer to the end users for optimal performance.

2.3.2. Smart City Applications and Autonomous Vehicles

The widespread adoption of autonomous vehicles is inevitable and will require a proliferation of edge computing services along roadways to ensure the cars can navigate properly. This will become particularly important in rural areas, where infrastructure will need to be purposefully built out to support autonomous cars in areas that may have no connectivity at all. Similarly, small rural towns and villages will need enhanced edge computing capabilities to implement smart city applications such as turning street lights on or off or monitoring traffic cameras [4].

2.3.3. OTT Content Delivery and Gaming

One of the consumer-driven use cases for edge computing that became a crucial benefit for many during the pandemic is content delivery and online gaming/streaming. Edge computing can help OTT service providers deliver better user experiences for customers and can improve online gaming experiences by reducing latency.

2.3.4. Industry 4.0 Use Cases

As a natural extension of cloud computing, the edge cloud construct is increasingly viewed as a key enabler for the "Fourth Industrial Revolution" in which the widespread deployment of the Internet of Things (IoT), the global sharing economy and the increase of zero marginal cost manufacturing deliver unprecedented communication-driven opportunities with massive economies of scale.

Despite its slow adoption rate, precision agriculture is a great example of this. Farmers using precision agriculture tools and applications will generate thousands if not millions of data points from things like

measuring soil moisture and nutrient content to plant growth and stress, to temperatures and precipitation—to even operating autonomous combines [4] (Figure-2).

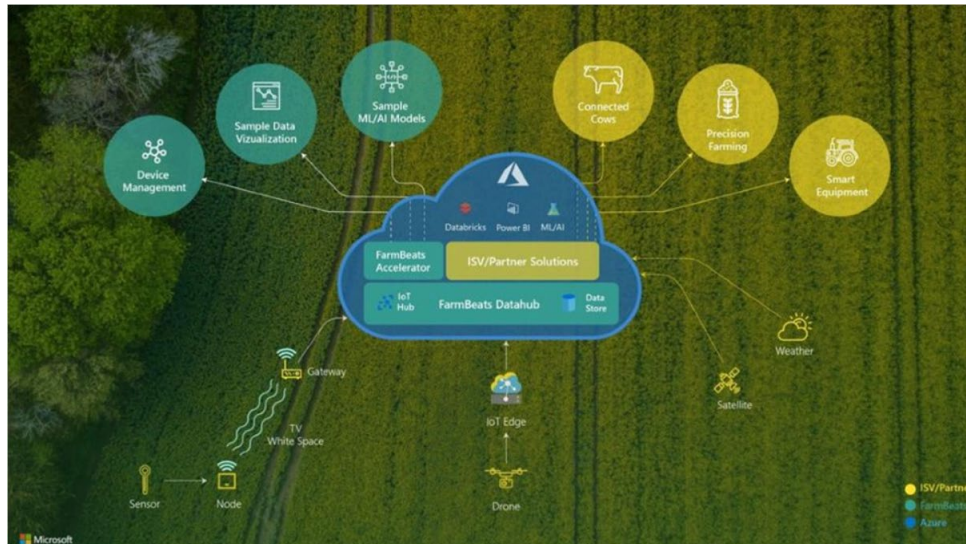

Figure 2 - Precision Agriculture

Other promising use cases are security via drone or camera across large agriculture sites, tracking herds and detecting imminent births or injuries (animal not moving for a long period), optimized feeding for dairy herds and worker safety. All of that data needs to be managed locally at the farm, for example, but it doesn't necessarily need to travel off the farm. Such applications will require connectivity, of course, but because the needs are localized, that connectivity can be served by an array of local network technologies (Figure-3).

Figure 3 - Security and Tracking via Drone

One of the most fascinating use cases is the notion of a digital twin: a near-real-time digital image of a physical object or process that helps optimize business performance. The digital twin can allow companies to have a complete digital footprint of their products from design and development through the end of the product life cycle.

A man wearing a VR headset is shown interacting with a futuristic, glowing blue mechanical assembly. The assembly appears to be a complex, multi-part device, possibly a motor or a sensor, with various components and wires visible. The background is a high-tech laboratory or workshop, with various equipment and tools visible. The overall scene is illuminated with blue and purple light, creating a futuristic and immersive atmosphere.

2.3.5. Content Delivery Networks

Typically, major CDN provider manages and operates a large number of content servers geographically distributed across regions, countries or even continents. Besides the origin server, copies of the content are cached on different servers. Cached content offers clients a faster loading experience since their requests can be answered by geographically closer servers.

Figure 5 – Content Delivery Network

3. Infrastructure Ecosystem for the Edge

At the edge, the physical infrastructure is disparate, vendor-agnostic and comes in various shapes and sizes. The layers are built on top of each other and form a harmonious relationship. From the underlying wholesale data center to the cloud infrastructure that it houses; to the multiple sources of connectivity that connects end users and moves data from the core to the edge; to the real estate that is able to support all these complex requirements. At the edge, each critical infrastructure component is crucial in and of itself, but they work together as part of a single integrated ecosystem.

3.1. Data Centers

Roughly everything important to data center design comes down to three elements: carbon, real estate footprint and scale. The overwhelming tendency in the industry has been to pack increasing amounts of power into ever smaller spaces without overwhelming the cooling systems, which themselves have become progressively more efficient. The end result of all these optimizations has been to increase the density of the compute, networking and storage equipment a data center is capable of handling.

The “rack” in “rack density” refers to a standard 7-foot equipment rack, the kind found in virtually every data center around the world, while “density” refers to how much equipment can be packed into that rack. Rack density, then, becomes a way of expressing the power density of a data center and this concept is being extended to new form factors.

For instance, a typical enterprise data center might average 6-12 kW per rack, whereas hyperscale data centers can handle densities upwards of 50 kW per rack. A data center with 50 kW rack density can consume four times the power of a typical enterprise data center on a rack-by-rack basis.

At the edge, rack density becomes important because space is scarce and expensive. The higher the density, the more we can do at the edge. Several approaches exist that can eliminate the limitations posed by the constraints at the edge by hosting multiple cloud-native network functions on a shared infrastructure which we will touch upon later.

3.2. Cable Headends and Wireless Towers

Real estate is gaining more and more importance in locations adjacent to cable headends, wireless towers, and fiber aggregation points, thereby attracting landowners who will likely become players in the ecosystem. Historically, landlords were involved in building wholesale data centers on their land with cloud infrastructure providers. Now, landowners are providing strategic real estate for edge cloud, however, at a multitude of locations due to the vast amount of viable use cases. Landowners provide the real estate, micro data center operators provide the colocation facilities, and then cloud providers, networking software vendors provide the necessary equipment and applications that operate in those facilities.

Edge cloud locations will also pave a way for new forms of interconnection and peering. Traditional hosting data centers turned out to be meeting points for networks, and akin to that the micro data centers at cable headends and wireless towers that will drive edge computing are generally located at the intersection of connectivity paths. These network regions will become very attractive for local interconnection and edge exchange, enabling more optimal routes for data.

3.3. Networking and Edge InterConnect

The rise of edge cloud is going to require interconnection to move from its traditional centralized Internet Exchange (IX) model, typically in primary locations within major metros like Frankfurt, London, Hong Kong and etc., to an Edge Exchange (EX) model [1]. End users and devices out at the edge are far away from primary IX points and the distance it takes for traffic to travel to these locations degrades performance and also increases transport costs significantly. To solve this problem, interconnection of networks will need to happen in edge data centers near the last mile network in much closer proximity to the end user. CableCos are using multiple real estate locations (and are perfectly positioned for/to take advantage of) such as headends for aggregation and backbone, and hubs that are hosting vCMTS' and other access equipment which can be used to deploy a next-generation cloud-native solutions to enable a plethora of edge use cases.

We will see edge exchanges emerge to allow peering and data sharing at the edge without necessarily involving the core. Edge cloud is not managed in isolated and independent fashion. It will allow more traffic to remain local, but it will also become an interdependent extension of the traditional IX.

Functions of the applications at the edge will be divided between the edge (real-time processing) and the core (primary functions, analysis, archiving) and only the required data will move back and forth through interconnection services. Having an exchange point at the core that is also tied to the edge will enhance performance and drive cost efficiencies.

3.4. Alliances and Partnerships

The diagram below shows the range of network access points and possible topologies, with a range of expected latency and network access:

COMPONENTS OF THE EDGE CLOUD

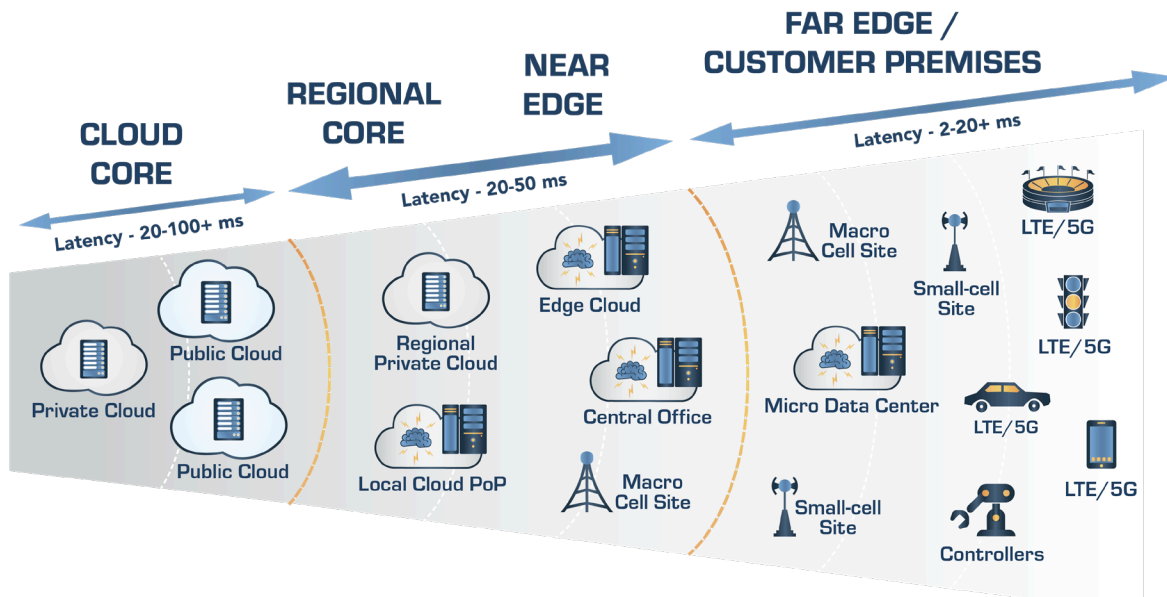

Figure 6 - Components of the Edge Cloud

The reality is that latency choices will depend on the applications. In some cases, it makes sense that compute functions are going to happen at the edge, whether that's a local node or even a device. In one example, retail analytics will use edge compute nodes at the location to deliver specific data or applications to the customers. Yet another example is a connect vehicle, which will process a lot of data on board while sharing telemetry and other information with the cloud. It's all about the data and where it's needed. Much of the data that's gathered at the edge has a short lifespan and really isn't economical to bring back into the core cloud.

At the end of the day, it is partnerships that will bring all these disparate pieces together. Wireless tower operators have considered owning data centers, but the most efficient way for them to get to market is to partner. Micro data center vendors are partnering with the service providers that host and manage cloud infrastructure and bringing them on as tenants. Meanwhile, micro data center operators are working with wireless tower and cable companies to access the real estate at headend/hub and tower sites.

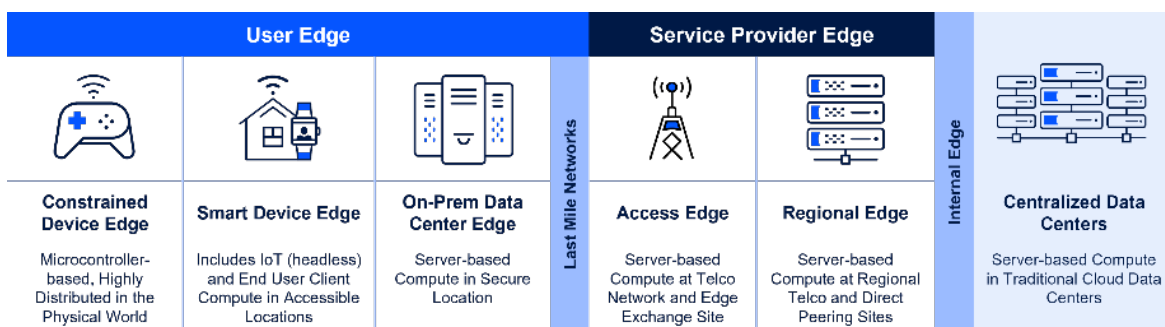

Figure 7 - Edge Continuum

An exceptional example of this kind of partnership is Open Grid Alliance (OGA), where industry leaders and innovative disruptive startups join forces to rearchitect the Internet. This alliance will work to evolve the Internet to be a global, shared platform that distributes compute, data, and intelligence to when and where it's needed, on demand [5].

4. Network Cloud

4.1. Evolution of Network Functions

A key consideration for the industry is how to shift Network Functions (NFs) from physical instances to containerized microservices and disaggregated business models. This poses new requirements for the orchestration and control of highly disaggregated and distributed capabilities.

Network Functions were originally deployed on dedicated physical appliances. Then with the widespread adoption of compute and storage virtualization Network Function Virtualization (NFV) initiative started to pick up steam and Virtual Network Functions (VNF) ran on x86 servers (on CPU) which was sub-optimal. It could scale to multiple servers, but the performance was not up to par. As microservices architecture became increasingly popular, Cloud native Network Functions (CNF) were able to run on the public cloud infrastructure and this enabled further growth. However, these NFs still ran on COTS x86 servers.

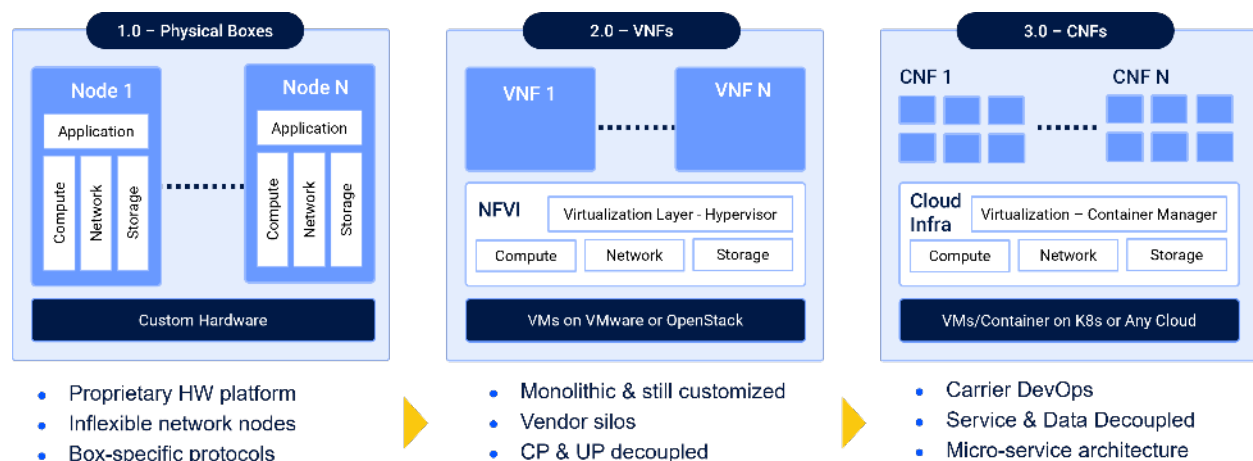

Figure 8 - Evolving from Bare Metal to VNFs to CNFs

Today it is commonly proposed to offload the NF to the Network Processing Unit (NPU) on a dedicated Input/Output (I/O) device. This can also be done through a “smart NIC” provider to offload the NF to the Data Processing Unit (DPU) and accelerate the NF as a result.

4.2. Edge Cloud Enablers

Hyperscalers have spearheaded the development and implementation of the open hardware and software data center solutions. Organizations like Open Compute Project (OCP) [6] and Telecom Infra Project (TIP) [7] have introduced Disaggregated Distributed Chassis (DDC) [8] and Disaggregated Distributed Backbone Router (DDBR) [9] architecture. It is based on whitebox architecture where each component of the standalone monolithic chassis router is distributed into individual components:

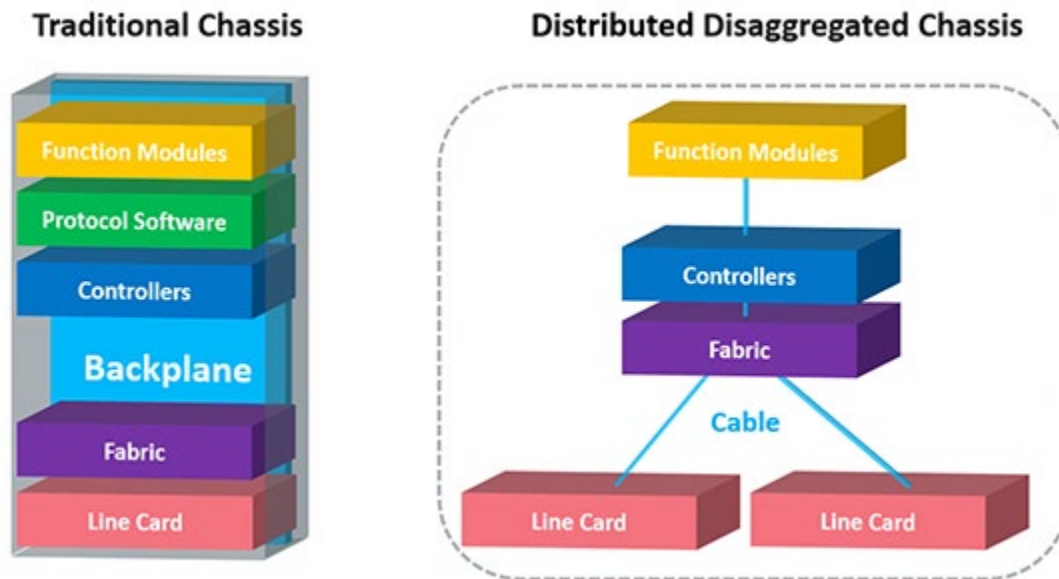

Figure 9 - DDC/DDBR Architecture

This allows the operators to scale out this re-architected chassis by simply adding whiteboxes that perform fabric and packet forwarding functions.

Evidently, this is an architectural improvement related to cloud-native networking, and potentially another indication of a future in which carrier networking is highly modular and disaggregated. The true value of such a disruptive model is not necessarily limited to up-front cost-savings. Rather, the value lies in the optionality that comes from building an infinitely scalable and malleable network cloud platform that is pay-as-you-go.

4.2.1. Edge Hardware

Hardware deployed at the edge has historically been purpose-built for specific workloads, frequently CDNs (Content Delivery Networks) or IoT. As edge computing grows in popularity and new use cases emerge, general purpose infrastructure is also being deployed to run cloud-like workloads.

Edge systems must take the path of the hyperscale cloud buildout – low-cost commodity hardware combined with high-powered software automation and distributed orchestration.

The above described DDC/DDBR architecture is perfectly suited to be deployed at the edge. A variety of Original Design Manufacturers (ODM) [10] have introduced open hardware based on merchant silicon certified by OCP and TIP which is already carrying production traffic in the backbone and aggregation networks of major cable and telecom operators.

Due to the disaggregated nature of the architecture where control and forwarding planes run on different physical platforms, there is only a need for a data plane to be installed at the edge whereas control functions run in the core cloud.

Figure 10 - Network Cloud

Packet and fabric forwarders (PF and FF) which comprise data plane, have very high port density (40x100GE, 36x400GE):

Figure 11 - Packet Forwarder

Figure 12 - Fabric Forwarder

By strategically placing these disaggregated clusters at the edge facilities (cable headends/hubs, wireless towers) operators can utilize this platform to run multiple CNFs in a cloud-like manner thereby eliminating the need to install separate physical appliances for each network function and utilize any port of the system for any service. The latter point is of a particular importance for the edge environment, because the cost of deployments is higher and rack density, power, cooling, scale, flexibility and even physical access to the site is very limited.

Figure 13 - Edge Locations for Network Cloud

4.3. Multi-Services Network Cloud Architecture for the Edge

Initially, it was believed that low-latency needs would drive edge compute, however, we believe the real advantage of network cloud edge is the flexibility, scale and automation provided in deploying new services wherever they are needed, using standardized and affordable software with cloud-based networking and automation software.

Many network edge projects have failed because of efforts to deploy proprietary platforms or complicated architectures and high costs. Following the cloud will be key: leveraging existing cloud-native technologies such as Kubernetes, APIs, and public cloud services and extending them out to the edge.

From a networking perspective, a distributed disaggregated carrier-class networking operating system predicated on cloud-native software principles and standard white-box functionality is required at the edge. This NOS should be predicated on the following cloud-native software design guidelines:

- **Natively Distributed NOS:** marks a departure from the monolithic network hardware designed around a proprietary model of equipment and separates logical routing functionality from the physical infrastructure.
- **Extensive Use of Containers:** designed from the onset to leverage Docker containers to ease development, deployment, and upgrade.

- **Optimized Resource Utilization:** anchored on small, highly cohesive, and loosely-coupled microservices.

There are solutions in the market that address majority of the inefficiencies at the edge and offer operators a way to significantly increase their resource utilization while gaining service & architecture flexibility, optimal scaling and software-paced innovation and time to market. Network Cloud for the edge architecture addresses many challenges by combining networking and compute resources over a shared, cloud-like infrastructure. It allows operators to put greater functionality at the network edge, even with space and power limitations.

The foundation for this significant value is the way the Network Cloud is built – in a disaggregated, cloud native architecture. This means the hardware resources of a cluster of multiple white boxes are abstracted by the NOS to a level in which it is consumed as a virtualized resource pool, based on the DDC/DDBR architecture mentioned above. Each networking function, which runs a containerized Service Instance (SI), can be allocated with its required hardware resource (Physical interfaces, NPU, CPU, TCAM, QoS etc.) out of the underlying shared hardware infrastructure.

The following diagram illustrates the software architecture that allows this:

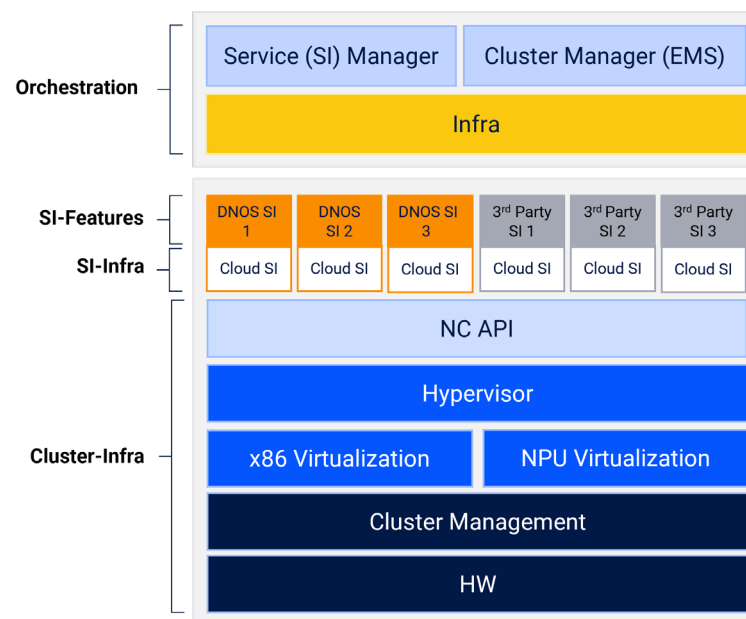

Figure 14 - Software Architecture of the Network Cloud

While different hardware resources are abstracted and different cloud SIs run over it, the system represents each network function as a standalone node, keeping the network manageable. This means that a single cluster can integrate multiple networking functions that are physically collocated, yet logically separated.

A multiservice architecture creates a separation of the data plane from the service plane (or control plane). Multiple services can coexist over the same virtualized physical infrastructure and as long as resources can be made available for a service to perform, the network cloud can launch this service into production through a centralized orchestration system.

This shared use of resources enables operators to place such scalable cluster at the edge locations while lowering footprint, power consumption, space requirements while reducing the need for engineers get on site for installation and troubleshooting activity. Additional network services can be enabled on this infrastructure on-demand in an automated fashion via an orchestrator that has a full view of the topology and hardware resources of all the components of the cluster.

In order to implement a multiservice architecture a couple of virtual entities were introduced:

- **Service Instance (SI):** a network function (e.g., PE router, VPN Gateway), which runs independently of any other networking function co-located on the same cluster. While the service instance is logical, it is assigned with dedicated resources out of the shared pool of hardware resources in the network cloud cluster.
- **Inter Service Link (ISL):** A logical connection between two SIs, which is represented as a (physical) link connecting the two networking nodes. This link allows control plane interconnection between the instances as well as data path features, including QoS and access lists. The ISL is totally logical, hence no cabling work is needed.

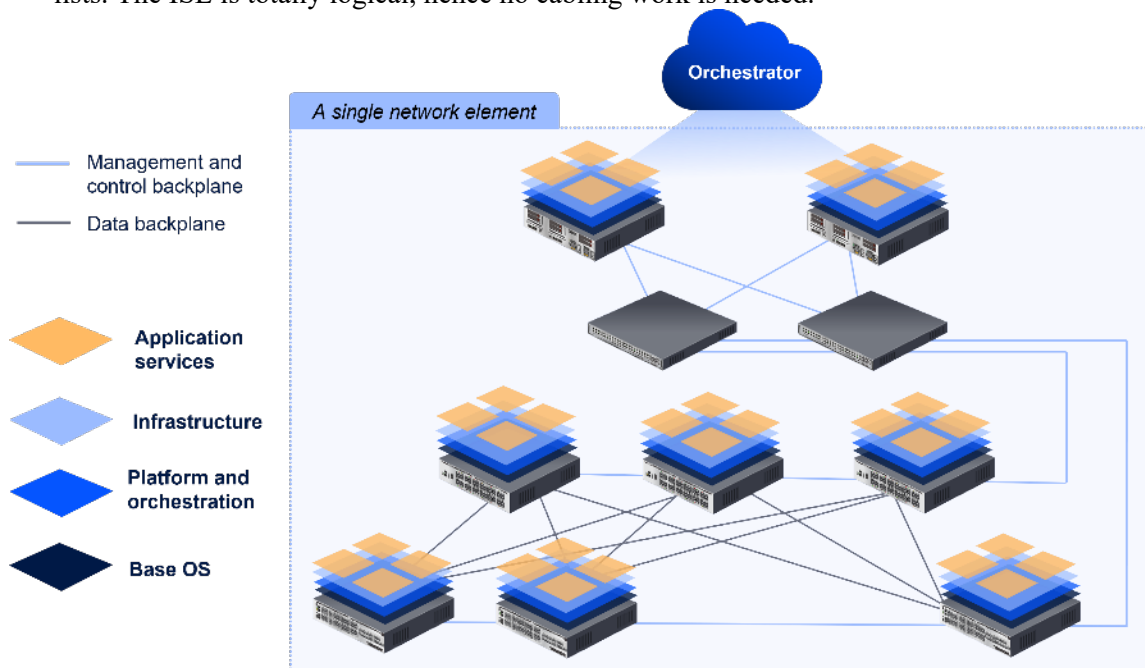

Figure 15 - Abstraction Layer of the Network Cloud

The multiservice solution allows for replacing the model of multiple network appliances at the edge, serving different functions and networks (e.g., Network Security, Mobile Backhaul and Broadband), with a single unified infrastructure that can support all the networking services on a software-based network and cloud-native technologies (i.e., microservices, containers).

Let's provide an example based on a TCAM allocation scheme. Three different services are allocated to the same physical ports (Yellow could be a VPN service, Orange – a Mobile Backhaul and blue – a DDoS Mitigation Application). Their TCAM requirements are different, so there might be a case in which a packet arrives to a port, under the yellow service and there are no TCAM resources available. In such an occasion, it will use a TCAM resource from a different whitebox, which has required resources at its disposal. This will be done over the cluster's fabric, as illustrated below.

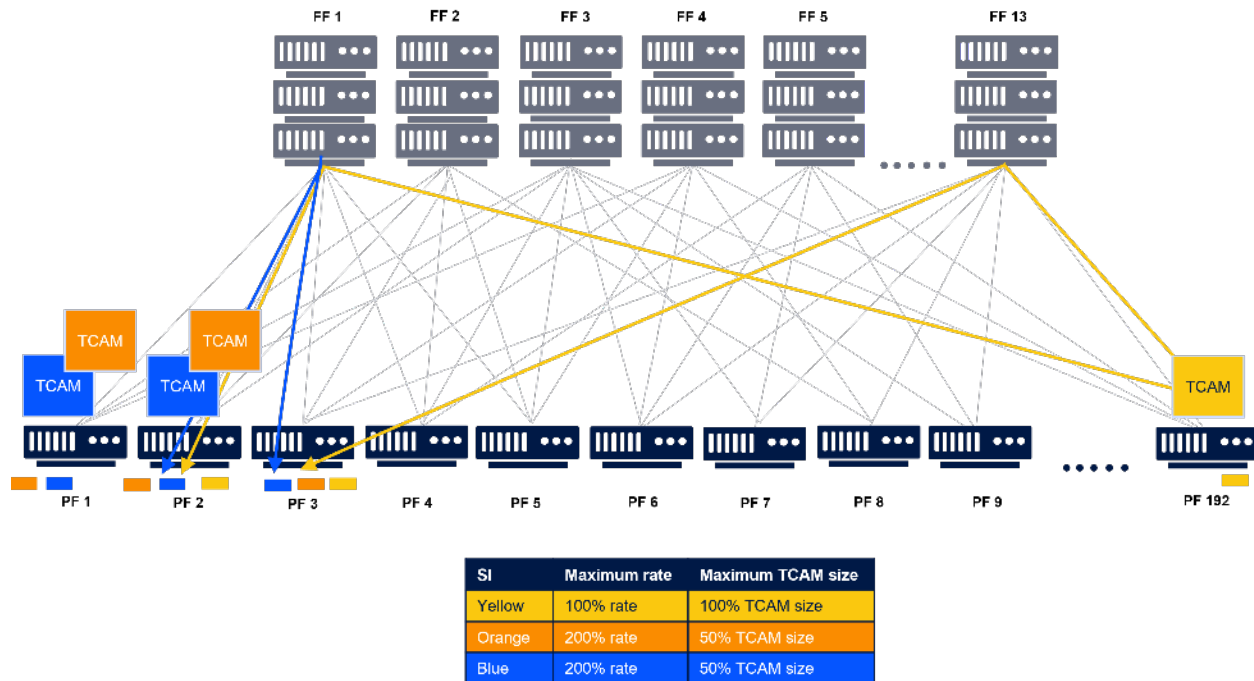

Figure 16 - An example of multiple applications running over the Network Cloud

The same edge cloud platform will also run the network's increasingly autonomous operational and management functions. This is providing operators with the opportunity to create a distributed cloud fabric that can unify multiple network domains and which they can then make available to third-party application pipelines [11].

We believe that operators who have already deployed this architecture in other places of their production environment will have an upper hand as they can utilize the same hardware and leverage new innovative features of the software like the multiservice functionality demonstrated above.

Rest assured – the new network edge is taking shape. But the most successful networking and compute edge deployments will have the characteristics of solving the challenges by simultaneously delivering new applications capabilities and radically lowering the cost of deploying these technologies.

5. Conclusion

The global expansion of internet infrastructure is happening at a rapid pace, and the pandemic was at the center of a junction of events that are accelerating the trends already in place. The next decade will see an explosion of activity as a result. There will be more opportunities for creation of a new infrastructure locations at the edge and in strategic and difficult-to-access places. Moving to the edge is fundamentally about getting infrastructure closer to end users, whether that be in new and emerging markets or wherever critical masses of end users cluster. The underlying infrastructure will be provided by a hyperscale platforms, internet service providers and innovative startup companies.

Operators are in a strong position because their networks are, by nature, distributed and ubiquitous across their geographic footprints. Network cloudification necessarily entails building a distributed, edge-native

cloud fabric across that footprint too. Cablecos and telcos are engaged in a series of network transformations that will eventually introduce cloud into different network domains (backbone, aggregation, mobile, fixed access and transport). Leading operators have a unified vision for such a network cloud, and anticipate that over the next few years, they will put in place a common, distributed and hybrid cloud-based platform to support all software-only network functions and their management and operational systems. The network cloud must extend to the network edge in order to support access network functions, but it will also need to be instantiated in many other locations, and operators will require a holistic way of orchestrating network function workloads across thousands of cloud locations to provide a ‘network’.

1. Introduction

The advent of Full Duplex DOCSIS[®] (FDX) technology is here as realized in a custom ASIC successfully implemented in an operational FDX R-PHY node reference design. This ASIC is also currently being ported to a node design for trial deployments in Node + 0 networks. A version of this ASIC is also being adapted for a prototype FDX amplifier utilizing the same echo cancellation technology employed in the node.

The original constraint in the DOCSIS 4.0 FDX specification anticipated deployments exclusively in a passive Node + 0 network without amplifiers. The initial evaluation in a demonstration of the implemented prototype FDX R-PHY node incorporating the first FDX RPD ASIC exceeded performance expectations [2]. The resultant performance of the echo cancellation technology suggests use in an FDX amplifier as a “repeater” of bidirectional FDX signals.

This paper considers this implementation for an FDX amplifier. Why this greatly expands the use of FDX technology in conventional Node + X amplifier networks is introduced. How the FDX amplifier is implemented and the resulting performance greatly increasing upstream capacity is analyzed. The performance of cascading FDX amplifiers is shown. Finally, the path to upgrading existing Node + X cable networks when the next generation FDX amplifier ASIC currently under development becomes available is discussed.

2. Origins of FDX DOCSIS

CableLabs launched a project to examine the potential of full duplex simultaneous upstream and downstream transmission and reception within the same cable system spectrum. The DOCSIS 3.1 specification provided the Physical Layer (PHY) transmission and reception based on OFDM/OFDMA as shown in Figure 1.

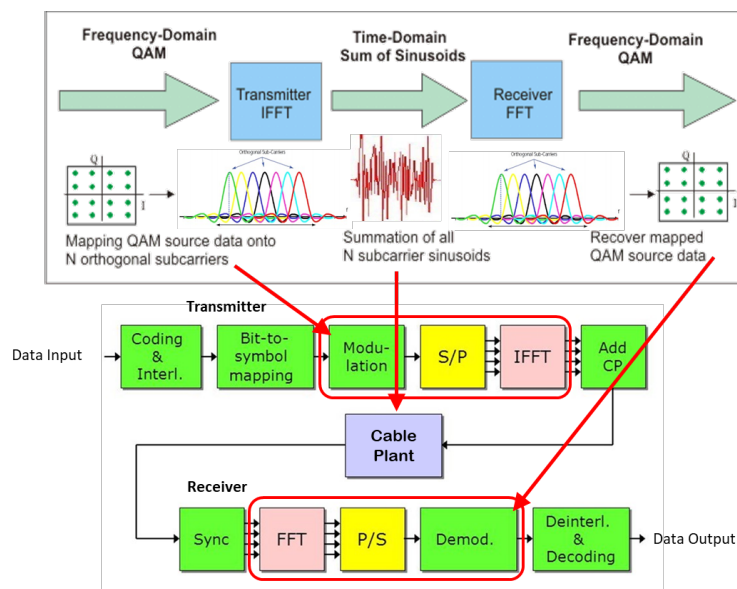

Figure 1 - DOCSIS 3.1 OFDM Transmission and Reception

The difference was the sharing of overlapping spectrum for simultaneous bidirectional transmission and reception. The addition of this spectrum sharing methodology was initially developed as an appendix to the existing 3.1 spec.

Eventually the addition was separated into a new DOCSIS 4.0 spec. The FDX node transmits downstream and receives upstream at the same time in the same bandwidth. FDX transmissions from node to modem and modem to node are overlapped both in time and frequency where new interference cancellation technology in the node allows this simultaneous bidirectional communication.

However, the simultaneous bidirectional communication between the node and the cable modems was limited to a passive coax plant without amplifiers due to the lack of duplex filters to separate upstream from downstream transmission. This is known as a Node + 0 plant where the node is connected to a passive cascade of taps and cable without additional amplifiers as shown in Figure 2.

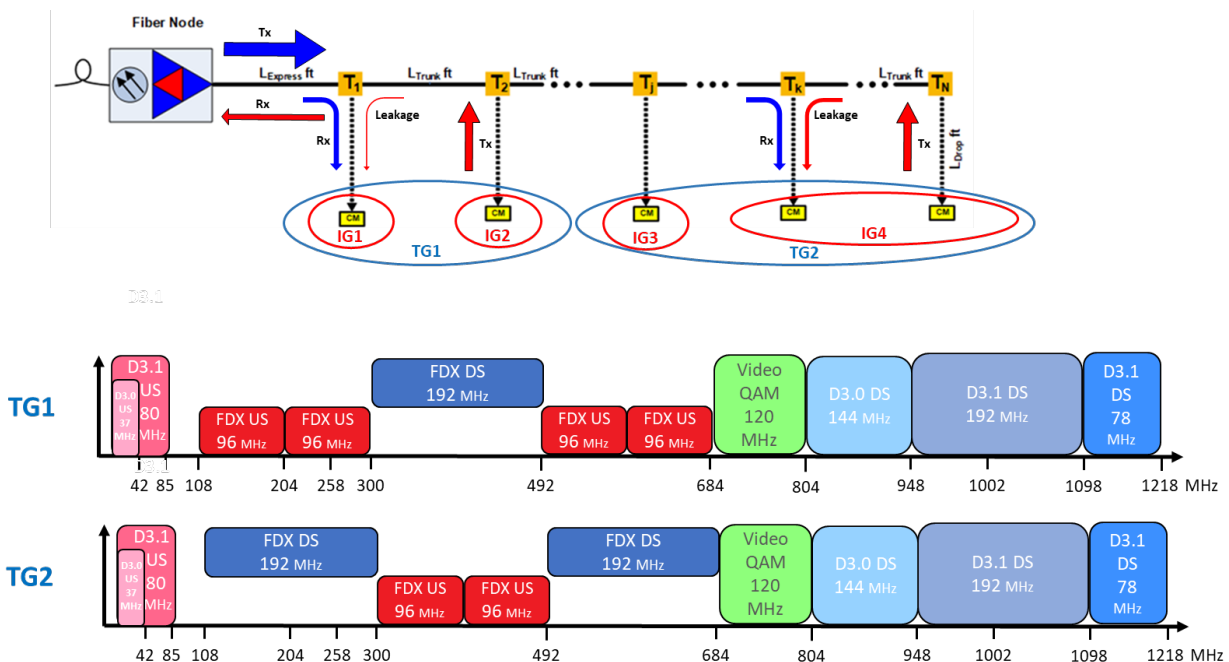

Figure 2 - Node + 0 passive cable system

Simultaneous true full duplex transmission and reception within the same frequency band only occurs at the node. Each cable modem utilizes Frequency Division Duplex (FDD) in a dynamic fashion across multiple channels within the full-duplex band. This is necessary to prevent upstream transmission of one cable modem in each channel from corrupting downstream reception of another cable modem in that same channel. Unlike the node where the transmitter and receiver are co-located, upstream transmitting modem and downstream receiving modem are located on a different tap or groups of taps with sufficient isolation from tap port-to-output leakage between them known as an Interference Group (IG) as depicted in Figure 2. Thus, the downstream receiving cable modem has no reference for the upstream transmitting cable modem signal making cancellation within the same frequency band impossible as discussed in [1].

The high-level node downstream signal is transmitted into the cable system of Figure 2 where that signal propagates down the cable transmission lines and encounters multiple taps with impedance mismatched to the coax transmission line by the tap return loss. A reduced amplitude reflection from each tap results as shown in Figure 3 using the model simulation approach derived in [1].

The node upstream received, downstream transmitted and cable system downstream reflected interference is shown on the right. All these signals combined from each TG occupy the same frequencies in the cable spectrum simultaneously as shown below.

Note in the upper right chart that the echo is well below the node transmission but is significantly higher (around 20 dB) than the low-level upstream received signal from the modems resulting in a negative upstream signal to downstream echo SNR.

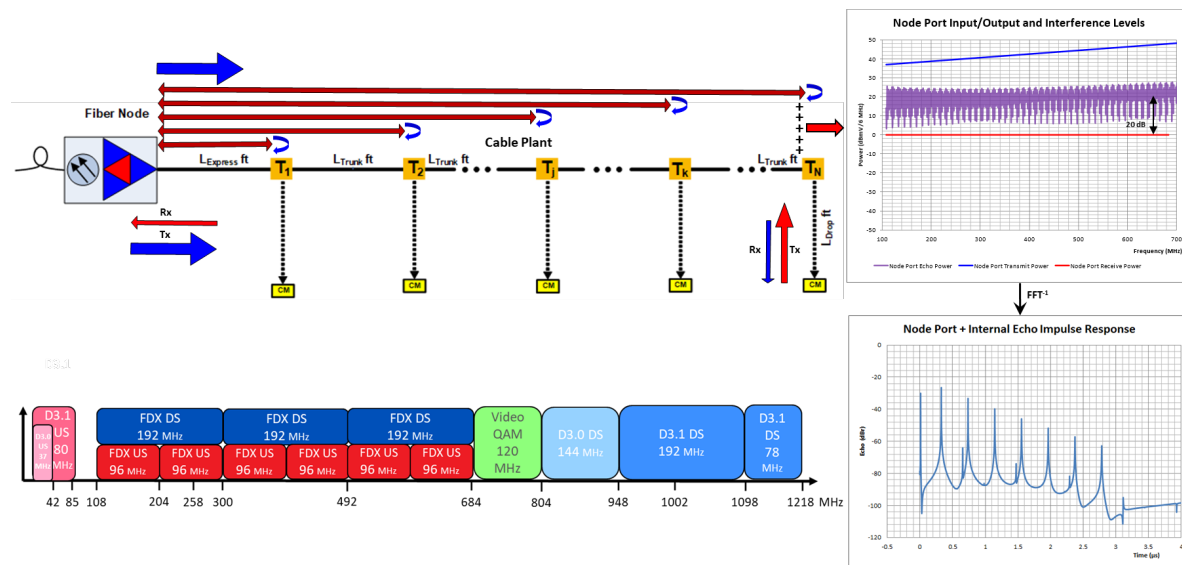

Figure 3 - FDX node operation with echo path interference

The node separates the received modem upstream signals from the transmitted downstream node signal using a directional coupler plus Echo Cancellation (EC) digital signal processing. The function of the FDX node is shown in Figure 4.

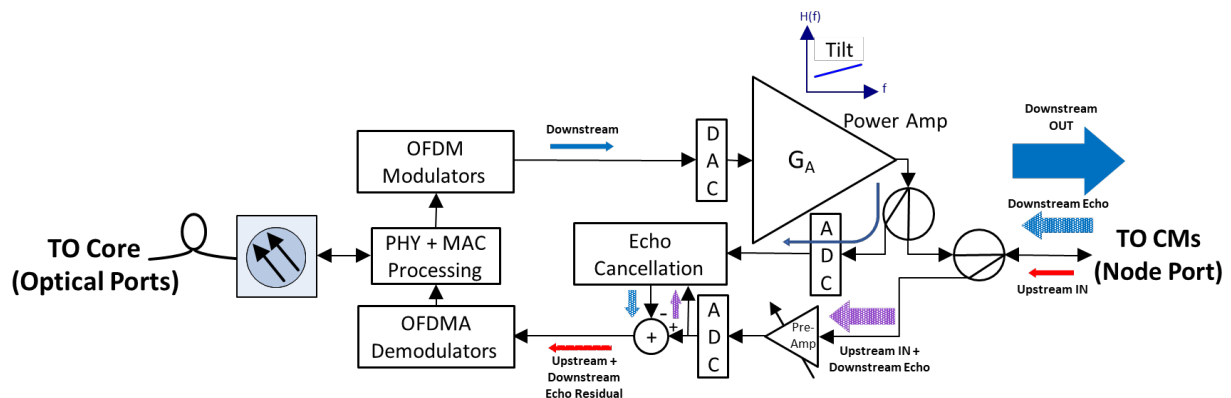

Figure 4 - FDX node with echo cancellation signal processing

A sample of the downstream signal is used as a reference for the EC of the reflected downstream signal. The upstream signal is filtered by an adaptive filter using the downstream reference to remove the echo in the same band. The filtering has a finite depth of EC which is a residual that is now lower than the upstream received signal as shown in Figure 5 resulting in a positive upstream signal to downstream echo residual SNR.

The first prototype FDX Node + 0 system with echo amplitudes producing a negative SNR with respect to the upstream received signal realized an EC depth resulting in a 35 dB SNR in a high downstream launch power Node + 0 cable system design. This demonstrated the power of the EC implemented in the first Broadcom FDX RPD IC as sufficient to consider embedding the same EC technology into an FDX amplifier IC.

Figure 5 - Upstream Front End Dynamic Range and Residual Downstream Echo/Noise Floor

3. Beyond Node + 0: The FDX Amplifier

A traditional cable system with amplifiers is depicted in Figure 6.

Figure 6 - Node + N amplifier cable system

Upgrading the cable system to FDX by replacing the traditional node with an FDX node and replacing the traditional amplifiers with FDX amplifiers is depicted in Figure 7. Note that the taps are unchanged and the amplifier spacing is maintained.

Figure 7 - Node + N amplifier cable system upgrade to support FDX

A similar echo environment found in an FDX node exists for an FDX amplifier. The echo interference paths for an FDX amplifier in a cascade is pictured in Figure 8.

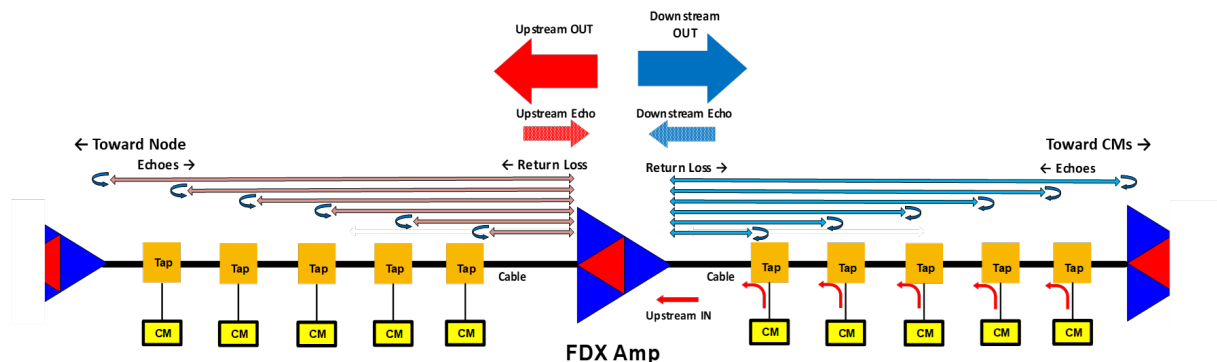

Figure 8 - FDX Amplifier Echo Interference

In the case of a bidirectional amplifier, the downstream transmission level is like that of the node. This results in very similar echo levels in the FDX band. Hence echo cancellation performance required is similar.

The addition of FDX amps requires a different TG grouping of cascaded taps and amps as shown in Figure 9. When a cable modem just upstream of an amp transmits, some of the upstream transmission leaks from the tap port to the output port due to limited tap port-to-output isolation, as depicted in the top amp in the figure. This upstream leakage enters the amp interfering with the intended downstream signal. The SNR is determined by the input downstream-to-upstream leakage ratio. This SNR will propagate downstream of this amp limiting bit-loading (spectral efficiency) thereby lowering downstream capacity. The tap or several taps before the amp and all cascaded taps and amps following the first amp become a single IG. This has been called “IG extension” due to the addition of FDX amps.

To optimize downstream capacity, the entire leg is assigned as a single TG which prevents downstream interference from simultaneous upstream transmission and downstream reception in the same frequency band at the cable modem. Different legs of Figure 9 are combined at the node. Each leg is assigned to a separate TG. The interference from the upstream transmission in one leg into the downstream transmission of the other leg(s) determines the downstream SNR.

Downstream capacity is increased due to the significantly higher isolation between legs of the node splitter/combiner. Traffic engineering of upstream bandwidth grants among the increased number of cable modems in a single TG needs to be considered in long cascades of amplifiers. Also, as explained in the following sections, the degradation of upstream SNR due to the number of amps in a cascade (i.e., Node + x) determines the upstream capacity at the node.

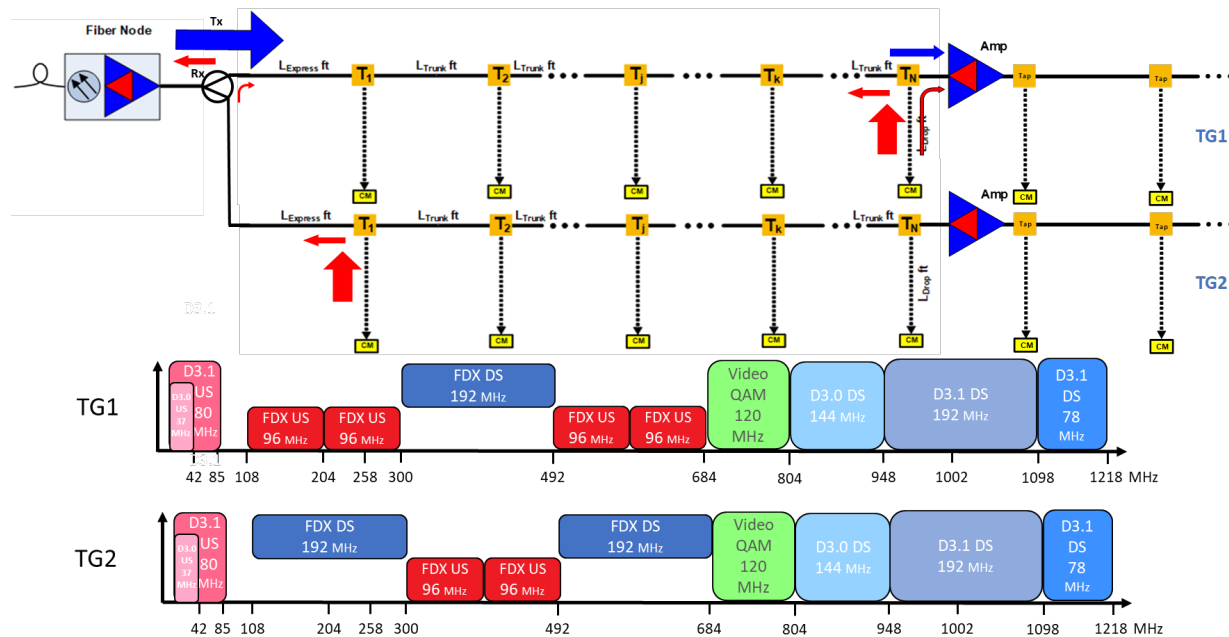

Figure 9 - Node + x cable system with FDX amplifiers

The upstream transmission similarly produces echoes in the received downstream. However, these upstream transmissions negate the reception of the downstream signal in the same band since the signals are in the same transmission group and cannot receive downstream signals in the same band as upstream signals when present from a transmitting modem in that leg of the plant.

The functional diagram for the FDX amplifier is shown in Figure 10. Note the similarity in the EC for the node of Figure 3 on the downstream port of the FDX amplifier. The same EC processing is used here resulting in a similar echo residual after cancelling the echo. This residual is present in the upstream signal. Gain and tilt are applied, and the upstream signal is then launched toward the next amp nearer to the node. Note that this launched upstream signal also produces an echo into the downstream. However, since the upstream transmission is granted in the single TG of the node leg containing the amp (due to IG extension discussed previously), the concurrent downstream signal is not received in the same frequency band.

The same situation applies for a transmitting cable modem producing echo interference in the TG of the node leg containing the amp cascade. This is depicted in Figure 10 where cable modem on the tap before

the north port of the amp transmits upstream introducing interfering leakage into the downstream due to limited tap port-to-output isolation.

The cascade of amplifiers each add additional downstream EC residual to the upstream signal. The nature of this EC residual noise buildup in an amplifier cascade and the resultant degradation to the upstream signal arriving at the node is derived in the following section.

Figure 10 - FDX amplifier with echo cancellation of the downstream echo

4. FDX Amplifier with Echo Cancellation Cascade Analysis

A model for the added noise due to downstream echo interference and the residual noise after echo cancellation is shown in Figure 11.

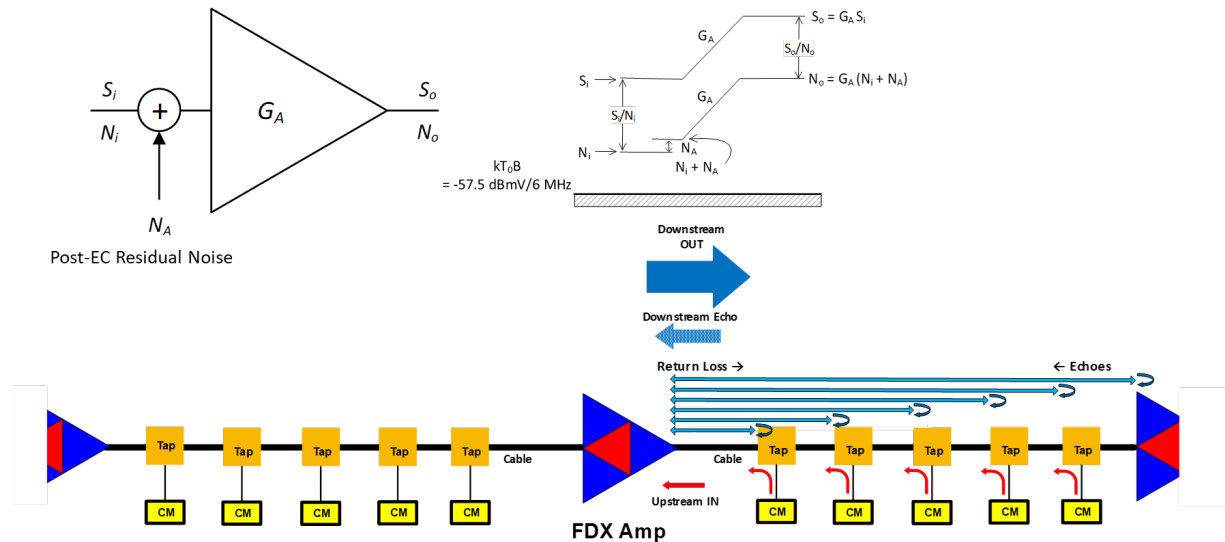

Figure 11 - FDX Amplifier Transmitted Downstream Echo Interference

The upstream input signal S_i to the downstream amplifier is accompanied by input noise N_i with an input SNR of S_i / N_i . Using downstream EC as shown in Figure 10, the EC reduces the echo to a level N_A in

Figure 11 which is substantially above the thermal noise floor. The added downstream echo residual noise N_A is added to the upstream input noise N_i .

The amplifier gain G_A including tilt compensation is applied to the input signal S_i and the combined noise $N_i + N_A$. Thus, the resulting output noise is $G_A (N_i + N_A)$ and the output SNR₀ is given by $S_i / (N_i + N_A)$.

This residual EC noise adds for each amp in the cascade as shown in Figure 12.

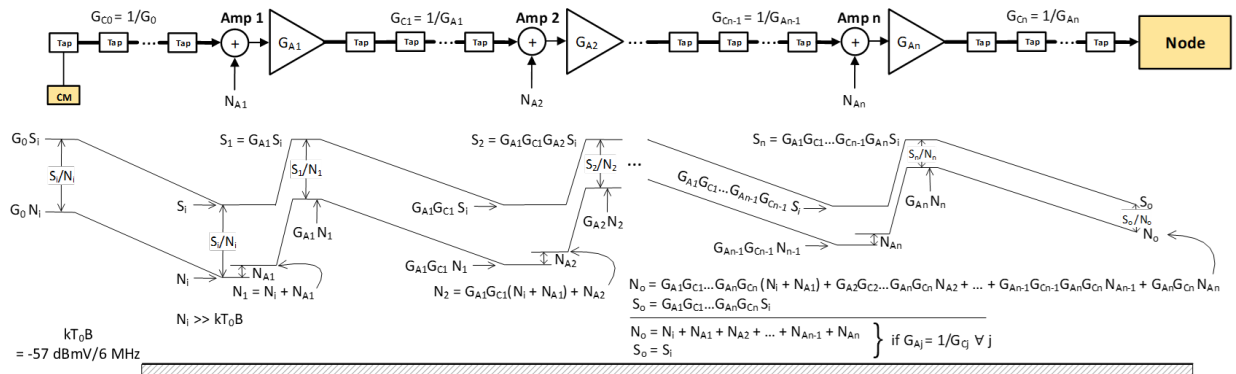

Figure 12 - Cascaded Noise of Amplifier Echo Cancellation Residuals

The node of Figure 4 receives the amplifier cascade upstream signals and accumulated EC residual noise resulting in the signal and noise levels shown at the node port input with an amp cascade CNR of S_o/N_o . This is plotted for a range of values in the bit-loading contour map of Figure 13 below.

Figure 13 - Bit-Loading Contour Map – Spec Bit-Loading SNR Thresholds

Node Upstream Background CNR vs. Downstream SIR (Signal/Echo Ratio)

The node produces its own downstream echo yielding a node signal/interference ratio (SIR) given by the upstream signal/downstream echo. The node reduces its own downstream echo and the node EC residual adds to the amp cascade EC residual. These two noise sources are uncorrelated and add on a power basis. The resulting bit-loading for the DOCSIS 3.1 spec threshold of the OFDMA receiver is shown in Figure 13 for all combinations of amp cascade CNR vs Node SIR.

Comcast utilized a Profile Management Application (PMA) using lower thresholds from lab and field measurements. Downstream PMA is typically 3 dB lower than spec. Current production OFDM PMA implementation leverages 3 dB of available headroom vs spec in setting downstream OFDM MER thresholds (4k-QAM @ 38 dB vs 41 dB; 2k-QAM @ 34 dB vs 37 dB, etc.).

Upstream is expected to be similar. The result for the bit-loading thresholds using upstream PMA is shown in Figure 14. Using PMA results in higher bit-loading values for the lower PMA thresholds.

Figure 14 - Bit-Loading Contour Map – PMA Bit-Loading SNR Thresholds
Node Upstream Background CNR vs. Downstream SIR (Signal/Echo Ratio)

5. SNR Calculations for the Node + N FDX Cable System

A representative system for most medium density designs is the single-family unit (SFU). An example of such a system design is shown in Figure 15.

A simulation was performed of the amp cascade upstream signal plus the EC residual accumulation (amp cascade CNR) as depicted in Figure 12 combined with the node EC residual SIR. Echo levels at the downstream port from the tap cascade were modeled using our return loss measurements of the most

The upstream throughput calculations using PMA bit-loading for an upstream receive level of 5, 8, 11, and 13 dBmV/6.4 MHz with an overhead assumption of 25% (75% of PHY Throughput) are shown in Figure 23.

Note that for a six-amp cascade, a minimum 11 dBmV/6.4 MHz upstream receive level across the entire 108 to 684 MHz FDX band (6 upstream channels) is needed for 5 Gbps throughput. Similarly, a minimum 11 dBmV/6.4 MHz upstream receive level across the 108 to 300 MHz FDX band (2 upstream channels) is needed for 2 Gbps throughput. Alternatively, a minimum 5 dBmV/6.4 MHz upstream receive level across the 108 to 396 MHz FDX band (3 upstream channels) is needed for 2 Gbps throughput.

6. FDX Moves into the Field

A prototype FDX node reference design in a Node + 0 multiple tap cable system was demonstrated in our labs last year. Echo cancellation technology in the FDX node was evaluated with results exceeding expectations [2]. Following the FDX node demonstration, multiple cable modems were evaluated in the Node + 0 FDX proof of concept cable system with a cable modem reference design in each of two transmission groups (complementary upstream transmit, downstream receive Resource Blocks). This included:

2021: Full End-to-End Proof of Concept of 10G FDX

- DOCSIS 4.0 vCMTS - Software Upgrade
- FDX Node Reference Design
- FDX CM Reference Design

Plans for this year include FDX amplifier development and several trials in the field, including:

2022: Move to the Field and Introduce FDX Amps (N+x)

- Ongoing: Addition of FDX features per DOCSIS 4.0 spec into the vCMTS code
- Now: First full FDX RPD Node
- Q2: First Comcast FDX MTA
- Q3: Prototype FDX Amplifier
- Multi-Gig symmetric over N+x
- Q4: Qualification of FDX Node Hardware and Software
- Q1 2023 and beyond: Trials
- Tech Trial Multi-Gig Symmetric N+0
- Tech Trial FDX over N+x

7. Conclusion

The successfully demonstrated echo cancellation (EC) technology developed for the FDX node enables the extension to FDX amplifiers. An EC noise model for FDX amplifiers has been developed to calculate the achievable bit-loading and resultant capacity for varying numbers of cascaded amplifiers.

Sufficient fidelity in reasonable amp cascades can ensure multi-gigabit symmetric speeds up to Node + 6. A powerful PMA engine enables true, adaptive bandwidth/capacity optimization. Straightforward RF guidelines for allocations of FDX upstream OFDMA spectrum can deliver Speed Tier objectives for 2 to 5 Gbit/second symmetric peak throughput.

A Full End-to-End Proof of Concept of 10G FDX cable system was demonstrated in 2021. A prototype FDX amplifier (Node + x) will be introduced in 2022. An FDX Node + 0 trial and Node + x amp trial is planned in 2023.

1. Introduction

Today, Wi-Fi is the predominant way telecommunication customers connect their untethered devices to the Internet, as well as access content like video, virtual reality, and gaming. In the near future, operators will shift compute closer to the end user, expanding the requirements for better Wi-Fi edge compute connectivity. The original Institute of Electronics Engineers (IEEE) 802.11 standard was released in 1997. Since then, the IEEE 802.11 working group has developed and released many amendments to keep up with the growing bandwidth demands of our customers and the industry. During this time, telecommunication operators, CableLabs[®], the SCTE[®], and vendors developed and deployed DOCSIS and other access network technologies to keep up with the same bandwidth demands.

Today operators are moving towards multi-gigabit offerings and are deploying Wi-Fi solutions using Wi-Fi 6 and Wi-Fi 6E customer premises equipment (CPE) to support these offerings. With the telecommunication industry on the road to 10G and beyond, the wireless industry is working on the next generation Wi-Fi standard, IEEE 802.11be, extremely high throughput (EHT). The IEEE 802.11be task group, or just 802.11be, is leading the development of the EHT amendment to the IEEE 802.11 standard. 802.11be is the amendment on which the Wi-Fi Alliance[®] Wi-Fi 7 certification will be based.

The 802.11be amendment is currently being developed and is scheduled to be released in May 2024. To help meet the tight development timeline, 802.11be has two sets of release features known as Release 1 and Release 2. The Release 1 features are outlined in Draft 1.0 and Draft 2.0 of the amendment. The Release 2 features will be defined in Draft 3.0 and Draft 4.0. Figure 1 depicts the development timeline, which the 802.11be task group continually evaluates. The Wi-Fi Alliance Wi-Fi 7 certification requirements will be released closer to the end of the 802.11be development cycle, close to the final amendment.

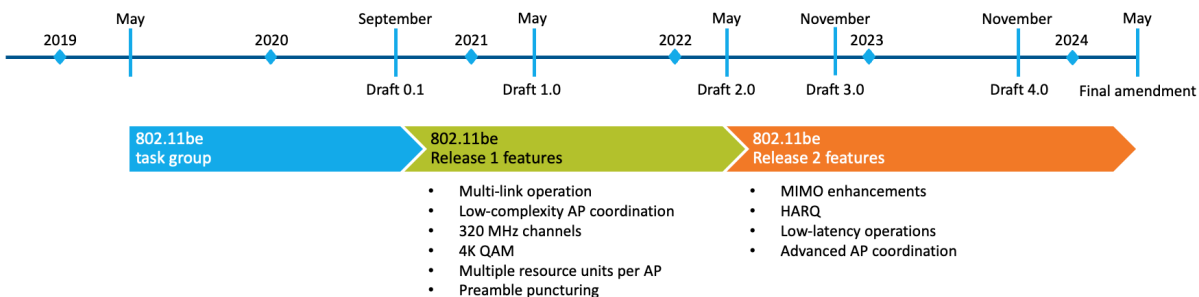

Figure 1 – 802.11be Release Timeline

This paper will explore the 802.11be releases and their features, along with key media access control (MAC) and key physical (PHY) layer techniques. Furthermore, the paper will explore how Wi-Fi 7 will impact the customer quality of experience (QoE) and enable telecommunication operators to support their 10G platform initiatives all the way to the customer premises.

2. The 10G pillars

As connectivity, in particular, Wi-Fi, becomes more crucial to how we live, work, learn, and play, we need a network that will support the hyper-connectivity of our future customers. In 2019, the industry announced the next leap forward in connectivity with the 10G platform, which also encompasses Wi-Fi.

The NCTA–The Internet & Television Association, CableLabs, GIGAEurope, and SCTE have been driving this initiative and the platform forward in the industry.

The 10G platform initiative is a combination of technologies that will deliver multi-gigabit symmetrical Internet services to our consumers in the United States and around the globe. The Wi-Fi 7 certification will dovetail neatly with our intelligent 10G platform initiative in the telecommunication industry. 10G will ensure our customers gain access to the most advanced infrastructure in the marketplace and over Wi-Fi. The pillars of the 10G network span across throughput/speed, low latency, reliability, and scalable security. These pillars will allow our customers to take full advantage of future services over a Wi-Fi network. These customers may be residential, multiple dwelling units (MDU), or business services.

The throughput/speed pillar focuses on consumer bandwidth, enabling Wi-Fi EHT as well as multi-gigabit symmetrical experiences. The low latency pillar delivers on customer QoE, enabling future augmented reality (AR), virtual reality (VR), artificial intelligence (AI), and new digital Wi-Fi experiences like holodecks and lightfield displays. A poor Wi-Fi connection that adds a delay of a few milliseconds (ms) will produce negative user experiences. Lower latency will reduce jitter and delay in a Wi-Fi network, optimizing its performance. While the reliability pillar addresses Wi-Fi network issues proactivity before they inhibit our networks and customers. Wi-Fi network reliability will be required to grow as our consumer devices increase per household or per business. Finally, the security pillar strengthens our more complex Wi-Fi networks' confidentiality, integrity, and availability (CIA) triad, enabling safer symmetrical communications for all.

Figure 2 – 10G

3. Why Wi-Fi 7?

The simple answer to “Why Wi-Fi 7?” is speed. While that is a good answer, especially when considering new features such as wide 320 MHz channels and dense 4K quadrature amplification modulation (QAM). These features enable a potential data rate of 30 to 40 Gbps. However, that does not tell the entire story here.

Many of the features for Wi-Fi 7 are designed to make better use of the available RF bandwidth. With the release of the 6 GHz band, up to 1.2 GHz of new spectrum became available in the USA and other parts of the world. Some areas, such as Europe, only have 500 MHz available initially, but that is still an incredible amount of new bandwidth. However, when designing the 802.11be amendment, the IEEE made some decisions on optimizing the use of all the spectrum. For example, a Release 1 feature called multi-link operation (MLO) allows a device to operate, transmit and receive in more than one band at a time. The AP may access the available links and determine which link will provide the best connection for sending data packets. The AP may even spread the data over multiple links to increase throughput and reduce latency.

Wi-Fi 7 also enables devices to better coordinate their use of the available spectrum. By coordinating resources and adjusting transmit power to reduce interference, nearby devices can share the available bandwidth and spectrum. This can provide significant benefits in high-density deployments, such as MDU and college campuses.

So, to answer the question “Why Wi-Fi 7?”. Wi-Fi 7 is designed to enable Wi-Fi networks to work together to maximize the available Wi-Fi airtime resources to provide faster and more reliable connections.

4. Release 1 Features

As mentioned earlier, the Release 1 features are defined in Draft 1.0 and 2.0 of the amendment. Some features improve upon Wi-Fi 6 features; these include 320 MHz channels, 4K QAM, multiple resource units (RU) per station (STA), and orthogonal frequency division multiple access (OFDMA) enhancements. The other features, multi-link operation (MLO) and low-complexity AP coordination, are new features. Let us explore the new features first.

4.1. Multi-Link Operation

Since Wi-Fi 4 (IEEE 802.11n), wireless APs and STAs have had two radios; one operating in the 2.4 GHz band and another operating in the 5 GHz band. With the release of Wi-Fi 6E and the addition of the 6 GHz band, STAs may have three radios, or potentially more with multiple 5 GHz radios. Regardless of how many radios an STA has, it will only use one radio at a time to carry traffic. MLO looks to change this.

The concept is simple: use any available radio to transmit or receive data. A challenge for multi-link is that the upper layers must treat the combination of the radio interfaces as a single interface with a single MAC address. To accomplish this, a new device concept, the multi-link device (MLD), is set in the amendment.

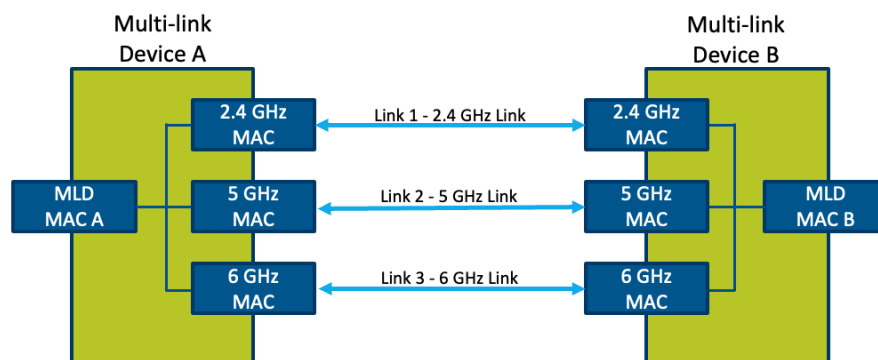

Figure 3 – Multi-link Device

The MLD splits the MAC layer into two parts the upper MAC (U-MAC) and the lower MAC (L-MAC). The L-MAC is the MAC that is tied to the PHY interface, and each wireless radio will have a unique L-MAC address. The U-MAC aggregates the L-MAC to a single MAC and performs link agnostic operations. The figure below shows the L-MAC and U-MAC layout and how they correspond to the upper layers.

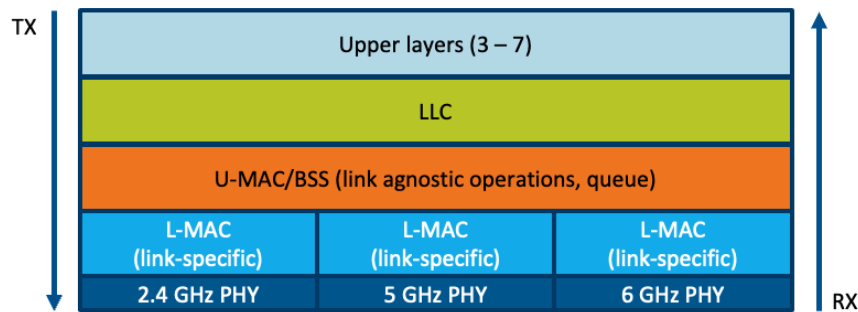

Figure 4 – MLO Architecture

The MLD must determine how to send the traffic. The MLD may be configured in two modes of operation, restricted mode and dynamic link switch mode. The restricted mode uses each link to send different types of frames. One link acts as a data plane and is only used for the data frames and the ACKs. The other link acts as a control plane and is used for the management and the other control frames. In the dynamic link switch mode, each link can send data or control frames, enabling Wi-Fi load balancing.

MLD's channel access can be either asynchronous or synchronous. Asynchronous is the preferred method since it provides more throughput, and when this method is used, it is called the simultaneous transmission reception (STR) mode. When using asynchronous channel access, the MLDs can transmit and receive at the same time using different bands. As noted in the image below, the 2.4 GHz link starts transmitting downstream, and then the 6 GHz link begins receiving data upstream. A little later, the 5 GHz band begins sending data downstream, while the 2.4 GHz sends different data downstream, and the 6 GHz link receives data upstream.

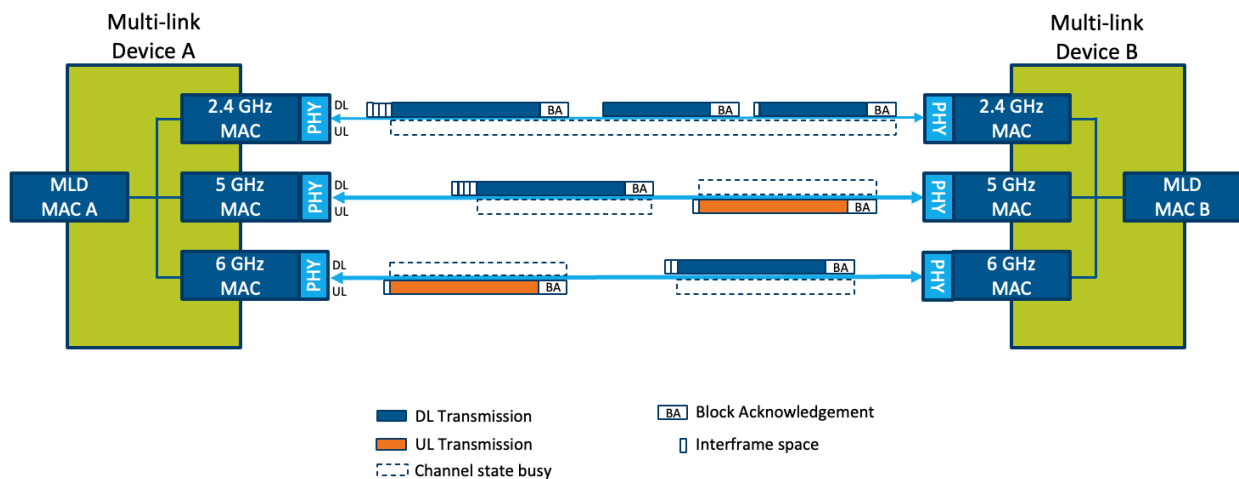

Figure 5 – Asynchronous Multi-Link Channel Access

Synchronous multi-link channel access sends the same data on both links. Synchronous channel access adds redundancy at the cost of reduced throughput. Synchronous channel access is better suited for environments with higher interference. If one link has a high amount of interference, the receiving MLD will examine each packet of the data stream and keep only the good ones. When the MLD uses synchronous channel access, it is in non-simultaneous transmission reception (NSTR) mode. In the image

Links do not have to stay in either asynchronous or synchronous mode. They can switch back and forth based on the link conditions. For example, an MLD has two links operating in asynchronous mode. During the transmission, link #1 gets a high number of errors. The MLD responds by switching to a synchronous transmission to ensure all the data is received. Once the conditions improve and the link quality is restored, the MLD can change back to the asynchronous transmission mode.

Multi-link channel access can potentially increase the time it takes for an STA to scan and discover an AP and its capabilities since it would have to send information for each link. To reduce the need for the STA to scan each interface, the reduced neighbor report (RNR) is used in the management control frames. Each link will provide information about the other links in the RNR, removing the need for the STA to scan the other interfaces.

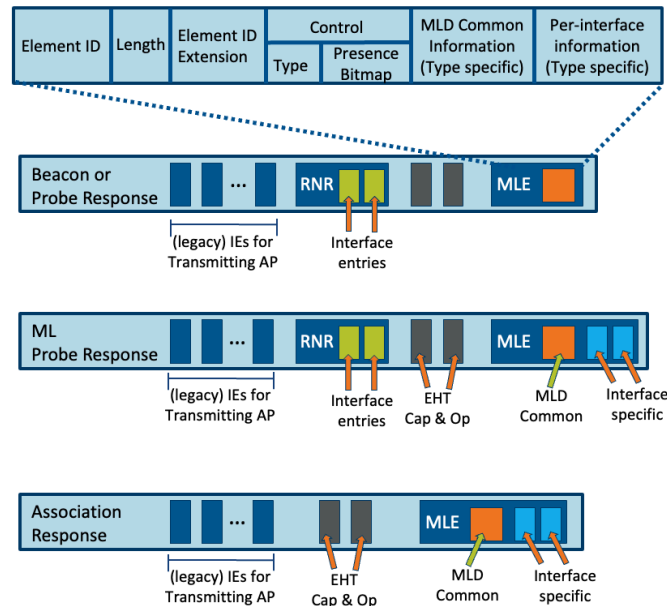

Figure 7 – Multi-Link Frames

Another important aspect of the multi-link channel access operation is the power-saving ability. Having multiple RF radios sending and receiving frames is not an efficient use of power, especially on battery-powered handheld devices. 802.11be will use the traffic indication map (TIM) and the target wake time (TWT) features to address this.

TIM uses beacons to inform the STAs that the AP has information for them. TIM uses an STA ID that is stored in a bitmap. In that bitmap, there is a bit that indicates if there is data for that STA. A binary one indicates there is, and the STA must wake up. A binary zero means there is no data for the STA, and it can stay in snooze mode. For TIM to work with MLDs, a link indication field is added to the bitmap. The link indication informs the STA which link has the data waiting for it.

TWT is based on a TWT schedule that is negotiated between the AP and the client. The TWT schedule includes the wake-up time, the wake interval, and the wake duration for the clients. With multilink, the MLD will negotiate the TWT schedule for each link with the AP. If all links follow the same schedule, then the MLD only needs to negotiate one TWT schedule.

4.2. Low Complexity AP Coordination

Environments such as MDUs where multiple APs are using the same channel and transmitting unique service set identifiers (SSIDs) create the potential for a high amount of Wi-Fi interference. Each AP is a basic service set (BSS), and when they overlap, this creates overlapping BSS (OBSS) interference, which impacts the quality of the wireless signal.

AP coordination can significantly improve Wi-Fi performance in these environments. Due to the complexity of AP coordination, the 802.11be task group split the features into two parts. Release one establishes the technologies used for low-complexity AP coordination, and release two sets the standards for advanced AP coordination. The AP coordination proposed in the 802.11be amendment identifies requirements for primary AP and secondary APs. These APs can be connected via cabling, but they do

not need to be connected. However, the secondary APs need to be able to communicate with the primary AP. The secondary APs do not need to hear each other.

The first method for AP coordination in the amendment builds on the spatial reuse (SR) feature introduced in 802.11ax. 802.11ax uses features such as BSS coloring and power management to handle OBSS interference. It controls the interference by managing the power of the secondary device. When the interference is detected, the primary AP will grant the secondary AP an opportunity to transmit simultaneously but using a lower power setting.

The drawback with this solution impacts a device trying to communicate with the secondary AP and can hear the primary AP. As shown in the figure below, STA 2, which is connected to AP 2, may interpret the signal from AP 1 as interference. If the signal is strong enough, it will not be able to communicate with AP 2.

Figure 8 – 802.11ax Spatial Reuse Drawback

802.11be looks to improve the 802.11ax SR with a coordinated spatial reuse (CSR) system. With CSR, when an AP that is part of a coordinated group receives a transmit opportunity (TXOP), it will coordinate with the other APs to share the TXOP. To reduce the impact of OBSS interference, the coordinated APs will adjust their power levels. Using the scenario mentioned above, AP 1 and AP 2 will adjust their transmit power relative to STA 2. AP 1 will reduce its transmit power to reduce the interference for STA 2, so it can communicate with AP 1.

Figure 9 – 802.11be Coordinated Spatial Reuse

The second method proposed for low complexity AP coordination is coordinated orthogonal frequency division multiple access (Co-OFDMA). OFDMA was introduced as part of the 802.11ax amendment, and it enabled APs to schedule time and frequency slots called resource units (RU) for devices to transmit and receive data. Co-OFDMA enables coordinated APs to share those resource units. APs will work together

to schedule RUs for devices to use. APs could schedule the same RU slots as long as the signals do not interfere with each other.

CSR and Co-OFDMA are being developed for Release 1 of the 802.11be amendment. We will look at the other AP coordination features proposed for Release 2 later in this paper.

4.3. 320 MHz Channels

Starting with Wi-Fi 4 (IEEE 802.11n), channel bonding was used to increase the potential data rate. Wi-Fi 4 added 40 MHz channels, using two 20 MHz channels. Wi-Fi 5 (802.11ac) added the capabilities for 80 and 160 MHz channels. In contrast, Wi-Fi 6 (802.11ax) did not expand the channel size options. However, it added the 6 GHz band, which made using one or two 160 MHz channels possible.

Wi-Fi 7 looks to expand the channel bandwidth to a massive 320 MHz channel (sixteen 20 MHz channels). The 320 MHz channels will only be possible in the 6 GHz band. The 320 MHz channels can also be non-contiguous, with two 160 MHz channels. If 320 MHz is unavailable, another option is a 240 MHz channel, which is made using one 80 MHz channel and another 160 MHz channel. Having a super wide 320 MHz channel sounds great. However, it will not always be possible, especially in dense AP environments. In these environments, channel reuse is important, and despite the 1.2 GHz of bandwidth in the 6 GHz band, there are only three 320 MHz channels.

4.4. 4K QAM

Another enhancement to previous Wi-Fi generation PHYs is increasing the modulation from 1024 QAM to 4096 QAM (4K QAM). 4096 QAM can potentially increase the data rate by 20%, compared to 1024 QAM. The challenge with 4096 QAM is that the SNR must be extremely high. Specifically, 4096 QAM requires an SNR of 40 dB, which will be difficult for many wireless networks to achieve. It can happen using beamforming in non-crowded environments, but it will be challenging in the best environments.

4.5. OFDMA Enhancements

One of the most significant additions to Wi-Fi 6 was OFDMA. Wi-Fi 7 looks to improve OFDMA to use the bandwidth more efficiently. This next section will look at these enhancements, including multiple RUs per STA, preamble puncturing, and a new physical protocol data unit (PPDU).

4.5.1. Multiple RUs Per STA

OFDMA schedules RUs for devices to use for uplink or downlink communication. The AP will allocate an STA the RU size based on the STA's bandwidth requirements. A RU is made up of a group of subcarriers called tones, and the size of the RU varies based on the number of tones. For a 20 MHz channel, the smallest RU has 26 tones, and the largest has 242 tones. The 26-tone RU is called an RU26 tone map, allowing 9 RUs in a 20 MHz channel. The table below shows the tone maps.

Table 1 – OFDMA Tone Map

RU Tone	Number of Tones			
	20 MHz Channel	40 MHz Channel	80 MHz Channel	160 MHz Channel
RU26	9	18	37	74
RU52	4	8	16	32
RU106	2	4	8	16
RU242	1	2	4	8
RU484	N/A	1	2	4
RU996	N/A	N/A	1	2
RU2 x 996	N/A	N/A	N/A	1

The image below shows the possible tone maps for an 80 MHz channel. The yellow lines between the tones are direct conversion, guard, and null tones.

Figure 10 – 80 MHz Tone Map

The 802.11ax standard allowed multiple devices to be allocated a single RUs for each TxOp. An example cited in the *Current Status and Directions of IEEE 802.11be, the Future Wi-Fi 7* paper, has two STAs sharing an 80 MHz channel. The AP grants a 242 tone RU to the 1st STA, and the 2nd STA can be granted a maximum of a 484 tone RU. That leaves 25% of the bandwidth unused. If the 2nd STA has more data to transmit, it must wait for its next TXOP.

802.11be looks to improve the spectrum efficiency by enabling APs to assign multiple RUs to a single STA. For the example cited above, the 1st STA would be assigned a 242-tone RU, and then the 2nd STA could be assigned a 484-tone RU and a 242-tone RU. This effectively gives the 2nd STA 726 tones to send data. With the move to larger channels, assigning multiple RUs to a single STA can significantly improve the ability of APs to use the available bandwidth efficiently. The task group is investigating how many RUs will be assigned to a single STA.

802.11be separates the RUs into two groupings based on their size:

- Small-size RUs: RUs less than 242 tones, ex. RU26, RU52, RU106
- Large-size RUs: RUs equal to or greater than 242 tones, ex. RU242, RU484, RU996

The 802.11be draft amendment lists all the possible multi-RU (MRU) possibilities in an MRU index. The only small-size MRUs are RU78 (RU52+RU26) and RU 132 (RU106+RU26). The 802.11be draft standard identifies the large-size MRUs based on the channel size. The following are mandatory RUs specified in the standard.

Table 2 – Multi-Rus for Large-Size RUs

Bandwidth	RU	Mandatory in non-OFDMA for:
80 MHz	484+242	AP, STA
160 MHz	996+484	AP, STA
	996+(484+242)	AP, STA
240 MHz	3×996, 2×996+484, 2×996 (any 2)	AP, STA
320 MHz	4×996, 3×996+484, 3×996 (any 3)	AP, STA

4.5.2. Preamble Puncturing

Wi-Fi 5 introduced dynamic channel bandwidth to go along with the large 80 MHz and 160 MHz channels. When an STA connects to a client, it connects on the primary 20 MHz channel. If the secondary 20 MHz channel is available, the connection expands to be a 40 MHz channel. Next, it will attempt to connect to the secondary 40 MHz. It will first connect to the primary 20 MHz of the secondary channels and then connect to the secondary 20 MHz of the secondary channels. When all four 20 MHz channels are connected, the STA has an 80 MHz channel to use. However, if the initial secondary channel is busy during this process, only the initial 20 MHz primary channel is used. The AP cannot use any of the secondary channel bandwidth, even if it is available.

Wi-Fi 6 introduced preamble puncturing, which enables an STA to avoid using a 20 MHz portion of a large channel (40 MHz, 80 MHz, and 160 MHz) that is busy. Using the 80 MHz channel example again. The STA connects to the AP on the primary 20 MHz channel. The AP will then check if the secondary 20 MHz channel is busy. If the channel is busy, the AP will skip the channel and attempt to connect to the secondary 40 MHz channel. Wi-Fi 6 identified eight bandwidth modes. Modes 0 – 3 are for the standard channel bandwidths with no puncturing, 20 MHz, 40 MHz, 80 MHz, and 160 MHz. Modes 4 – 7 are the puncturing modes, which are pictured below.

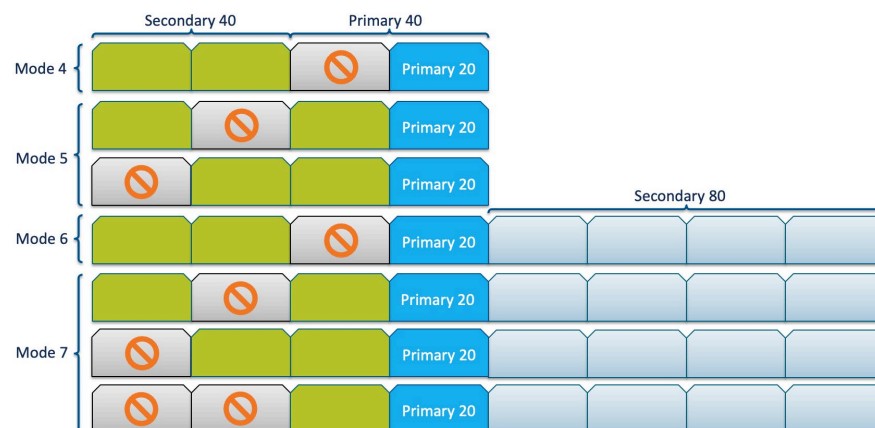

Figure 11 – Wi-Fi 6 Preamble Puncturing

802.11be will build on existing puncturing techniques by expanding the modes to cover the 240 MHz and 320 MHz channels. Also, preamble puncturing is being applied to primary channels. This technology is called preamble puncturing because the preamble is removed from the frame for the channel that is being punctured.

Figure 12 – Preamble Puncturing Frame

4.5.3. PPDU Frame Format

When designing the PPDU, the 802.11be task group aimed to have backward compatibility with previous Wi-Fi standards and provide a framework for future standards. The backward compatibility is maintained by the first four parts of the frame, and the rest of the frame is designed to support future Wi-Fi 7 and future versions.

Figure 13 – Wi-Fi 7 PPDU

The 802.11be PPDU begins with using the same legacy preamble training fields as previous Wi-Fi versions. These fields are the legacy short training field (L-STF) and the legacy long training field (L-LTF), and they are used for frame detection and synchronization. The next field is called the legacy signal field (L-SIG), and it is a carry-over from 802.11a to indicate the MCS and frame length. However, since Wi-Fi 4, the values in the field were not related to the MCS. The data in there is fake data as placeholders to maintain compatibility. Wi-Fi 4 and 5 send the MCS and frame length data in the following field. Wi-Fi 6 transmits it after the following field, the repeat legacy signal field (RL-SIG). Wi-Fi 7 will also use the RL-SIG field.

The PPDU frame variation for 802.11be starts with the universal signal (U-SIG) field. The U-SIG field is created with an eye toward compatibility with future Wi-Fi standards. The U-SIG has two parts: the version independent and the version dependent fields. The version independent field includes a PHY version identifier, an uplink (UL)/downlink (DL) flag, the BSS color field, the TXOP duration, and the bandwidth. The 802.11be task group is still defining the information sent in the version-dependent fields of the U-SIG. Some of the information may include the guard interval duration, EHT-STF, EHT-LTF size, space-time block coding, and information about specific 802.11be features.

The EHT-SIG field will provide information not included in the U-SIG but is needed to implement 802.11 features. The EHT-SIG has two parts: the common field and the user-specific field. The common field has the RU allocation information, the MCS, the guard interval duration, and other signal information. The user-specific field will be present in multi-user (MU) frames and will have information directly related to an STA. The last two fields of the EHT preamble are the EHT-STF and EHT-LTF. These training fields are similar to the training fields at the beginning of the PPDU. They provide synchronization for multiple in multiple out (MIMO) configurations.

5. Release 2 Features

As per the original timeline, the Release 2 features will be added in Draft 3.0 and 4.0. Some of these features build on existing 802.11 standards and the Release 1 features. These features are still being investigated at the time of this writing, and the 802.11be task group has not given final approval. They are reviewing multiple proposals for implementing these features. The features that are part of Release 2 include MIMO enhancements, hybrid automatic repeat requests (HARQ), low latency operation, and advanced AP coordination.

5.1. MIMO Enhancements

Since MIMO was introduced with 802.11n (Wi-Fi 4), MIMO has been enhanced with each release. Wi-Fi 7 continues that trend by doubling the number of spatial streams from 8 to 16. This can potentially double the throughput an AP can handle. However, there are some restrictions on the 16 spatial streams. The first restriction is that the maximum number of STAs using spatial multiplex per AP is eight. The second restriction is that each STA can have a maximum of 4 spatial streams. This will not restrict client capabilities significantly since most mobile devices support a maximum of two spatial streams for power efficiency reasons. As the bandwidth needs of the devices increase, manufacturers can add additional spatial streams up to 4. The other reason for limiting the number of spatial streams is to limit complexity and overhead.

5.1.1. Channel Sounding Optimization

For MU-MIMO to operate effectively, the AP and clients must have accurate information about the channel quality. This is done through channel sounding, and previous 802.11 standards implemented two different versions, implicit and explicit sounding. 802.11ac and 802.11ax use explicit sounding, which replaced the implicit sounding introduced in 802.11n.

The explicit sounding used in 802.11ax works by the AP sending out a null data packet announcement (NDPA). This informs the STA about the null data packet (NDP) that the AP is sending. The STAs use the NDP to assess the channel's status and provide channel state information (CSI) for the channel to the AP. The CSI is sent via a beamforming report (BFR). The BFR provides the SNR for each spatial stream, a comparison of the SNR for the subcarrier compared to the spatial stream, the Givens rotation angles (ϕ and ψ), and other relevant channel quality information. The CSI for a 160 MHz channel with one spatial stream will provide BFR information for every 16th subcarrier, for a total of 128 subcarriers. As the number of spatial streams and channel size increases, the amount of CSI data sent from the clients to the AP will increase. The overhead will increase dramatically, and the information will not be relevant as the channel state constantly changes.

At the time of writing this paper, the 802.11be task group is investigating multiple methods to reduce the overhead. Some of these solutions use implicit sounding. Even though implicit sounding was first introduced in 802.11n, it was never really implemented in APs. The reason was that the APs could not perform the AP-self calibration needed. Self-calibration is needed since the UL and DL signals will vary slightly for each antenna. So, the APs must compensate for these differences. Implicit sounding works by having the STA send NDP sounding information in the UL. The AP will measure the channel using the sounding information. It takes less time to send the NDP than it does to send the BFR, especially when there are many spatial streams and STAs. Reducing the time needed to receive the channel information is more current.

To improve the self-calibration, newer local AP self-calibration techniques can be used where the STAs are not involved in the calibration process. The AP will select a reference antenna and send out a pilot signal from every antenna. It estimates each antenna's baseband to RF gain variations and makes the necessary adjustments. An example of how implicit sounding is used in one of the proposals begins with the AP sending out a trigger frame requesting the STAs to send the UL NDPs. The AP analyzes the NDPs from all the STAs. It then can send beamformed data to each STA. This method is estimated to save approximately 60% of the airtime.

5.2. HARQ

Hybrid automatic repeat requests (HARQ) aims to reduce the amount of traffic on the wireless network by reducing retransmissions. Current Wi-Fi implementations require an entire packet to be retransmitted if the receiving device did not receive a complete packet. This will continue until the receiver gets a complete packet and can lead to a high number of retransmissions and impact the performance of a network. HARQ looks to improve this by combining the failed- transmissions, which will improve the SNR, and the receiver should be able to rebuild the complete packet with the information that it has. In the end, this will reduce the number of retries on the network. Another benefit is that since the SNR is being improved, a higher MCS can be set for the connection.

The task group is evaluating three methods to implement HARQ: chase combining (CC), punctured CC, and incremental redundancy (IR). The lowest complexity solution is CC. With CC, every retry has the same information as the failed packet. Since the information is the same, it makes rebuilding the packet less complex. However, there is the potential for more traffic than other HARQ methods. The second method being examined is punctured CC, which reduces the amount of overhead compared to CC. With punctured CC, the transmitter only repeats the part of the failed transmission. On the receiver side, this version will require more computation than CC. The most complex and bandwidth-efficient method is IR. IR requires the transmitter to use different codewords to represent the same information. The receiver gets more information to rebuild the original packet by using a different set of codewords.

5.3. Low-Latency Operation

Network latency is an essential part of all networking solutions. Residential applications such as virtual reality gaming and commercial applications such as industrial IoT are real-time applications (RTA), and they need networks to have very low latency. The IEEE has done a lot of work looking at time-sensitive networking (TSN) applications. They have established an 802 TSN task group to study these solutions. Most of their work applied to 802.3 Ethernet networks, but now the 802.11 working groups are looking at ways to implement TSN solutions with Wi-Fi.

The solutions being investigated focus on improving the worst-case latency instead of the average latency. Many of the 802.11be features outlined in this paper are a big part of the solutions. Multi-link operation, AP coordination, multi-RU per station, and other techniques are designed to use the spectrum more efficiently, resulting in data packets waiting less to be transmitted.

Two operations scenarios are identified by the 802.11be task group, managed and unmanaged. Examples of unmanaged scenarios are home networks and Wi-Fi hotspots. Managed scenarios are more the corporate and enterprise networks that use controllers to manage the network. The big difference in these scenarios is that the controllers and the APs can better deal with interference and optimize the environment. Unmanaged networks can do things to control latency and jitter, but they have little control of the impact of outside interference.

One way to reduce the latency for RTAs is to use QoS. Wi-Fi uses enhanced distributed channel access (EDCA) to provide QoS in Wi-Fi networks. Currently, EDCA uses four categories of traffic; background, best effort, video, and voice. Voice has the highest priority for getting channel access. The 802.11be task group is investigating adding additional categories. While voice traffic will continue to have higher priority, some applications need to have higher priority than video. A typical example used is gaming. Gaming does not require as much bandwidth as high-resolution video, but the latency must be much less. Adding a category for gaming that is a higher priority than video can reduce the worst-case latency for gaming applications.

The challenge is getting access to the medium. In Ethernet networks, collisions can clear the medium so that the higher priority traffic can get access. Wi-Fi does not have collision detection. The device using the medium cannot do any sensing on the channel while transmitting. The solution for this is different on managed and unmanaged networks. With managed networks, the controllers can coordinate the channel access. They can give access to the channel to the device that has the higher priority traffic. This can be done via scheduling using hybrid coordinated function-controlled channel access. This function is not used in WLANs today. Another option is using a trigger frame. The controller can allocate medium access to high-priority applications using short trigger frames.

On unmanaged networks getting access to the medium can be more difficult. 802.11be enhancements like multi-link operation will help with this since there are multiple mediums to carry traffic. One solution is a busy tone. A busy tone can let a device that is transmitting lower priority traffic know there is higher priority traffic waiting to be sent. When the busy tone is detected, the device stops transmitting, so the higher priority traffic can be sent. Multi-link devices can use another link to send the busy tone. Another way multi-link is being used to reduce latency is by implementing asynchronous communication, also known as joint mode. The AP will use multiple links to send different data in joint mode.

Figure 14 – Multi-Link Joint Mode

5.4. Advanced AP Coordination

Release 2 looks to add more advanced ways of doing AP coordination. The two methods being investigated for Release 2 are coordinated beamforming (CBF) and multi-AP joint transmission and reception.

5.4.1. Multi-AP Joint Transmission and Reception

Multi-AP joint transmission and reception creates a way for multiple APs to serve a single STA. This is a similar concept to multi-link operation, but in the reverse scenario, where there is one STA being served by multiple APs. However, the challenge for this system is the synchronization of the APs. This challenge is extremely difficult in the DL as it requires a high-speed, low latency backhaul to create synchronization among the APs. The backhaul is needed because it must provide the data to all the APs to transmit. The APs need to be in synchronization so they know which parts of the data were transmitted and received. For the UL, multi-AP systems distributed successive interference coordination (SIC) can be used to improve the data reception at the APs. With SIC, each AP receives the data from their STAs. The data is then sent to the other APs for interference subtraction. The APs remove the interfering signal from the received signal to get their data. The other method being investigated for the uplink is joint frame reception. With this method, the APs process the data from all the STAs. The high-bandwidth backhaul is needed to synchronize the APs for handling the STA traffic. The APs share signal time stamps to stay in synchronization.

5.4.2. Coordinated Beamforming

CBF is also called null steering. It is called null steering because the AP sending the traffic will attempt to cancel or null the interference from neighboring STAs. The nulling of the interference happens while the AP is creating the beamforming signal to the STA. To know what interference there is, the AP must collect CSI information for all nearby STA, including the ones it is not serving.

For UL transmissions, each AP must collect interference information for neighboring STAs. During the UL reception, the AP configures its receiver so it can receive data from its STAs while ignoring interference from other STAs.

6. Security

The Wi-Fi Alliance sets security standards for Wi-Fi networks as part of its certification process. The standards identify which Wi-Fi protected access (WPA) version and modes that a device must support. The Wi-Fi Alliance has not announced any new security requirements around Wi-Fi 7. At the time, it is expected that the Wi-Fi 7 device certification will have similar security requirements as Wi-Fi 6 and Wi-Fi 6E. Those certifications brought significant updates to Wi-Fi network security. Wi-Fi 6 added the following security updates:

- WPA3-Personal
 - Simultaneous authentication of equals (SAE) for authentication and association
 - Management frame protection (MFP) used to combat deauthentication attacks
- WPA3-Enterprise
 - 802.1X/EAP
 - Management frame protection (MFP)
 - 192-bit security key optional
- Enhanced Open
 - Provides encryption on open networks

To obtain Wi-Fi 6 certification, the Wi-Fi Alliance requires that devices support these new and legacy security standards such as WPA and WPA2. To enhance the security of devices operating in the 6 GHz band, the Wi-Fi 6E certification requires that devices only support the new security standards. Wi-Fi 6E devices do not support legacy standards.

Some of the questions around Wi-Fi 7 security are:

- Will the same security requirements from Wi-Fi 6 and 6E be carried over as they are for Wi-Fi 7?
- Will there be a separate Wi-Fi 7E certification, similar to 6E?
- Will multi-link devices support legacy security standards on non-6GHz channels?

The Wi-Fi Alliance has not established a time frame for Wi-Fi 7 certification and security requirements. It is expected to be ready in early 2024 to align with the release of the 802.11be standard.

7. Benefits to Customers

As noted in previous sections of the paper, Wi-Fi 7 increases the potential maximum data rate. Wi-Fi 7 takes advantage of the extended available spectrum and increases its efficiency for spectrum using wider channels, preamble puncturing, and 4K QAM. Besides the throughput/speed benefits, Wi-Fi 7 offers lower latency and better reliability in high interference environments using Co-OFDMA, RUs, and tones. The benefits in reliability extend beyond residential and into MDU and business environments. Wi-Fi 7 builds on the security benefits of Wi-Fi 6/6E, making it a viable choice for untethered connectivity. The increased throughput/speed, lower latency, reliability, and solid security in WPA3 makes it easier for operators to achieve their 10G platform pillars.

7.1. MDUs

In MDU environments, where there are many APs operating close to one another, it is important to identify areas of interference, like co-channel interference (CCI) or adjacent channel interference (ACI). One thing that is not changing with Wi-Fi 7 is, as with previous Wi-Fi versions, performing a Wi-Fi site survey at the MDU is important to understand the operating environment. Most Wi-Fi site survey tools offer a Wi-Fi heatmap to represent the coverage and RF signal strength visually. These heatmaps are often overlaid with MDU floor plans, increasing their effectiveness as a deployment and troubleshooting tool. This overlay also provides operators a visual map of the location of trouble zones, the location of APs and other relevant survey data.

Figure 15 – MDU

Besides the high areas of interference, the MDU is a dense environment. Wi-Fi 7 has access to an increased amount of RF spectrum and tools to use this RF spectrum better. Preamble puncturing is one of those features mentioned, along with Co-OFDMA. These features greatly benefit those using Wi-Fi to

communicate in MDU environments. Wi-Fi 7, like Wi-Fi 6E, takes advantage of the 6 GHz spectrum and may leverage MLO to increase throughput/speed and reliability in MDUs.

As mentioned, adjusting AP transmit power can provide big benefits in high-density deployments, reducing OBSS interference. Environments such as MDUs where multiple APs are using the same RF channel and transmitting unique SSIDs create the potential for a high amount of Wi-Fi interference. Furthermore, MDUs will benefit from the low complexity AP and advanced AP coordination features of Wi-Fi 7.

7.2. Business Services

Business services are transforming their enterprise networks with a host of digital elements that require higher data rates than residential. Wi-Fi 7 has a roadmap of throughput/speed options that extend the certification out to 40 Gbps. Today, service offerings like private/public/hybrid cloud, software-defined networking (SDN), and virtualization will benefit from the added Wi-Fi 7 throughput/speed options. Technologies like the 3rd Generation Partnership Project's (3GPP) 5G, citizens broadband radio service (CBRS), along with Wi-Fi 7, will be used to transform the access network edge for enterprise services using SCTE's generic access platform (GAP) enclosure (ANSI/SCTE 273-1 2021) and module (ANSI/SCTE 273-2 2021) specification standards. Further transformation of the edge will occur with the reality of 3GPP's 6G and Wi-Fi 7 Release 2.

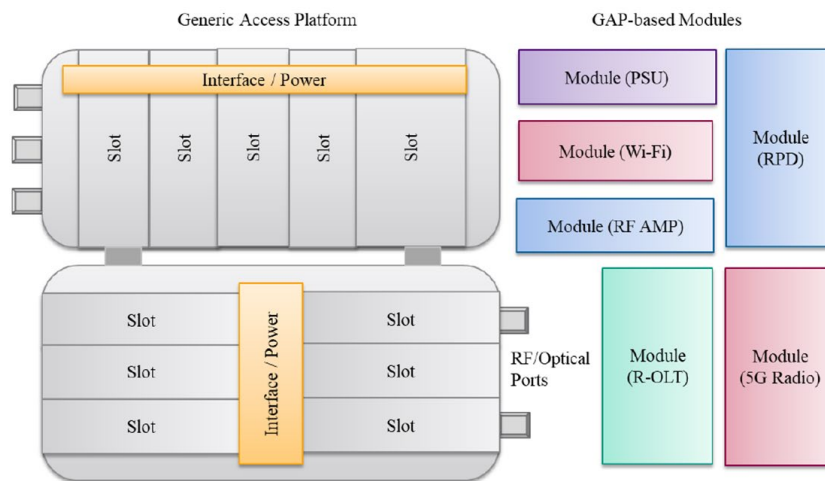

Figure 16 – SCTE GAP

For improving reliability in the enterprise, Wi-Fi 7 offers a toolkit here as well. Business enterprise time-sensitive applications require latency that is deterministic, offering high reliability and quality of service (QoS). Deterministic latency offers predictable jitter and network delays for enterprise networks. Operator enterprise Wi-Fi 7 networks must be designed to cope with the compromise between throughput/speed and deterministic latency. Wi-Fi 7's latency features and Co-OFDMA will benefit the explosion of IoT and industrial (IIoT) smart devices making their way into the enterprise.

The enterprise features mentioned will improve reliability, a key performance indicator (KPI) on the health of a Wi-Fi network.

8. Wi-Fi Performance Management

Subscribers want a consistent wireless/Wi-Fi experience, making performance management an important topic for Wi-Fi 7. A few of the top issues for operators with in-home or business service Wi-Fi are throughput/speed, range, interference, congestion, and compatibility.

In any Wi-Fi network, a high number of users or STAs may overload an AP, reducing the available RF energy in a BSS. In addition, as the STA distance from an AP's radios increases, the receive signal strength indicator (RSSI) value decreases towards the noise floor of -90 dBm. This is because extending the range from the STA to the AP reduces the power due to free space path loss (FSPL). Each 3 dB of signal loss in the RSSI equates to a reduction in milliwatt (mW) power by one-half (1/2). A reduction in RSSI also reduces the data throughput/speed of the AP, like how cellular devices operate with a base station. Leveraging the benefits of Wi-Fi 7 MU-MIMO, preamble puncturing, MLO, and AP coordination will increase performance in these scenarios. An additional consideration that might benefit performance here would be load balancing STAs, additional APs, and decreasing STA to radio distance.

In high multi-path environments, interference and signal fading are always top of mind and an operator's priority. Multi-path environments, or indirect line of sight (LoS) communication, occur from reflected, scattered, and other RF extrinsic factors in a Wi-Fi environment. Wi-Fi 7 offers 16x16 MU-MIMO and spatial diversity to reduce interference and signal fading in high multi-path environments. Spatial diversity allows an AP to select from multiple input signals for the best reception. Furthermore, to identify interference, always perform a Wi-Fi site survey to understand the operating environment and talk with the subscriber about the Wi-Fi coverage in the BSS. A site survey is a great step to providing a good Wi-Fi service in residential, MDU, and business service enterprise environments. A survey identifies items that may reduce RF coverage, range, or performance in the Wi-Fi network. The survey tool offers data to discuss options with subscribers.

Not all Wi-Fi site survey tools are the same. Most survey tools offer a heat map characterization, as well as a Wi-Fi extender and mesh characterization. The heat map produces images utilizing a color map to show the AP's RSSI and RF throughput levels. With most Wi-Fi networks deploying extenders to create mesh networks for range and coverage improvements, we must characterize their range and throughput/speed. Heatmaps will show ways to improve range, coverage, and throughput/speed for larger dwellings. Heatmaps also look for CCI and ACI, as well as an elevated noise floor.

Figure 17 – Heatmap

WI-FI networks operate between -30 dBm and -90 dBm, where -90 dBm is the noise floor. The higher the RSSI, the better the performance of the Wi-Fi network. For example, a -80 dBm is considered poor, while a -60 dBm may be considered acceptable. A dB is a decibel or relative power measurement used to compare two dBm values like the SNR metric. SNR refers to the Wi-Fi signal level of the received signal versus the ambient noise on the RF channel, meaning measurable RF energy without a signal, referred to as noise. For example, Figure 18 below shows a plot of a Wi-Fi signal and the noise floor. The noise floor is a little higher than normal at -79 dBm, and the signal is around -41 dBm, which makes the SNR for this connection 38 dB. Depending on the Wi-Fi design, operators may want an S/N of 35 dB or greater.

Figure 18 – Signal to Noise Ratio

The dBm is a decibel relative to a milliwatt (mW), where 0 dBm equates to 1 mW of RF power. The mW is an absolute power measurement often used in combination with dBm in Wi-Fi networks. RSSI and S/N will still apply to Wi-Fi 7 networks and will vary based on the radios used, 2.4 GHz, 5 GHz, and 6 GHz.

<div> <div>Wi-Fi</div> <div>6 / 28 Radios</div> <div>17 Scan</div> <div>01:54 Length</div> <div>SCTE-5G 9C:C9:EB:99:96:E1</div> <div>CH 149 (149-161) / 80 MHz 0.8 μs / 5 GHz / 5745 MHz</div> <div>802.11 ax d e h i w / 6. Kyrio	9C:C9:EB:99:96:E3	-37 dBm	58 dB	149	ax	80 MHz	2		
SCTE	9C:C9:EB:99:96:C1	-29 dBm	72 dB	6	ax	20 MHz	2		
SCTE-5G	9C:C9:EB:99:96:E1	-37 dBm	58 dB	149	ax	80 MHz	2		
SCTE-Guest	9C:C9:EB:99:96:E4	-37 dBm	58 dB	149	ax	80 MHz	2		

Figure 19 – RSSI

As with Wi-Fi 5/6, it is operating in the 5 GHz as opposed to 2.4 GHz reduces the range of a Wi-Fi network. Then we have newer STAs that will take advantage of 6 GHz from Wi-Fi 6E and Wi-Fi 7,

further reducing the range of the RF signal and the RSSI value. This is because the wavelength of 6 GHz is much shorter than 2.4 GHz. Mesh networking will be an important component of the deployment of these Wi-Fi 7 networks.

Figure 20 – Wavelength of 2.4, 5, and 6 GHz

Other tests may be conducted to determine airtime fairness implementation in the AP. These tests look into the throughput/speed of the AP and how it allocates bandwidth to each of the STAs. These types of tests help operators understand scenarios where a good QoE or QoS may not be delivered. A different kind of test that is useful is determining the band steering capabilities of an AP. Band steering will become more important as Wi-Fi 6E/Wi-Fi 7 utilize multiple radios, especially when multi-link capacity is available. Having the AP and STA choose the best bands to operate in will be crucial for providing the best possible QoS.

9. Conclusion

Residential, MDU, and business service wireless communications will support the mission of the 10G platform, extending the benefits of throughput/speed, low latency, reliability, and security. In addition, Wi-Fi 7 will offer a more carrier-grade version of wireless while driving a more positive customer QoE. In all the access network technologies an operator deploys, it is the premises' Wi-Fi experience that will determine the image of an operator. The Release 1 features like PHY enhancements, OFDMA, MLO, and preamble puncturing will be critical to the next generation of connectivity. Release 2 features will solidify the experience with MIMO enhancements, channel sounding, HARQ, low latency, and AP coordination.

Managing the impact of Wi-Fi 7 will require benchmarking devices with partners like Kyrio and truly understanding the metrics that lead to a healthy Wi-Fi ecosystem. With any new Wi-Fi certification, workforce education and credentialing will be the tools to manage our talent teams, further pushing positive interactions and experiences with Wi-Fi 7. Any such educational program (e.g., SCTE BWS and SCTE CWNP) must measure the return on investment (ROI) to quantify the reduction of call volumes,

truck rolls, etc. related to wireless technology in our industry. Stay tuned as advancements in Wi-Fi 7 take place, and look to the trusted applied science leader in telecommunication to keep you ahead of the curve on this exciting technology.

1. Introduction

Managing and maintaining highly scalable networks has historically been a challenging task. A plethora of ISPs/CSPs have been trying to simplify processes and procedures; yet this task gets more complicated as they are faced with the growing cost pressure of supporting today's IP network traffic demands (driven by video, gaming, and remote working) and future 5G/6G cellular traffic volumes. Based on several reports, the internet usage has increased by 1,355% over the last 22 years [1]! With the coming deployment of the Full Duplex DOCSIS 4.0 system in the access networks [2] and the proliferation of the 400/800Gb/s Ethernet technology [3] in the aggregation/core layers, traffic utilization could continue to accelerate in the upcoming decade.

As Mannan Venkatesan, a Distinguished Engineer from Comcast Cable, notes in his NANOG N81 2021 presentation:

“There is a significant amount of port growth we need to support. We all know the internet traffic has exploded within the last decade. The ports you would need to support the traffic are also proportional to the traffic volume, so we must make sure we stay on top of the port capacity we support on core and aggregation routers” [4].

All these trends and market forces are impelling cable operators to rethink and rearchitect their existing IP networks and operations to maximize performance and efficiency.

Network operators must also consider the total cost of ownership of various hardware and software options, not just that of an individual component or software option. Network components don't operate in a vacuum, so choosing feature-light hardware may necessitate greater investment in hardware and vice versa. There is always a tradeoff between feature-rich software and bare bones hardware. It's critical for network operators to understand what's needed for end-to-end delivery, rather than just individual component costs and specs, which may not paint the whole picture.

Due to the above-described forces, a new innovative system is desired to solve these problems. The primary requirements for such a system are that the cost per bit and time to market of new services be reduced, and yet be able to permit the simplicity of the network operations while minimizing the blast radius or failure zone of the network. Losing one router has the potential to impact millions of customers and puts the network in a hazardous condition. Another failure can isolate the whole network, either the one managed by the operator or a peer's network. The main goal is to reduce the blast radius and impact of one router or component and increase the availability of the network.

Disaggregated Distributed Chassis and Disaggregated Distributed Backbone Router (DDC and DDBR) are powerful solutions based on open-source specifications that solve current operational challenges when building and scaling IP backbone/aggregation networks [5, 6]. These two options addresses and mitigates many of the issues described above. These models arm operators with the flexibility of selecting the best breed of IP products in the market.

In this paper we dive into how cable operators can leverage open transport building blocks across different segments of their transport networks (access, aggregation, backbone) and implement concepts of real DDC/DDBR architecture, while utilizing orchestration, automation, and analytics. We will also touch upon how they can overcome operational challenges and pitfall considerations while proactively positioning themselves for future disaggregated network solutions.

2. Disaggregation as a success criteria for ISPs/CSPs

2.1. DDC and DDR

Disaggregated Distributed Chassis and Disaggregated Distributed Backbone Router are open-source specifications for carrier grade routing systems put forth by Open Compute Project (OCP) and Telecom Infra Project (TIP), respectively, which are global collaborative communities focused on innovation and development of open, disaggregated, and standards-based technology solutions [7, 8]. One of the main motives for the inception of these organizations was the huge influx of new registered users and data which resulted in an exponential growth of services and platforms developed and deployed by hyperscalers. These developments incurred unforeseen control costs and energy consumption which can only be optimized by the benefits of open source and open collaboration to hardware. This collaboration model is now being applied to advance the telecommunications industry as ISPs/CSPs experience similar pressures of unprecedented traffic growth.

Telcos and Cablecos are rigorously researching, testing, and deploying disaggregated networking solutions across their footprint. To cope with the tremendous demand, they have been envisaging an evolution path to their core/aggregation networks to introduce innovation, efficiency and mostly openness. Ideas have been entertained to initiate a shift in the IP backbone architecture from the traditional single chassis-based routing systems to more disaggregated distributed ones.

ISPs/CSPs not only desire to meet current needs when deploying core/aggregation transport networks but also staying ahead of the evolving trends in terms of resiliency, capacity scaling & End-To-End (E2E) network automation.

Before going into the nitty gritty details of the challenges that operators face, let's review the key points of the DDC/DDBR solution [5, 6]:

- **Disaggregation is driving competition:** creating opportunities for new players in the market driving costs down.
- **Pay as you grow:** model that allows operators to purchase capacity incrementally as it is needed.
- **Innovation:** open software and hardware to improve flexibility and innovation while reducing time to market.
- **Operational Efficiency:** Taking advantage of centralized control and monitoring tools.
- **Reliability:** Always targeting higher availability & multi-level redundancy while minimizing blast radius impact to decrease customer impact and outages.

This system can be placed not only in the IP/MPLS backbone but also in the access layer and act as an Internet Gateway Router (IGW), as depicted in Figure 1. The same hardware can be utilized for these routing functions regardless of Network Operating System features or implementation.

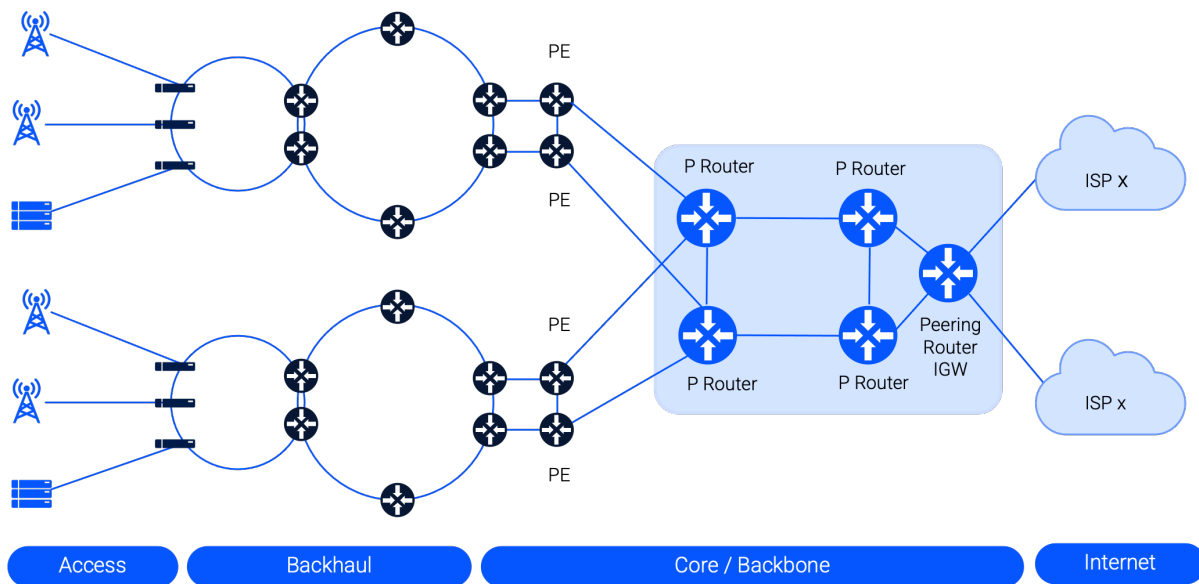

Figure 1 - DDC/DDBR placements in the network

2.2. Difference between DDC/DDBR and traditional routers

2.2.1. Modular Chassis

To understand why DDC/DDBR is an evolutionary architecture, a reasonable convenient starting point would be to analyze the traditional routing platform architecture first.

Figure 2 shows a front and back view of a finished product view of a typical modular chassis routing system from one of the vendors in the ecosystem.

Figure 2 - Front and Back View of a Modular Chassis [5]

There are multiple components that comprise this system which reside inside the chassis and are not visible: line cards, fabric modules, Route Processor modules, PSUs, and FAN FRUs to name a few. Modular chassis routers use pluggable line cards to scale up capacity and service features and form the foundation of ISPs/CSPs' backbone and aggregation networks today. If a service provider needs more ports, more linecards can be bought and inserted into the system. The growth ceiling for this type of system is dependent on how many available slots there are on a modular chassis. One more option to scale up is to purchase a totally new chassis with higher port density and replace the old one due to the scarcity of slots for line cards. An example would be replacing a ten-slot chassis with a twenty-slot chassis.

Edson Erwin invented the highly scalable Clos architecture/Clos Network in 1938 and which then was formalized by Charles Clos in 1952. Later in 1953, Charles Clos published a paper titled "A Study of Non-blocking Switching Networks" in the Bell System Technical Journal [21] where he describes a method of designing arrays of cross points for use in telephone switching systems. In recent years, the variation of a Clos network had been widely deployed by hyperscalers and is now being adopted by the largest telcos and cablecos.

Another possible course of action is the scale-out (horizontal disaggregation) model. This model decomposes the chassis system into a spine and leaf Clos architecture which has been pioneered and successfully adopted in data center designs by hyperscalers. ISPs/CSPs are now making a significant effort to take these concepts and apply them to the routed Wide Area Network (WAN).

As can be seen, these traditional routers mainly scale up hardware, with some scale out options existing such as multi-chassis racks or back-to-back multi-router options. It is viable to architect incremental growth, but then there is a need to account for the same incremental up-front cost for cooling, power, space along with rack, stack, and cabling installation costs. The power per rack may be limited at the facilities and new next-generation single chassis systems have very high-power demands, more cooling is needed and there may be space limitations at the headend or datacenter. This traditional option is not portable.

At one time, this routing system (RS) architecture was an effective way to build backbone/aggregation networks. It was a one-stop shop to have all your port, fabric, and software needs in one fixed chassis. This made troubleshooting easier as well since the networking vendor would be responsible for any software or hardware issues encompassing the whole chassis. The limitations of this system lie in its mechanical design to solve thermal and spatial challenges and live Online Insertion and Removal (OIR) of modules within the system which sometimes can cause traffic impact and may require multiple maintenance windows to ensure business continuity. On top of that, the mentioned hardware design and the software controlling the system are solely proprietary to the specific vendor thus preventing potential ecosystem players to participate and compete in either HW or SW market.

However, with the evolution of networks and traffic patterns, ISPs/CSPs had to adapt and adopt disruptive and innovative technology solutions. DDC/DDBR RS architecture that resembles Clos Spine-Leaf (S/L) topology in terms of interconnections between elements but operates as a single routing system is the optimal way for operators to accelerate business agility and drive revenue growth. This solution also allows per port or speed step function which we will discuss later.

2.2.2. Disaggregated Routing System

So, you may wonder, what is a Distributed Disaggregated Routing System? All the elements that were shown in the Figure 2 traditional refrigerator single chassis router; namely the line cards, fabric modules and route processors are all disaggregated onto separate physical “pizza” whitebox and commercial off-the-shelf (COTS) x86 server components that run virtual machines and software containers. This variation of Spine/Leaf Clos design allows various scalability options. Clos has been already deployed previously in datacenters, backbone/core networks for many decades as we will learn more about later. Now, we have the ability of taking it one step further to the regional area networks or closer to the edge.

In Figure 3 we can see a conceptual diagram that demonstrates such a system from a birds-eye View [5]:

Figure 3 - High-Level View of a DDC Routing System

In this graphic, the disaggregated distributed RS is comprised of a certain number of fixed-RU Packet Forwarders (PF) which represent the leaf of the cluster and act as the line cards, and several Fabric Forwarders (FF) which represent the spine of the cluster and act as the backplane. The “brains” of the system are running on redundant on-premises COTS x86 servers or as containers in a cloud-native fashion which execute all the sophisticated route computation algorithms and performs management of the whole cluster. The external ethernet switches provide distributed communications channels between all 3 described components. This routing system can be implemented across multiple physical racks with proximity at a headend or data center, thus making it portable and having the flexibility to overcome any potential space or rack issues.

Packet forwarders perform strictly forwarding functions and do not store protocol state information which allow them to support line-rate forwarding across all ports without any limitation. Fabric forwarders are responsible for interconnecting all PFs in a full mesh and transporting cells between them. The interconnections between the PFs and FFs are not IP based but rather leverage proprietary cell-based technology from multiple merchant silicon manufacturers to achieve optimal redistribution of traffic across fabric links.

Figure 4 demonstrates an example of how PFs can be interconnected to FFs in 3-stage non-blocking Clos topology. The S/L based architecture has helped the web-scale companies to efficiently grow their infrastructure to a massive scale that can deal with many technical challenges they have faced before. There is an ability to scale vertically by adding more FFs or spines to increase the fabric throughput and redundancy, while also allowing to scale horizontally by adding more PFs or linecards to accommodate port demands and future growth.

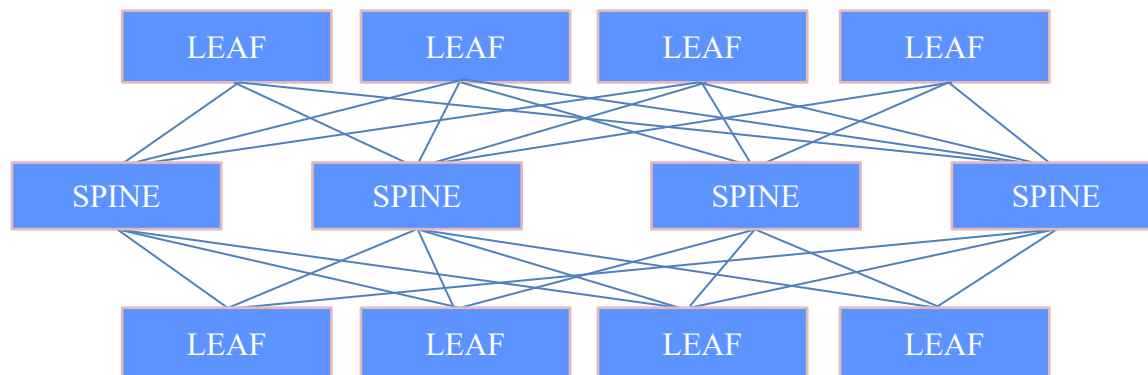

Figure 4 - 3-stage non-blocking Clos topology

However, the Spine & Leaf architecture by itself has multiple drawbacks when trying to apply it to the carrier grade networks. We will provide a detailed comparison of these 2 architectural approaches in an upcoming section.

The combination of the Spine & Leaf based architecture and disaggregation can lead to phenomenal advantages such as disjointed innovation paths between data plane and control plane. As control plane is completely decoupled from the data plane, the innovation of these 2 components can happen independently. For example, with the evolution of the ecosystem ISPs/CSPs can easily change Routing Network Operating System vendors according to their current needs while using the same hardware or even combining hardware from different Original Design Manufacturers (ODM). In recent years, merchant silicon manufacturers have developed products that are on par with custom silicon developed by Original Equipment Manufacturers (OEM). Disaggregation enables operators to purchase simplified hardware based on merchant silicon resulting in significant cost savings as compared to traditional modular chassis routers. Now, ISP/CSP's do not have to be bound to a specific router vendor's hardware/software roadmap and can freely mix and match different whitebox server hardware with custom vendor software applications/containers.

Multiple modern network operating systems (NOSs) are based on Linux, however, most of them use a custom-built command-line interface which means they don't have a look and feel of Linux. However, since operating system components are running as services in containers, engineers should learn how to deploy container management software to create, deploy, and scale and them.

This combination also promotes more open-source configurations and concepts where different API's can "hook" into this custom routing platform. Some NOS's even make the whole disaggregated cluster made up of different components seem like a "virtual" chassis, providing the best of both worlds [\[9\]](#).

These options allow potential for seamless integration into the existing network while maintaining small failure domains or a blast radius. While N+1 redundancy gives you an extra component, node, or link to failover to, N+M design provides a whole node or cluster redundancy giving a whole other level failover capability. This allows hitless maintenances and updates. Now, it is possible to direct traffic away from a segment of spines and leaves and upgrade the software or configurations while having traffic run across the rest of the S/L cluster. This reduces the failover impact of traffic and does not put such a hazardous condition strain on the system, like it used to with a single chassis system. This S/L design makes an In-Service Software Upgrade (ISSU) more reliable than in single chassis routers. This allows any time maintenance, even daytime since it will be Non-Service Affecting. Now, a single failure of a component doesn't impact traffic in multiple directions and reduces the impact to services.

2.3. Processes and skills needed

2.3.1. Skills

It is no secret that to keep up with innovation, engineers and technologists must set out for a lifelong learning and development journey. Having the right skills has always been important in IT, especially if you want to stand out in the industry. This is certainly going to become even more critical as the pace of change and innovation continues to accelerate. Technical experts will come to find that the technology they have come to know on such a deep level is constantly evolving. Carrier-grade networks are highly dependent on the expertise of network professionals

who build, operate, and maintain them. The skillset of these engineers had been evolving for a while and now with the proliferation of new innovative disaggregated network solutions there is a new set of skills and capabilities which they must master. They now need more DevOps, programmability, and scripting skills to leverage automation tools because the newer open software is more API/GNMI/Model driven. There is a trend and requirement by management to move away from traditional CLI network device management, where you have the chance of repetitive human error. Based on the “Annual outage analysis 2021” report by Uptime Institute an aggregated year-on-year average of 63% of failures are due to human error [\[32\]](#). Network engineers now need to blend their skill sets and learn and utilize server sysadmin skills to make them future-prone, ready, and stay marketable in the job market.

2.3.1.1. *Microservices*

Traditional architecture has been a classic software design pattern since the origins of the industry in which the user interface and the source code are combined into a single program. Though in the past this was convenient to have the networking vendor be responsible for any software issues, there are many drawbacks to this approach such as complexity of the code, scale limitations, reliability among many others. A software code bug may affect both the SW and HW, but when decoupling the two and disaggregating them, there is now a clear demarcation point for the hardware components versus the software. The industry is moving towards the microservices architectural style for developing applications. Figure 5 provides an illustrative example of these two approaches.

Microservices allow a relatively large application to be divided into smaller parts, having their own autonomy and realm of responsibility. With microservices in containers, it's simpler to take advantage of hardware and easily orchestrate services, including networking. Network engineers and architects should learn how to operate and maintain the container orchestration platforms like Kubernetes and Docker because many NOSs designed for disaggregated networks are based on the cloud-native, distributed architecture. Cloud Native Computing Foundation (CNCF), which is the vendor-neutral hub of cloud native computing, states that microservices and containers form the foundation for the cloud-native application development [\[10\]](#). Therefore, it is paramount for network professionals to develop their Linux skills and System/Server Admin skills so they can easily operate on both sides of the domain.

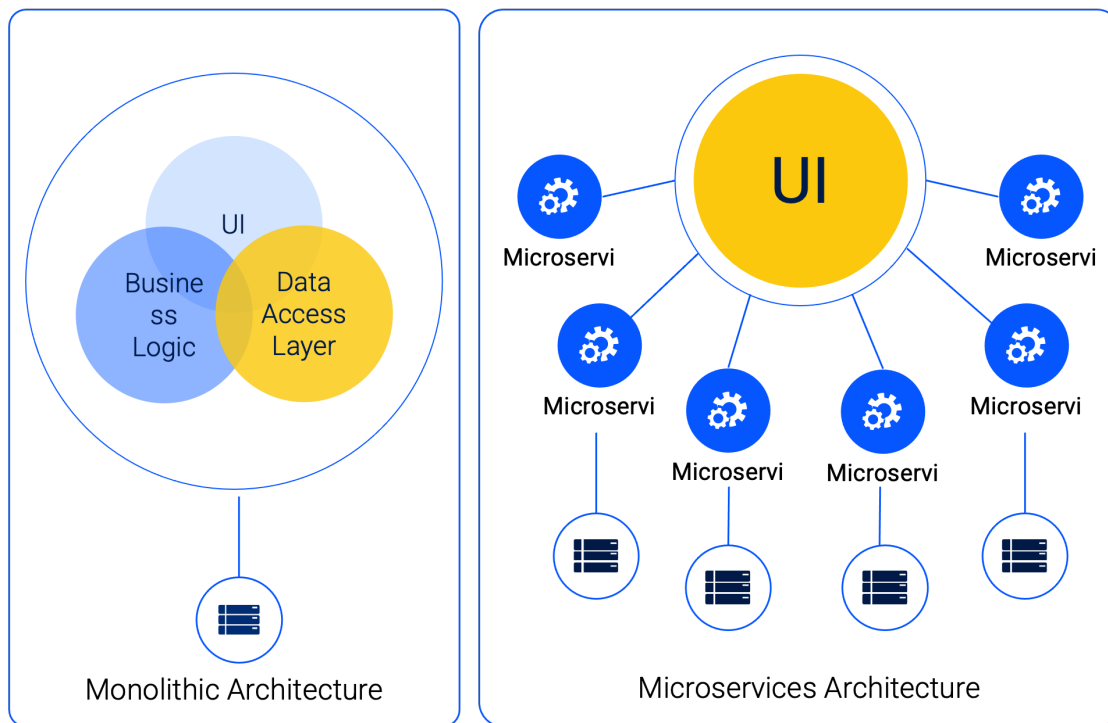

Figure 5 - Traditional versus Microservices Architecture

2.3.1.2. Linux

Refer to Figure 6 for the high-level view of Linux containers. Open organizations like OCP are actively developing and deploying new Linux distributions that are specifically targeted and tailored for network equipment [\[11\]](#). Many vendors in the ecosystem have already started offering NOSs based on these distributions. Network engineers and architects are expected to understand and implement the fundamentals like navigation in the filesystem from the shell, which is the server CLI interface, manipulation of files and directories, running programs and working with background services, also known as daemons. On top of that, engineers must learn how to manipulate network interfaces, how to view and manage routing on a Linux system because interface and routing configuration go together. Also, due to the openness of the hardware, a huge number of logs and event traces are available which can be viewed “under the hood” via the Linux shell. To be able to troubleshoot and analyze the sequence of events or even take the packet captures of control and data plane traffic, an engineer must be familiar with text editors which offer the tools to sift through large amounts of data and even observe events in real-time. Additionally, many of the tools that we will discuss in the future section have their origins in Linux and require to be run from the Linux system.

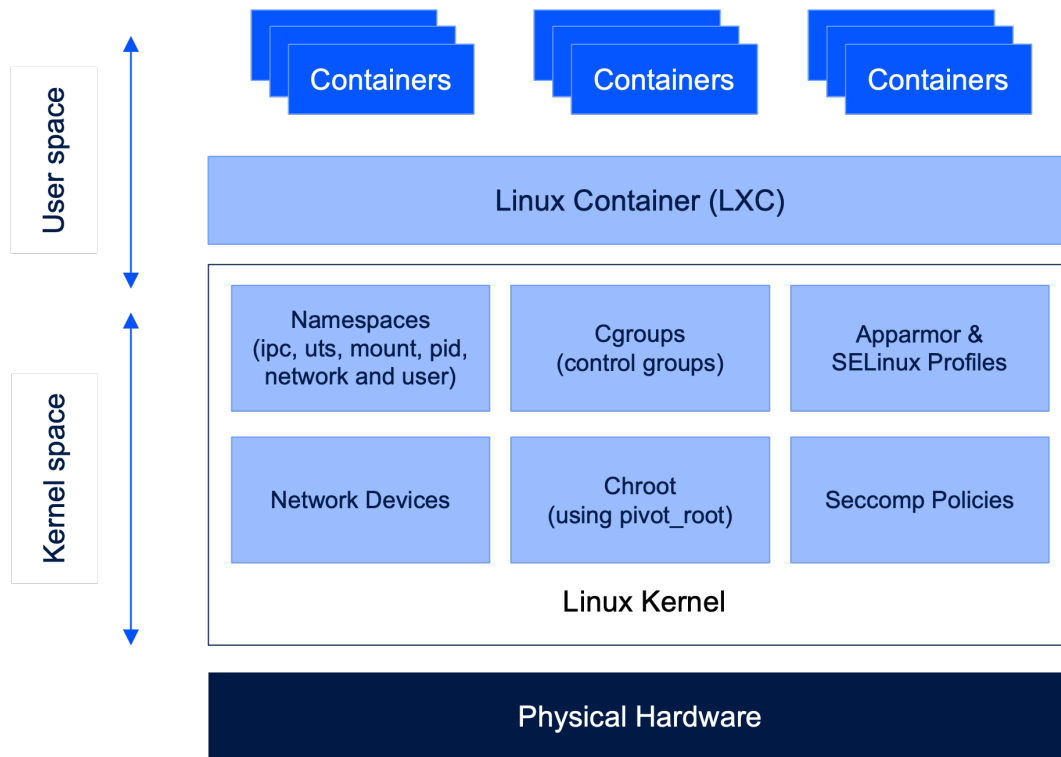

Figure 6 - High-level view of Linux Containers

2.3.1.3. Data Formats and Models

Protocols like BGP, OSPF, ISIS, and TCP/IP were created out of need for devices on the network to have a single language to communicate across a globally distributed system – the Internet! The data formats were conceived for a similar reason – for computer systems to freely understand each other.

With the significant increase of the quantity of network devices and the proliferation of the Internet of Things (IoT) it became apparent that it is beyond the bounds of possibility for humans to manage them [\[12\]](#). The solution here is to automate configuration management and maintenance as much as possible and streamline the deployment of new services. Engineers should get familiar with network automation tools and methodologies as many modern NOSs expose programmatic interfaces that offer an API. Traditionally, each network device is closed (locked from installing third-party software, as an example) and only has a command-line interface (CLI). Although the CLI is still a well-known and even preferred method of access to the router by network professionals, it does not offer the flexibility required to truly manage and operate this brave new Internet.

Imagine operating a disaggregated cluster comprised of fifty or so components or nodes. Each node may need its own Loopback IP for management and its own configuration file. In the past with traditional routers, the network engineer had to create the fifty separate config files and load them onto each component in the cluster. This also opens the system up to human error and the configuration files can be prone to typos and errors. Pushing configurations and updates to

multiple nodes in a S/L system might result in unexpected errors, takes a lot of time to prepare configurations or writing scripts to automate the process. One way to easily automate it is to set up a central system and network platform or orchestrator. This system can now treat all the nodes like a virtual cluster, where the Orchestrator pushes the software and configurations to all the components of the cluster. This buys the best of both worlds where there are benefits of a traditional system with the flexibility of S/L. Thusly, automation becomes key and “table-stakes” to implement any type of disaggregation.

One of the most optimal ways to push and retrieve the configuration from the devices is via the HTTP-based APIs like RESTful and non-RESTful APIs [13]. Another one is NETCONF [14] which is a network management protocol conceived specifically for configuration management and retrieving operational state data. In order to leverage these tools, professionals need to understand the data formats like XML and JSON [15, 16], YAML [17] and data modeling language YANG [18]. Refer to the Figure 7 for the overview of these tools.

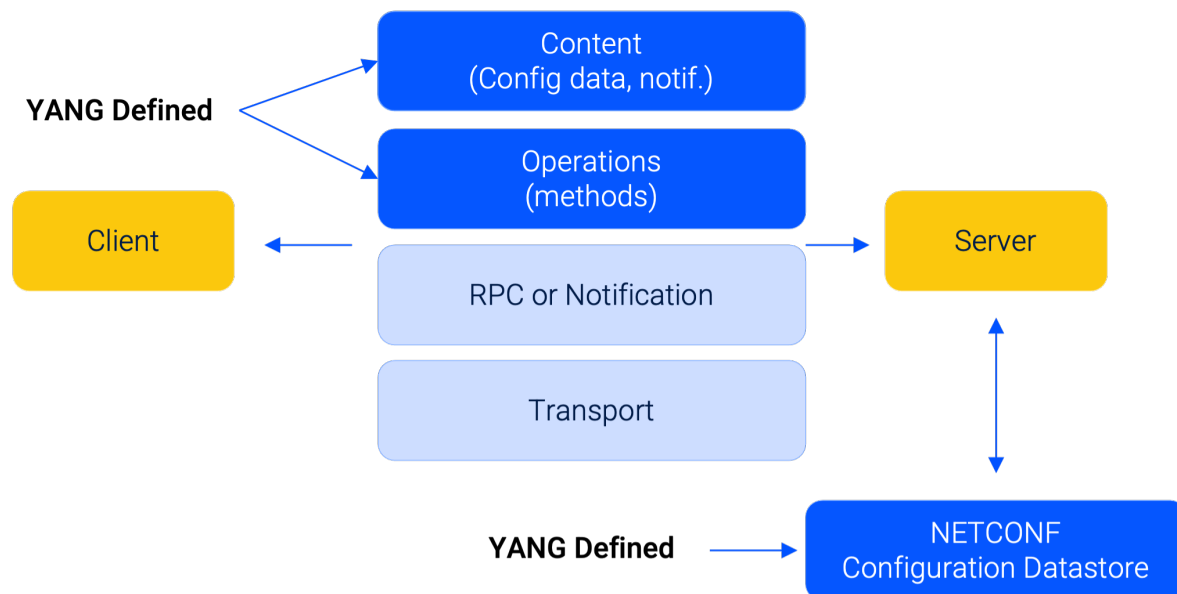

Figure 7 - Overview of YANG and NETCONF

2.3.2. Processes

The processes to deploy and maintain the disaggregated solutions are simplified due to multiple factors like less planning efforts and faster installation time.

2.3.2.1. Less planning efforts

IP network planning can be quite complicated and take months. The planning time is heavily influenced and considers the number of components, service requirements, capacity forecasting, site constraints, and more. While traditional chassis solutions are limited in their abilities to simplify the overall process, disaggregated distributed solutions offer one design process and ease of expansion by relying on only two standard data plane building blocks: Packet Forwarders and Fabric Forwarders, as compared to five to ten integrated router solutions with multiple line

card models which must be compatible with fabric modules and different software revisions for different features on a line card.

2.3.2.2. *Installation Time Considerations*

In this high-paced, modern era of networking, field installations and maintenance are some of the most comprehensive and costly operational activities. They include the engagement of multiple teams, materials, and dedicated planning to adapt to each physical location's constraints like space, power, and cooling. In the disaggregated model, installation process is identical across all node sizes, eliminating the need to constantly train staff and avoid costly installation errors. This cookie-cutter method of installation can be used for the deployments across all fields of use in the network (peering exchanges, cloud exchanges, edge cloud etc.). However, there is a lot of backend fabric fiber and ethernet connections (fondly referred to as "spaghetti-wiring") since it looks like strands of spaghetti that must be installed to connect the nodes as a cluster as opposed to simply sliding in a linecard in traditional chassis case where only the service ports must be connected as the fabric is hidden in the backplane.

There is a lot of up-front cost and effort in a DDC/DDBR architecture in performing the physical install work initially to obtain a longer roadmap, but the benefit is savings in port migration to the new chassis. When forecasting growth and installing with the mindset of room to grow, this eliminates the need to come back and install any additional fabric forwarders and disrupt the system later. Also, unlike scale up in a single chassis router, when the system grows beyond its size, all the client ports ought to be replumbed to another chassis whereas in a disaggregated model scale out consists of only adding another PF or two. This positions the network to consider any un-forecasted growth surges, such as the one a lot of networks experienced during the COVID 19 pandemic. This follows the "set it and forget it" ideals.

3. Operational Considerations and Challenges

DDC/DDBR is an optimal solution that overcomes the most relevant challenges that ISPs/CSPs are facing today when deploying and scaling their IP backbone/aggregation networks. The role of these networks is to route the mobile, voice, broadband & commercial traffic between different network segments at a national and regional level while providing connectivity with external networks such as other service and cloud providers, content data networks, Internet exchange peers and IP transit providers.

The IP backbone networks must regularly scale to support the internet traffic growth, to improve resiliency and reliability, and to meet the expectations of mission-critical types of communications. The essential objective is to lower the cost per bit and improve the overall customer experience and satisfaction.

In the following sections, we will dig deep into the key challenges that exist in the IP backbone networking space, how DDC/DDBR architecture can help in overcoming them, and comprehensive comparison of DDC/DDBR and Spine-Leaf architecture.

3.1. Challenges with traditional router architectures

3.1.1. Supply chain concerns

Akin to all sectors of the telco and cableco networks (Transport, Core, Aggregation, Access), the continuous mergers and acquisitions in the core routers market have resulted in the following limitations, no less important of which is a lack of diversity:

- Notable reliance on a very limited number of suppliers.
- Market which is extremely difficult to enter and compete in leading to an ever-increasing risk from soaring costs.
- Insubstantial innovation and time-to-market speed.
- Unsatisfactory interoperability across different hardware components. For instance, line cards and fabric modules compatibility issues.

3.1.2. Traditional nature of the components

Historically the cablecos have been deploying traditional IP backbone/aggregation routers which are based on proprietary components as demonstrated in Figure-8:

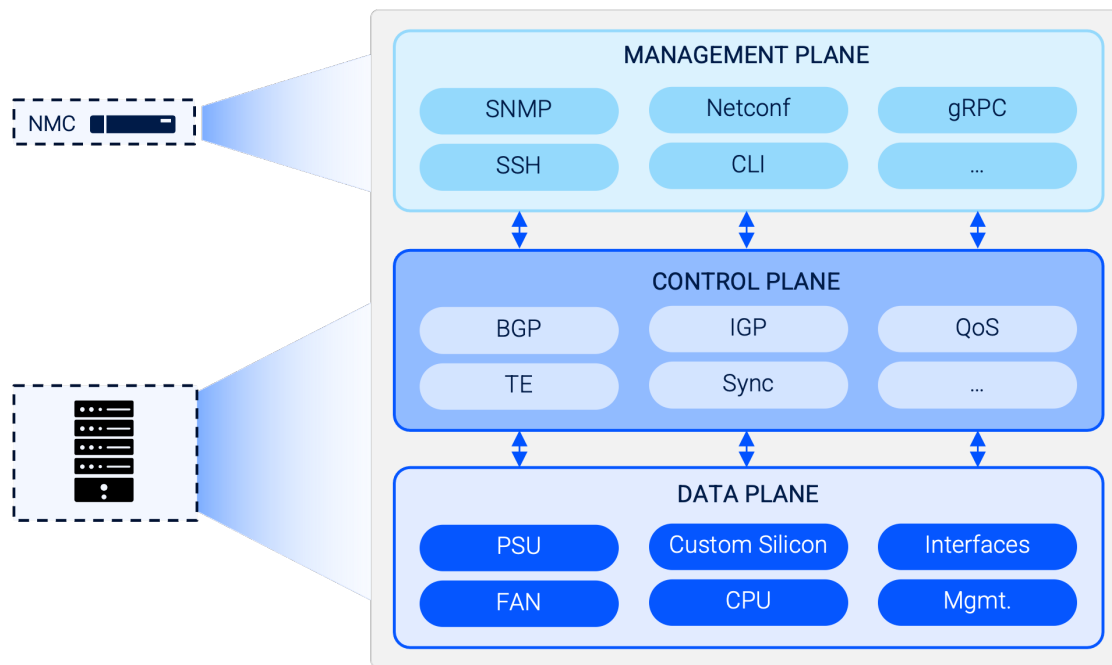

Figure 8 - Traditional Routers

The data plane hardware which contains line-cards is where custom silicon chips are implemented to manipulate the packet processing, traffic management and forwarding. Multiple line cards serve different purposes and have differing applications depending on the place in the network which introduces additional operational complexity and overhead. For example, there

are availability concerns when replacing or upgrading a line card inside the chassis. In the live production environment, an issue with a fabric module or a line card can have an adverse impact on the whole system rather than being limited only to that component consequently increasing the blast radius.

The disaggregated model has a cloud-like pay-as-you grow approach where fixed form-factor PF whitebox servers can be purchased as needed from multiple ODMs for a significantly lower price. Packet forwarders enable operators to utilize any port on the whitebox for any service regardless of the implementation area. This adds tremendous flexibility to enable multiple services and reduce their time to market. The ports on these whiteboxes come with variable native interface speeds which can be reconfigured to operate at different speeds. For example, native 400GE port can be reconfigured to be utilized as 100GE port or can be broken down into 4x100GE via a breakout cable. For the access use case, 100GE can equivalently be adjusted to operate at 10GE speed or, also, broken down into 4x10GE or 4x25GE ports. This allows for gradual growth into the port step functions depending on your deployment budget.

A custom NOS which is specifically designed to efficiently run only on the custom hardware and is comprised of proprietary code and licensing runs the control plane. That includes the drivers which are in control of the hardware components like power, cooling, etc. The firmware is responsible for loading the NOS image when the router boots up including the networking software stack.

In the disaggregated model, multiple NOS vendors in the ecosystem can install their software onto the open networking hardware. The Open Network Install Environment (ONIE) [\[19\]](#) is an open-source initiative that defines an open “install environment”. Before the invention of ONIE, routing equipment was procured with pre-installed NOSs, essentially creating networking devices that locked operators with vendors whose supply chain is integrated and owned completely by them. ONIE runs in the management subsystem of the whiteboxes utilizing capabilities in a Linux kernel. This allows ISPs/CSPs to install target NOS as part of the provisioning process, in the same way the COTS servers are provisioned.

The third component is the management plane, which takes care of the overall platform management: for instance, the interfaces configuration, services provisioning, inventory management, alarm reporting, fault handling, and performance monitoring, all which is tightly coupled with control and data plane; thereby introducing a single point of failure.

This traditional architecture has met the essential needs of operators (capacity, availability, etc.) and has served them for an extended time. Nonetheless, it has impeded them from unleashing the true potential of open networking and has significantly decelerated the innovation in the backbone/aggregation networks.

For instance, having the data and control plane so closely tied together leads to a significant and uncomfortable dependency on the incumbent vendor’s roadmap and prevented them to benefit from features available in a 3rd party NOS supplier. Operators are dependent on the vendor to deliver the HW or SW roadmap on time to upgrade the environment for addressing the growth pressure. The below graph depicts this port growth need versus availability.

Figure 9 - Non-linear growth of ports [4]

Even though multiple software companies have offered powerful Network Management Systems (NMS) and software controllers to manage the traditional routers' management plane, ISPs/CSPs are still exposed to various challenges. One of the major one is the complicated and high integration cost to manage third party products via their existing homegrown NMS. Even though the promising NETCONF protocol is capable to address them, there is a colossal amount of work yet to be done to come up with a vendor-neutral data model for network and device configuration.

3.1.3. Chassis limitations

The current backbone routers are primarily designed based on a chassis structure with front access where the user network interfaces (UNI), network-to-network interfaces (NNI) and the control boards are interconnected into a backplane.

Based on the crucial role of these routers in the network and the huge volume of traffic they pass through, they were required to offer:

- Resiliency to maintain uninterrupted connectivity to the mobile, broadband, and business customers.
- Significant computing and storage capability to store IPv4 and IPv6 global routing tables.
- Port density and capacity enough to support the growth of the customers and services.

Therefore, the chassis had to be equipped with:

- High availability at all levels: control processing, switching fabric, cooling, and power.
- Large TCAM (Ternary Content Addressable Memory), strong computing capability, deep buffers.
- Variety of sophisticated control plane features which includes NSR (Non-Stop-Routing) & ISSU (In-Service Software Upgrade).
- Large port density, number of slots for line cards and backplane switching capacity.

The above requirements have resulted in a platform of considerable size with high cost and huge power consumption, and which necessitates an upfront capital allocation without a guarantee of a reasonable return. This system takes a lot of space and demands a lot of advanced cooling system deployments to ensure adequate operating thermal levels in datacenters and head ends and lacks a capability to adequately grow based on the current capacity needs.

Additionally, due to the limited number of slots in the chassis, running out of ports may turn out to be quite disruptive to an ISPs/CSPs' operational model. This could lead to having to purchase an entirely new chassis resulting in an unnecessarily complex network topology, possible suboptimal traffic flows and a non-linear cost per port model as depicted in Figure-9. This chassis upgrade process is not even remotely agile to empower service providers with a capability to react to unplanned upgrade requests in a timely manner, which results in missing the opportunity to gain more market share by increasing the customer base. This chassis upgrade becomes akin to forklifting the chassis out from the rack and performing “open-heart surgery” to rip-and-replace with an upgraded traditional chassis.

Furthermore, all the NNI & UNI interfaces are centralized on one chassis which creates undesirable operational risks of losing the entire node in the event of a software failure, power issue, executing the Method of Procedure (MoP) document in the wrong order etc. Since telcos and cablecos are dependent on a single chassis in the core of their network, they have the potential to isolate services in case the redundant site goes down increasing the blast radius once again. Even an un-expected fiber cut or an environmental issue that no one has control over can blackhole all services in the network.

3.1.4. Openness and ease of upgrades

According to Yole Développement's “Optical Transceivers for Datacom & Telecom Market 2021” report [\[20\]](#), the optical transceiver market will highly likely grow 14 percent in the next 5 years. This growth is driven by the need of the operators to utilize high data rate modules above 100G.

With the industry trends in the optical pluggable transceivers and the dawn of 400G and 800G QSFP-DD (Quad Small Form Factor Pluggable-Double Density) optics, the ISPs/CSPs need to replace the existing hardware with higher capacity, more compact proportions, elastic thermal management ports which facilitate supporting higher capacity links with advantageous port density per rack unit.

Notably, the 10G/25G/40G user network interfaces need to be upgraded to 100G or even to 400G, and the 100G network to network interfaces or fabric interfaces to 400G and 800G. This means line cards or entire chassis replacement needs to happen to take advantage of the new interfaces and benefit the most from the interface's capacity through the backplane.

To that end, the disaggregated networking approach gives telcos and cablecos an upper hand when replacing or upgrading the installed base to protect their investment in IP backbone/aggregation networks, as the components are based on open hardware. There is no need to use specialized proprietary optics between packet and fabric forwarders because of cell-based packets, keeping with the open-standard theme.

3.2. Comparison of DDC/DDBR and Spine-Leaf architectures

A 3-stage Clos network is the smallest version of a Clos network, and it is relevant to modern scalable carrier and hyperscalers' networks. As its name implies, this network has 3 stages: ingress, middle and egress. Figure-4 from the earlier chapter gives a high-level view of that architecture.

A Spine and Leaf architecture is a derivative from the 3-stage Clos network. Occasionally, it is referred to as a "Folded 3-stage Clos Network", where the ingress and egress points are folded back on top of each other [\[22\]](#) as shown below in Figure-10:

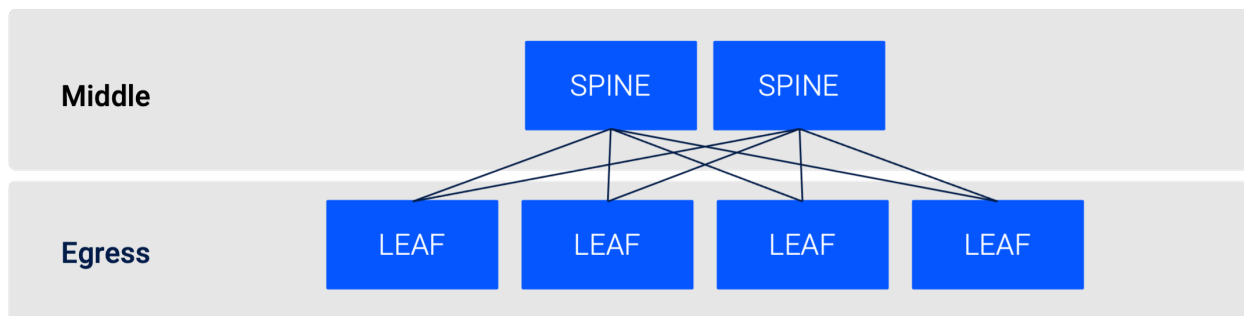

Figure 10 - Folded 3-stage Clos network (also known as Spine-Leaf)

Let's dive into a detailed comparison of DDC/DDBR architecture and Spine/Leaf:

- Over-subscription of Leaf to Spine links in S/L versus equal or over-provisioned fabric to leaf ports bandwidth in the disaggregated solution:

In the S/L architecture oversubscription of links is a common occurrence causing a lot of operational overhead in cases when more bandwidth is needed.

When oversubscription of links ensues (meaning, if there is more traffic on the ingress than the egress on the active link at one time), the procedure for enlarging capacity is complicated. A whole new spine switch or router must be added, and uplinks need to be expanded to every leaf switch thereby adding more cable density within and between the racks. In instances

where device port capacity reaches its limit, a totally new leaf switch/router must be added accruing to the operational complexity introduced by the addition of a spine.

In the disaggregated model on the other hand, clusters are built in a way where bandwidth is equal or over-provisioned to leaf ports [23]. Below is the table with variable cluster sizes ranging from a standalone whitebox with 4Tb capacity up to the large cluster with 192Tb throughput:

Table 1 - DDC/DDBR cluster sizes

	Standalone	Small Cluster	Medium Cluster	Large Cluster
Max Capacity	4Tb	16Tb	96Tb	192Tb
	40x100G	160x100G	960x100G	1920x100G
Port Density	10x400G	40x400G	240x400G	480x400G
	80x10G/25G	320x10G/25G	1920x10G/25G	3840x10G/25G
Packet Forwarder White box	1	4	24	48
Fabric White box	-	2	7	13

- Elephant flows:

In a large Clos network, a typical approach for using the built-in multipath on NNI links is to utilize reliable Layer 3 routing, including on the leaves. Point-to-point links between the spines and leaves are in a specifically allocated subnet and common Equal Cost Multipath (ECMP) routing can be implemented to distribute traffic equally over them. This leads to maintaining large numbers of subnet routes in the tables of the nodes in the topology which results in a requirement to purchase expensive custom hardware with large enough ternary content-addressable memory (TCAM). Although, this architecture is designed using Layer 3 routing, ECMP and provides distinguished bandwidth and latency performance, the preeminent complication here is insensitivity to the workload. Carrier network traffic tends to feature a mix of latency sensitive “mice” flows, and bandwidth intensive longer-lived flows, also known as “elephants”, for which throughput is of higher priority than latency and which constitute only 10% of flows, while accounting for nearly 80% of traffic.

Mice flows are very bursty and short lived, however, elephant flows tend to “pile up” on certain paths even though others are available and ready to be used, filling network buffers, creating congestion events and suppressing mice flows on these links.

This leads to a detrimental degradation of application performance such as online gaming, web requests, multimedia broadcasting and VoIP which are of a particular importance for cable operators who continuously strive to improve quality of experience for their customers [24].

In the DDC/DDBR solution, the NNI links do not rely on ECMP or any sort of Layer 3 routing rather taking advantage of the capabilities enabled by merchant silicon for redistributing traffic equally with remarkable precision.

- Variable sized ethernet frames versus cell-based fabric traffic:

In the Spine-Leaf network architecture packets that are passing through fabric links (NNI links) are of variable size.

Packets transiting the fabric in the DDC/DDBR architecture are proprietary formatted fixed sized cells [\[23\]](#). Thus, monitoring systems must account for differences in the way the payload is transmitted.

- Spreading of traffic over fabric ports:

In the Spine-Leaf network architecture the traffic is spread over disparate NNIs via ECMP and the routing protocols' logic, and the processing occurs in the control-plane by the NOS where the routes are programmed in the tables of the forwarding ASIC.

In the disaggregated solution, cell-based traffic is used on fabric ports and the spreading logic is being executed at the microcode level of the forwarding ASIC and is completely transparent to the NOS. Fairly sophisticated credits/tokens mechanism is involved in the implementation of this feature [\[5, 23\]](#).

- Managing a folded Clos topology of N-independently functioning elements versus all elements are under control of a single NOS:

In the DC Leaf-Spine design, each node ordinarily runs a NOS that is independent. In this case, forwarding decisions are made individually on each node which lack a global view of the network, so the best path computation algorithms are at best locally optimized.

In the DDC-RS, the Packet and Fabric Forwarders function under the oversight of a single NOS. The virtual router needs only a single network management interface and is considered as one big virtual chassis. Subsystems of the operating system can be distributed to the elements of the cluster but the "Brains" of it are centralized on the powerful compute nodes. This also makes monitoring and onboarding automation frameworks easier.

From this point of view, multiple routing algorithms are optimized through a single routing system, The traffic is just traversing through one router – from one port to another port on a separate Packet Forwarder from the end-to-end network perspective [\[5\]](#).

- Easier upgrade process:

Software and firmware upgrades usually take more time and require multiple maintenance windows in the S/L case.

Due to multiple independent components, each of them must be upgraded separately. In many cases, not all traffic can be migrated away from the pod which introduces a need to move traffic away from certain leaves and spines within it to proceed with the upgrade which negatively contributes to the already complex process.

Due to a single point of management, disaggregated backbone/aggregation router upgrades have the potential to upgrade either some or all the elements of the cluster within one maintenance window considerably reducing the operational overhead and the amount of scheduled maintenance windows. This gives the user the flexibility of shifting traffic off the cluster, where in the past with traditional routers or in the S/L network upgrading sets of spines and leaves left the potential to be exposed to being in a hazardous condition.

Furthermore, in the traditional S/L model convergence of the IGP takes more time before the traffic is soaked out of nodes but there is a minimal negative impact on Quality of Experience (QoE) for customers. However, in the DDC/DDBR case due to this being a single virtual chassis traffic can be diverted immediately and converges instantaneously.

There is of course a tradeoff between a graceful traffic soak from S/L with minimal negative impact on the customer Quality of Experience which can take more time and leave the system exposed, whereas in the yank and replace method the protocol must fail the traffic over and traffic reconverges more abruptly but is quicker. There is a certain impact on the customer's QoE in either method.

4. Orchestration, Automation and Analytics

Despite bringing meaningful scale and cost advantages to the table, this new disaggregated network operational model might potentially be considered a risk. This approach has emerged recently in the industry and service providers are weighing the extra complexity related to the orchestration, automation, and management of this open model, specifically in the areas of field installation, upgrades, capacity growth, and troubleshooting.

Cloud orchestration is a solution that is required to deliver the operational simplicity, automation, and visibility to the DDC/DDBR architecture to drive the acceleration of the deployment of this cloud-native networking solution. It should offer detailed visibility into the system's internal architecture including hardware and software components, KPIs related to SLA, alarm, and fault management.

4.1. Automated Operations

This encompasses the lifecycle management of resources and services – from provisioning to decommissioning, which includes:

Zero-touch provisioning (ZTP) – automatically integrates multi-vendor white box hardware and NOS into a working routing platform supporting a secure deployment prone to less errors with limited manual intervention. Ahead of entering the protected and controlled operator network's environment, white boxes go through an extra security measure which is the bootstrap process to ensure system integrity.

Hardware inventory management – grants detailed data on every element within the cluster, including location, model, serial number, firmware version etc. This becomes even more so critical as the cluster scales out and the inventory management gets too complicated to manage manually.

Modular software orchestration – covers the entire stack and can be done selectively per specific software component, counting firmware, base OS, NOS image/container. This capability becomes extremely handy because upgrades can be initiated per component without affecting the overall software stack reducing the risk of failure in cases when the whole cluster is upgraded. Another advantage is the real-time orchestration status which helps engineers to monitor the activity and potentially prevent issues before they occur. Software rollback can also be easily performed in cases when the upgrade was unsuccessful.

4.2. Health Monitoring and Assurance

The orchestration tool automates event and KPI monitoring and ensures availability and performance SLAs such as:

Cluster topology – live view of the cluster's nodes, their states, formation and connectivity across clusters and the entire network, including:

- Hardware components: CPU, memory, PSU, fan, temperature, ports, and interfaces.
- Software components: base OS, firmware, processes, containers, and microservices.

Fault, performance, and alarm management: on top of 3rd party applications that collect data for events management, the cloud orchestration system can provide all these details for the clusters under its management:

- Supports alarms and KPIs at every level of the system – from hardware components to software containers.
- Alarm dashboard to monitor and categorize system alarms.
- Real-time and time-series alarm view.

Tech support integration for in-depth system diagnosis and debugging: being able to retrieve tech-support files when there is a potential software or hardware bug is paramount for network operations teams. The orchestration tool should allow a simple way to retrieve such a bulky file from the clusters for analysis by the NOS and hardware vendors.

4.3. Telemetry

Historically, SNMP has been the de-facto protocol for data collection, however, it may not be suitable for the management of truly large networks because of the performance limitations of polling.

gRPC is Google's project for Remote Procedure Calls between applications. gRPC based telemetry streaming allows to export performance monitor counters and operational-state parameters in a flexible and scalable way which will help operators tremendously as the number of devices in their networks grows exponentially [25]. Unlike traditional performance monitoring (PM) collection methods such as SNMP walk, gRPC based telemetry uses push method for delivering PM data from router to the PM collector. Such an approach gives the following advantages:

- PM Collector does not need to poll each router individually.
- PM Collector can define different set of counters for collection from specific routers.
- Push parameters can be configured to each pushed counter specifically (e.g., sample rate, telemetry packet DSCP value etc.).
- gRPC interface when combined with Protobuf encoding is more efficient in terms of network channel utilization than SNMP and other interfaces such as NetConf and RestConf.

5. Real-life deployment of the DDC/DDBR model

DDC/DDBR architecture is a field-proven concept deployed in the core and aggregation layer of the largest telcos and cablecos in the world [\[26\]](#).

The implementation started with the channel partners wiping the received whiteboxes and installing the ONIE and BaseOS on top of it in preparation for the NOS integration. After this step had been completed, all the elements were shipped to the respective data centers for the site installation and wiring.

Once the cabling was finalized and all elements within the cluster powered up, the route controllers were discovered by the orchestration system which initiated the cluster creation via the Zero-Touch Provisioning process. At this point, the cluster is ready for the enablement of the control plane and for passing traffic.

There are several tools and dashboards needed to monitor production grade Clos networks including the need to monitor the load sharing over ECMP paths, scale of the databases in the IGP domain due to the large number of nodes. On the other hand, with a virtual cluster:

- It became easier for the NOC team to manage the network and respond accordingly to the events within the system.
 - For example, the load sharing on fabric links is astonishingly equal and does not require any monitoring because it is done at the microcode level, as we have mentioned earlier.
- No IGP or any other routing protocol required between the components of the cluster as is needed in a S/L system, thus reducing the number of nodes in the IGP domain.
- There is also no need for a multi-level BGP design within the cluster and consequently no requirement for BGP enhancements and features to improve recovery time during convergence.

Now, an abstraction layer is introduced which hides all the complexity of the Clos network and appears as a single router which is so familiar to network engineers. The next figure demonstrates an example of a large national backbone network:

Figure 11 - Large National Backbone Network

Every backbone site either has a traditional router or a spine-leaf cluster. Let's zoom in into one of the sites that hypothetically contains a spine-leaf cluster:

Figure 12 - Spine-Leaf cluster within a Backbone Site

As can be seen from the above figure, there is an ISIS and BGP mesh that must be maintained within the cluster on top of interconnections between different backbone, aggregation, and peer networks. The next image showcases a similar topology but with a virtual chassis:

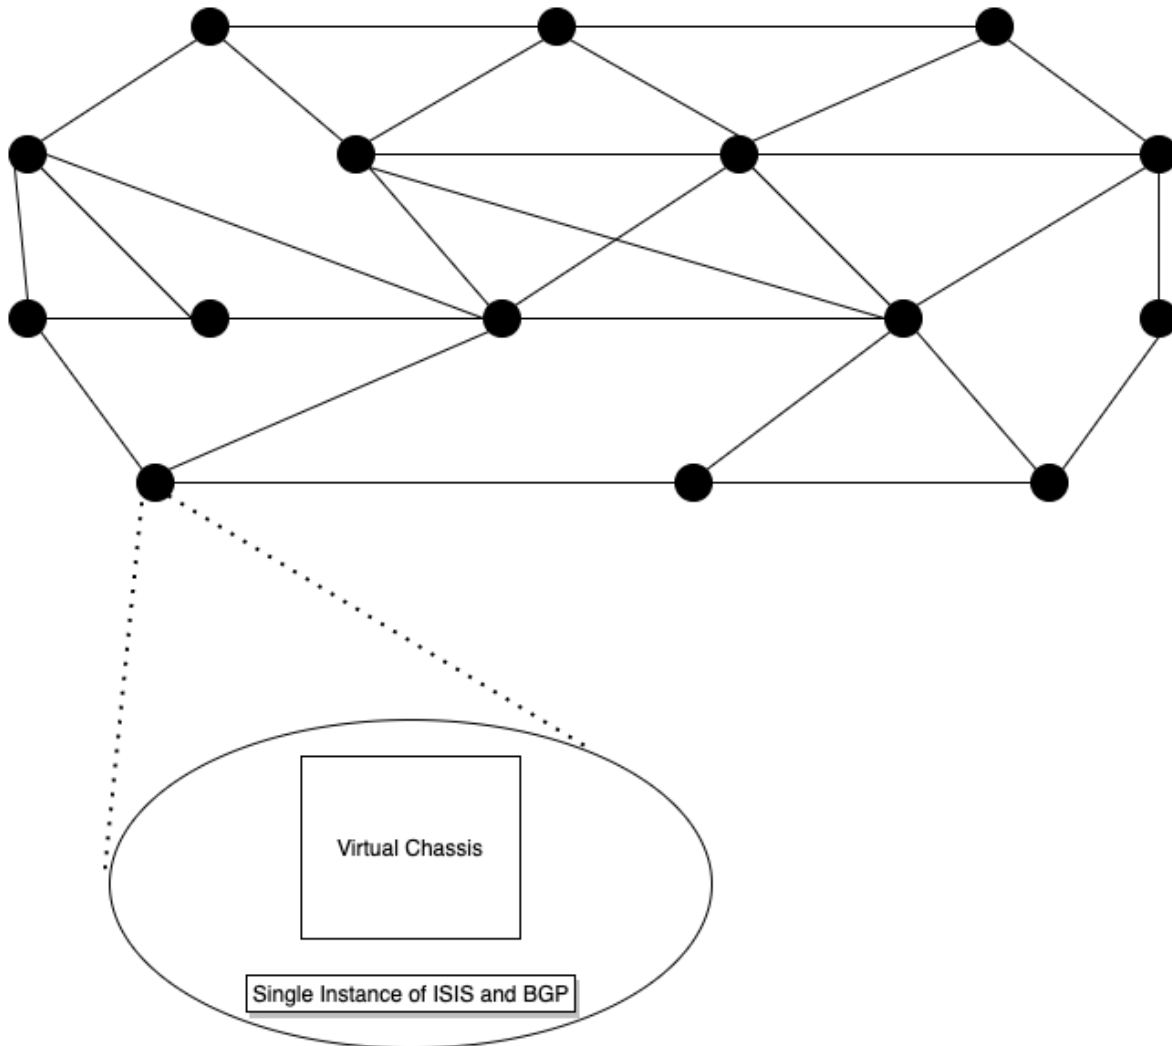

Figure 13 - Virtual Chassis within a Backbone Site

The virtual chassis depicted in Figure-13 eliminates the requirement for intra-cluster control-plane. Now, network architects can focus on mission critical services rather than assuring the SLAs within the cluster.

Any future launches of a virtual chassis in the network will be done by the orchestration system which supports comprehensive validation methods of spaghetti-wiring fabric cabling, management of the code upgrades and device configurations. Another important activity of the engineering and operations teams is auditing the provisioned components count against the actual operational count so that N+M redundancy can be maintained which is already incorporated into the orchestration system alleviating the need for engineers to do it manually.

With a disaggregated approach comes a challenge of the identification of the responsibility domain: hardware and software. Since there are 2 vendors delivering these components, occurrence of the issues requires an understanding of which domain it belongs to, to deliver necessary tech-support files and logs to the respective TAC. There is a need for cooperative collaboration between HW and SW vendors during troubleshooting of such systems so that the root cause of an issue can be reached quickly and amicably.

6. The future of the disaggregated solutions

In the words of the ancient Greek philosopher Heraclitus, “The only constant in life is change”. Nowadays, this most vividly applies to the technology world. The pace of innovation must keep up with the demand and new emerging use cases. Telecommunications companies along with vendors will keep driving innovation in disaggregated network solutions. Essential future developments are multiservice functionality on top of the shared pool of resources, OpenOffload and data center sustainability.

The average number of devices connected to the internet per household and per capita is increasing. Expanding machine-to-machine applications contribute in a major way to device and connection growth and push the expansion of data center infrastructure. With the growth of IoT and “smart” appliances, almost any type of device needs connectivity to the home network. Examples of this are laundry machines, refrigerators, stoves, microwaves, thermostats, garage openers, and even the front door keypad of a home! If one would check the number of devices connected to their home Wi-Fi network, they would be surprised at the number.

One of the promising concepts being developed is utilizing the network as a cloud resource leveraging this model’s High-Availability (HA) capabilities. By applying modern, cloud-based, shared resource methodologies to networks, telcos and cablecos can enhance their network resource utilization by taking advantage of the unified infrastructure that supports multiple network functions as software-based services, such as enterprise, broadband, mobile, firewall, load-balancer etc. [\[27\]](#). Any part of the cluster, designated for a specific function, can be used to enable this service. Sharing the physical infrastructure for various services extensively lowers the physical footprint within data centers and reduces the number of unused ports, resulting in a more efficient employment of compute and networking resources. In the past we had core, edge, and backbone nodes that were separate units. Now they can be aggregated onto a unified cloud-native infrastructure.

Spinning up various network functions is very demanding from the compute resources perspective which calls for original approaches in dealing with processing. There is an initiative in the industry that defines APIs to accelerate network functions and applications by offloading packet processing to the packet forwarders rather than x86 servers which already have their fair share of load. One of the APIs is for applications like Virtual Firewalls and Intrusion Detection Systems called OpenOffload [\[28\]](#), and another one is for functions like VPN Gateways that are designed to offload IPSEC and GENEVE [\[29, 30\]](#) tunnel processing to the hardware. This development will allow ISPs/CSPs to efficiently use the disaggregated clusters by running virtual functions on top without a compromise in throughput.

Network operators are continuously seeking technologies to reduce carbon footprint. One of the sustainable solutions can be found when what was once a sophisticated deployment becomes antiquated for its environment due to the changing conditions on the ground. Decommissioning a disaggregated cluster and re-using its hardware in a developing country where it can be practical for many years to come paves the way for more sustainability. It is the function/capacity separation of the DDC/DDBR architecture that facilitates resiliency in reusing the existing hardware to serve different geographical regions [\[31\]](#).

7. Conclusion

The explosion of the traffic growth over the last two decades has been somewhat unexpected and has urged telecommunications companies to explore alternative routing solutions. The disaggregated approach to the traditional chassis routers has been gaining significant interest from ISPs/CSPs' driven by a variety of motives such as cost reduction, the removal of vendor lock-in and service innovation. Regarding the talent pool, due to the proliferation of the innovative networking solutions, network architects and engineers should master new skills to stay relevant in the industry. Traditional chassis router architectures, having dutifully served for decades, impose multiple challenges like the traditional nature of the components, and the hurdles to overcome upgrade simplicity. DDC/DDBR architecture solves many of the outlined issues while presenting service agility and faster innovation. Spine-Leaf architecture has been deployed in the data centers of hyperscalers and backbone networks of the large telcos and cablecos. Although this approach has multiple drawbacks which are now addressed by the disaggregated solution, this approach is not only valid on paper but there are multiple scalable DDC/DDBR deployments in the backbone and aggregation networks of the largest cable and telecommunications companies in the world. On the automation side, cloud orchestration system is leveraged to streamline cluster management, device configuration and critical files retrieval. In the foreseeable future, development in the network disaggregation domain will focus on multiservice, session offload by leveraging open source OpenOffload API all while trying to remain cognizant of sustainability of the network. It seems as if we are getting closer to a more complete automated, portable, and easily scalable network for the future!

1. Introduction

Cable Operators pursuing Flexible MAC Architecture (FMA) deployments are facing the prospect of a N-fold increase in the number of managed devices in their HFC access networks. The increase is a result of a necessary replacement of integrated CCAPs with Distributed Access Architecture (DAA) components including MAC Managers and Remote MAC Devices (RMDs), where RMDs serve a much smaller service-delivery footprint. Typically, RMDs provide services for just one service group. As part of the DAA transition, N-number of RMDs displace each I-CCAP, a large-scale platform supporting N service groups. The number “N” could reach or exceed 128. This dramatic increase in scale requires a shift towards zero-touch, automated provisioning processes. While FMA specifications already provide tangible solutions for this problem at the interface between the MAC-NE and the MAC Manger, the paper examines the impact of this transition on the provisioning tasks within the operators’ back-office.

Two additional key observations lay the technical foundation for this paper. First, a complete configuration dataset of each RMD is unique in that it includes many configuration attributes that are specific to a particular device and its deployment topology. The examples of such device-specific attributes include power levels configured on the RF components, the geographical location, and the inventory tag. Second, most of the device configuration attributes, including service group configurations, are common across large groups of RMDs.

The paper outlines a framework that capitalizes on abstraction of repeatable patterns from the standardized YANG configuration models of RMDs with creation of configuration templates corresponding to the identified patterns. YANG-based configuration templates coupled with unique device attribute values maintained in a relational database allow automated systems to generate complete device configuration datasets enabling effective management of the configuration lifecycle, including software or service upgrades.

The framework provides benefits to Cable Operators by reducing the overall size of fundamental configuration data and by providing structure better suitable for automation. For example, a Cable Operator deploying thousands of RMDs may be able to reduce the footprint of their fundamental configuration dataset to just a few dozen YANG-based configuration templates and use predictable, automated system to dynamically generate full-formed, operational configuration datasets from these templates. The outcomes are in the form of modular, automated, and streamlined provisioning system with increased agility and reduced OPEX.

The paper outlines a YANG-based configuration template framework, based on FMA YANG models developed by CableLabs[®], while providing several real-world examples of the benefits.

2. Flexible MAC Architecture

CableLabs has released a suite of Flexible MAC Architecture specifications and continues to expand the specifications through industry collaboration. The FMA project is a key element of a larger CableLabs Distributed Access Architectures (DAA) program. The DAA program includes additional projects, such as Remote PHY (RPHY) and Coherent Optics as well as an industry-wide YANG model standards library and YANG model development pipeline.

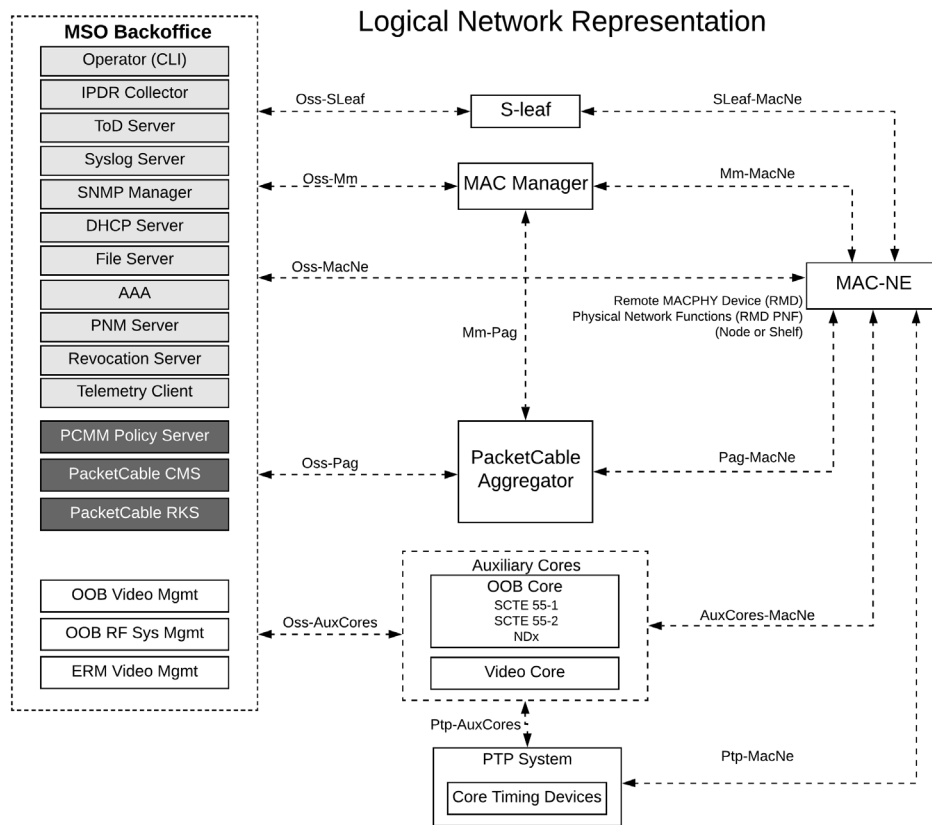

Figure 1 - FMA Phase 1 Reference Architecture

The suite of FMA specifications have achieved a level of stability with the Phase 1 scope officially concluding at the end of CY 2021. The Phase 1 FMA Reference Architecture, as defined in [FMA-SYS], is illustrated on Figure 1. A detailed description for each FMA system component and interface displayed in the Reference Architecture can be found in [FMA-SYS] and [FMA-OSSI].

The following sections of the paper will narrow the focus to those FMA components and interfaces (realized as APIs) which are relevant to the YANG-based configuration template framework. The goal is to align the framework against the FMA Reference Architecture.

Figure 1 depicts the interface between the MAC Manager and the MAC-NE (e.g., RMD). This interface is generally referred to as the MAC Manager to MAC-NE Interface (MMI), labelled as ‘Mm-MacNe’ in the diagram and specified in [FMA-MMI]. The interface’s implementation relies on the RESTCONF protocol, and a library of MAC-NE YANG models developed by CableLabs. The IETF defines the RESTCONF protocol as specified in [RFC 8040].

The MAC Manager fulfills the role of a RESTCONF Client at the northbound of the Mm-MacNe interface, while the MAC-NE operates as the RESTCONF Server at the southbound. Among other primitives, the MAC Manager is responsible for transferring all configuration information to the MAC-NE over the MMI/Mm-MacNe interface. Since the RESTCONF protocol facilitates unicast communication, the MAC-NE YANG models have been designed for transfer of configuration to an individual MAC-NE (RMD).

Another FMA Reference Architecture interface relevant to the subject of the paper, extends between the MAC Manager and the operator's back-office systems, labeled as 'Oss-Mm' in Figure 1. In addition, Figure 1 lists several back-office applications used in the management of an FMA deployment, however it should be pointed out that a network Configuration Management System (CMS) is not included. The CableLabs' FMA specifications do not explain whether configuration management was purposefully omitted as out-of-scope for Phase 1, or under the assumption that configuration of MAC-NEs is an internal domain of the MAC Manager. This paper makes an assumption that a CMS is a mandatory part of the Cable Operators Network Management System (NMS) infrastructure and focuses on selected issues revolving around configuration management functions in FMA deployments.

Figure 2 illustrates an updated reference architecture diagram and outlines the scope of functionality covered by the paper.

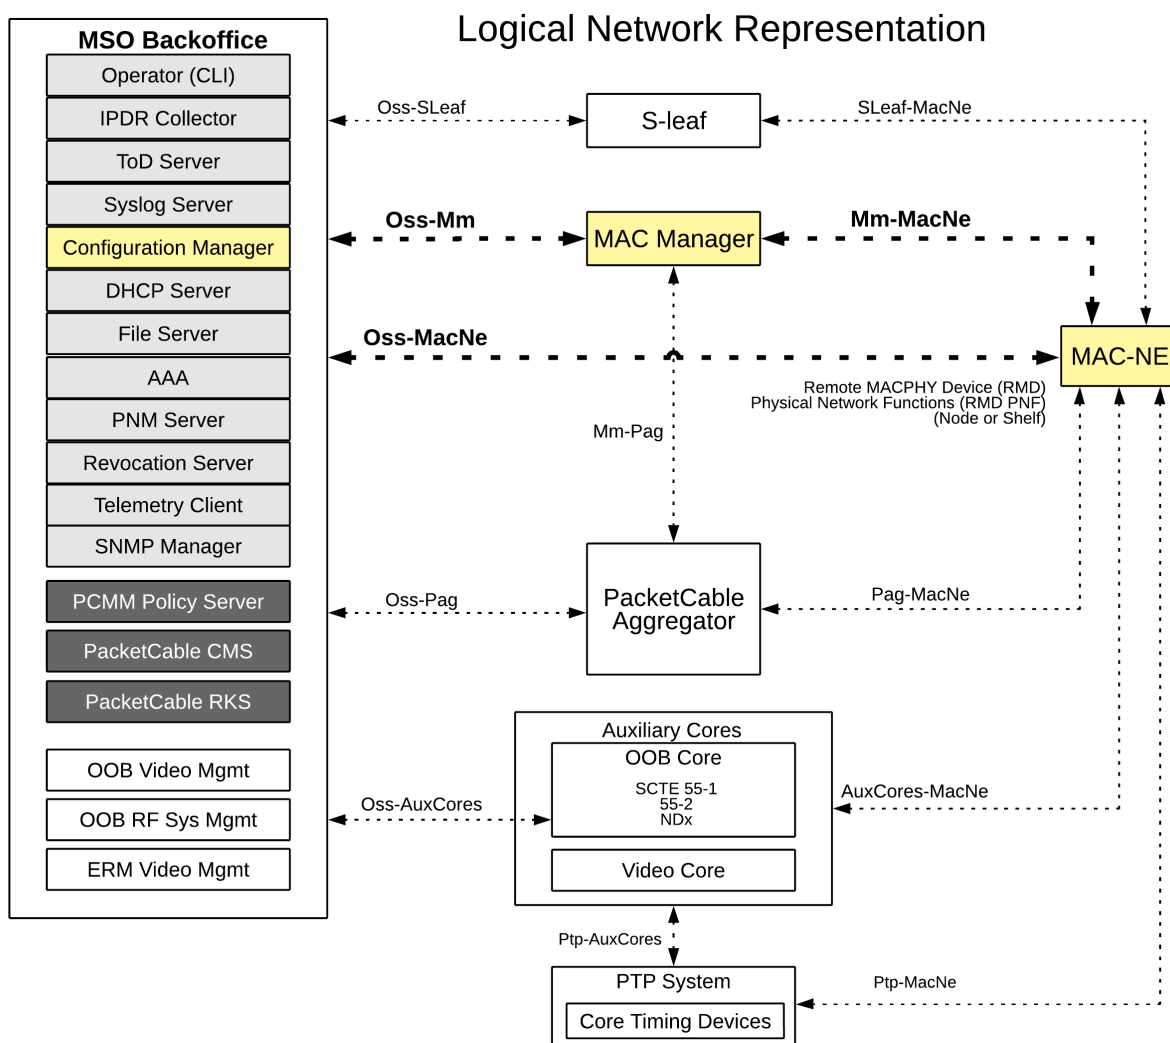

Figure 2 - YANG-based Configuration Template Framework Scope

3. Addressing the Problem of Scaling Configuration Management Data

Let us first briefly illustrate the scale of the provisioning problem faced by Cable Operators deploying FMA through examination of the following example. An HFC network of a medium-sized Cable Operator with a few million paying subscribers may consist of 100,000 service groups. If each service group corresponds to exactly one RMD and considering that an average size of an initial configuration dataset can undoubtedly exceed 500 KB (or 10,000 discrete configuration attributes), and the cumulative size of the initial configuration dataset for such an operator could amount to $500 \text{ KB} * 100,000 = \mathbf{50 \text{ GB}}$ (or 1 billion discrete configuration attributes). This is the volume of the initial configuration information, often referred to as “day-one config”, for all RMDs in this example. This data is encoded and transferred across the ‘Oss-Mm’ interface presented on Figure 2 via the RESTCONF protocol, in a unicast fashion, one-by-one between the FMA MAC Manager and each RMD in the Cable Operator’s network whenever an RMD is initialized or reinitialized.

A data footprint of such scale can very well fit into the storage of an average smartphone. How is that a problem, one might ask?

While storage and transfers of several gigabytes of data cannot constitute a problem for any modern networked computing system, managing “the source of truth” of such sizable footprint of configuration data through the lifecycle of 100,000 independent systems is an entirely different ballgame.

The data abstraction approach presented in the paper takes advantage of the repeatable patterns in the deployment environment, the cookie-cutter like HFC access network design and the standardization of device configuration management interfaces using YANG data models. This methodology relies on breaking down the devices’ configuration datasets into smaller, more manageable modules, extracting individual configuration attributes and their values into a standalone database and creating reusable configuration templates from common, shared datasets. The key enabler of this approach is YANG and its powerful, modular definition of data models.

3.1. The Intended Audience

The intended audience for this paper is the personnel of Cable Operators who are designing or preparing to deploy FMA based systems in their HFC networks, including network provisioning architects, engineers, application developers and business analysts. This paper assumes that readers have some working knowledge of YANG modeling and protocols designed to transport YANG data such as RESTCONF or NETCONF.

4. YANG-based Configuration Templates

4.1. What are Configuration Templates?

This paper adopts the term “Configuration Template” to be commonly understood as **a predefined prototype for instantiated configuration data** that can be further customized and applied to multiple systems in various scenarios.

Configuration Templates are broadly deployed across the software technology industry and distinctly in the networking and cable sectors. For example, some CCAP manufactures provide templates as means to reduce the size of the CLI configuration payloads for network interfaces and selected functions.

4.2. YANG-based Configuration Templates

FMA relies on YANG as a modeling language for MAC-NE status and configuration datastores. YANG was originally defined in [RFC 6020] as a modeling language for the description of data carried in the NETCONF protocol. Since then, YANG has graduated to version 1.1 [RFC 7950] and a wide array of RFCs and other technical standards have been developed to cover adjacent aspects such as encoding, metadata, versioning, translation and handling operational issue with multiple datastores. Today, the networking and cable industry operates with the collateral of thousands of YANG modules, some of which have been published or remain in private distributions.

However, there is no standard or formal definition for YANG-based Configuration Templates (YCTs). No IETF RFC, nor an open-source project or framework provides a formalized definition for a YCT. A YANG-based Configuration Template is a term coined herein. In this context, a YANG-based Configuration Template is a Configuration Template in which the instantiated configuration data is compliant to a particular YANG model and the data encoding generally follows the common encoding rules for YANG data as defined in relevant IETF standards. A YCT can be programmatically validated against the corresponding YANG model.

Each YCT consists of two sections:

1. Data Payload
2. Metadata

The YCT sections are explained in greater detail in the following sections of the paper.

4.2.1. Data Payload

The most essential part of a YCT is the data payload. The data payload contains the instantiated configuration dataset corresponding to a branch of the device's YANG schema. The data payload must not contain any status or operational state data, but partial datasets are permissible. The data payload of one template is typically compliant to a model defined by multiple YANG modules.

The data payloads can be represented in several human and machine-readable formats, such as XML, YAML or JSON. This paper uses JSON for the format of the payload data in the following examples due to its compactness and human readability. The template data in the paper adheres to the standard JSON encoding rules for YANG-defined data per [RFC 7951].

In the simplest form of a YCT, the data payload contains the complete configuration dataset for a branch of the device's YANG schema tree. The example in Figure 3 shows the data payload for configuration of MAC-NE security parameters. Such a template can be incorporated into the target configuration without further changes. The configuration target is defined in section 5.2.

```
"security": {  
  "sav": {  
    "sav-control": {  
      "cm-auth-enable": true  
    }  
  },  
  "tftp-security-config": {
```

```

    "config-file-learning-enabled": true
  },
  "cmts-encrypt": {
    "encrypt-alg-priority": "AES128_CBC_MODE DES56_CBC_MODE DES40_CBC_MODE"
  },
  "certificates": {
    "cert-revocation-method": "NONE",
    "online-cert-status-protocol": {
      "signature-bypass": false
    }
  }
}

```

Figure 3 – Yang-Based Configuration Template

More interesting scenarios ensue when YCT data payloads include variables and/or expressions.

A template variable constitutes a data node value, which is kept within the template as a human and machine-readable name in the form of a character string. Variable names in the paper examples, by convention, are presented as strings that start with the '\$' character (e.g., \$my-variable-name).

The values for the template variables are maintained outside of the template definition, in a Target Database, which is described in a later section of the paper. A variable designates a node value specific to the template target, which is typically an individual MAC-NE device or a group of MAC-NE devices. The Configuration Management System replaces variables with actual values during the process of rendering a template. The template rendering process and the template-oriented configuration management system are described in a later section of the paper.

The example provided in Figure 4 shows a data payload for a configuration of a MAC-NE for Precise Time Protocol (PTP) with a variable for the value of the attribute "ptp-master-addr". The name of the variable in this example is '\$ptp-master-ip-address'.

```

"rdti-cfg": {
  "core-ptp-clk-cfg": {
    "ptp-clk-profile-id": "00:19:a7:02:01:00",
    "ptp-master-addr": "$ptp-master-ip-address",
    "ptp-master-priority": 0,
    "ptp-clk-priority1": 128,
    "ptp-clk-priority2": 255,
    "ptp-clk-domain": 24
  }
}

```

Figure 4 – YANG-Based Configuration Template Data Payload

When such a template is rendered for a selected target, the system retrieves the actual IP address of the PTP master clock from the Target Database entry and inserts it into the configuration dataset. With this approach, the PTP master clock server's IP address can be individually applied for each target and combined with common data from the template to form a complete configuration dataset for the device.

A template expression is a logical or a mathematical formula for algorithmic determination of a value of a data node in the template. An expression can include operations on constants, template variables and values of other data nodes contained within the template, including the key attributes of YANG lists. Similarly, as with variable replacement, expressions are evaluated during the rendering of a template for a selected target.

A familiar example of a template expression could be the formula to calculate the value of frequency of a downstream SC-QAM channel when several such channels are grouped into a single, continuous block. Such a formula can be the sum of the value of a variable representing the center frequency of the lowest channel in a block and channel index multiplied by 6 MHz.

*\$channel-frequency = \$start-frequency + channel-index * 6,000,000*

The syntax of expressions and their usage rules are quite complex. For this reason, and because expressions' encodings are not essential to the purpose of the paper, the detailed definition of template expressions is left out of the scope of the paper.

4.2.2. Metadata

Template metadata consists of a set of attributes that hold miscellaneous properties of a template outside of the configuration data payload. The most important metadata attributes are the **template-name** and the **template-schema-root**.

The template name serves as the primary identifier of the template within the system. The system refers to templates by their names. For this reason, each template name needs to be unique within the system.

The YANG modelled data maintains a tree-like hierarchy where each node can be uniquely identified with a schema path. The template schema root defines the parent node of the target's YANG data schema tree from which the data within the template is in scope. Thus, the template schema root is a YANG schema path. It can include keys and variables so that different templates can be rendered onto specific elements of a single YANG list. A template metadata defines exactly one or zero template schema roots. When the template is rendered for a selected target, the system can override the template schema root with a custom template schema root configured for the target. For example, the template schema root can refer to an individual entry of a list, or to all entries of a list. In the former case a template provides data for the referenced list entry. In both cases, the set of data nodes corresponding to the list can be formed from multiple templates.

Other metadata attributes provide information which can be helpful with administrative tasks. The example of template metadata shown below comprises several other attributes, such as **template-description**, **template-notes** and **template-revision-history**.

The metadata encoding is consistent with the JSON encoding rules for YANG data nodes. All metadata attributes, just like the data payload, are encoded as JSON key-value pairs. Template metadata encoding follows the rules from [RFC 7952].

An example of template metadata is shown in Figure 5.

```

“template-metadata”: {
  “template-name”: “ptp-config-101”,
  “template-schema-root-point”: “/mac-ne/networking/”,
  “template-description”: “This template defines configuration for MAC-NE PTP
operation for G.8275.2 PTP profile”,
  “template-notes”: “This template is incomplete. It is missing a number of
mandatory configuration attributes”,
  “template-revision-history”: [
    {
      “revision”: “2022-01-01”,
      “description”: “Added ptp-clk-domain attribute.”,
      “Author”: “George D.”
    },
    {
      “revision”: “2021-10-01”,
      “description”: “Initial revision”,
      “Author”: “Bob D.”
    }
  ]
}

```

Figure 5 – YANG-Based Configuration Template Metadata Payload

5. Template-Oriented Configuration Management System

This section describes an environment in which all data configuration originates from a template. The difference between a template and configuration payload is the name.

This section provides a rough framework for a system which creates MAC-NE configuration payloads from YANG configuration templates. The paper limits the description of the system to a minimum necessary to illustrate the principles of operation of a system based on Configuration Templates. In the context of this paper, the system is referred to as a Template-Oriented Configuration Management System, or TOC System. The TOC can become an integral part of the Cable Operator’s Data Operations platform architecture.

The TOC System is presented on Figure 6 and consists of three main components:

1. Repository
2. Target Database
3. Template Management Application

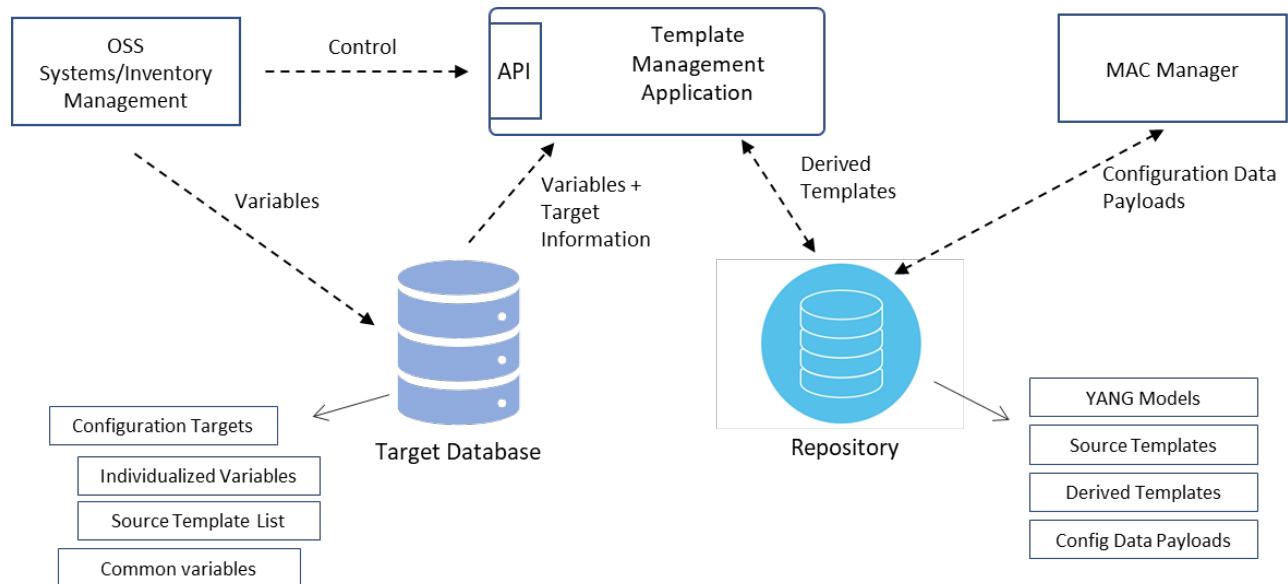

Figure 6 – Template-Oriented Configuration Management System

5.1. Repository

The Repository serves as a storage location for files which house YANG models, source and derived configuration templates, as well as the fully instantiated configuration payloads. The Repository can be implemented on top of a distributed Version Control System (VCS) such as Git or on top of a versioned object storage system such as Amazon S3. However, a distributed VCS provides the features required for a repository of templates. Such features incorporate sophisticated versioning tracking, management and security controls, including user access controls and what is most important, built-in integration for automated CI/CD pipelines. Therefore, the paper considers a VCS such as GitLab or GitHub as a default choice for the Repository.

Fully instantiated configuration payloads from the Repository are communicated to the FMA MAC Manager through a standardized API, e.g., RESTCONF.

5.2. Target Database

The Target Database contains information necessary for rendering configuration targets. The Target Database can be implemented as a relational database, such as an open-sourced Redis database.

This section defines the types of supported configuration targets. The TOC System operates on two categories of configuration targets: Derived Configuration Templates and Configuration Data Payloads.

Derived Configuration Templates are templates which the TOC System generates as the product of rendering of one or more source configuration templates. For example, a derived template representing the configuration of a downstream RF Port of a MAC-NE can be created from multiple source configuration templates where each source template contains configuration payload for one type of channel, for example, a list of downstream SC-QAM and OFDM channels and forward SCTE-55-1 OOB channels.

Another supported type of configuration target, the device Configuration Data Payload represents a portion of, or the entire configuration data instance intended for the target device. The Configuration Data Payload format is essentially the same as the Derived Configuration Template except all variables have been replaced with values, and all expressions have been fully evaluated. Configuration Data Payload must strictly conform to the branch of the YANG schema it represents and its intended use case.

The information maintained in the Target Database includes the following attributes:

- The target identification.
 - The name of the configuration target.
 - The location of the target file within the Repository.
 - Necessary metadata for creation of target payload, including YANG model information.
 - Target revision information.
- A list of source templates from which the target needs to render.
 - A substitution schema root that are optional for each source template. As mentioned earlier, each source template maintains the template-schema-root attribute, which can be overridden by the substitution schema root from the target.
- The YANG schema root for the target, in the form of the YANG path to the root node in the target.
- A list of variable replacement values for the target. When variable values are specific to exactly one target, then the database record of the target contains the values. In other cases, when variable values are shared by multiple targets, the Target Database record of the target provides an indirect reference to the value maintained in a common, shared record. This way the Target Database contains only one record with definition of the value, the single source of truth for multiple targets. The set of variable replacement values can grow quite large, when variables are leaves of multi-dimensional configuration lists.

Most of the information in the Target Database originates from the Cable Operator's BSS/OSS systems, while the information about the relationship between source templates and targets comes from human-assisted YANG schema breakdown into template hierarchy.

5.3. Template Management Application

The third component of the TOC System is the Template Management Application (TMA).

TMA implements all necessary configuration manipulation logic, including the rendering and the validation of target Configuration Data Payloads. The TMA also incorporates machine-to-machine APIs to the BSS/OSS systems through which the processes of rendering and validation of configuration payloads can be automatically initiated, and the status of these processes can be communicated back to the requestor.

5.4. Template Rendering

Template rendering is a procedure for creating target configuration payloads in accordance with their YANG models. It can be summarized as a five-step process:

1. The TMA retrieves the target information from the Target Database.
2. The TMA extracts the payload from all source template payloads identified in step 1.
3. The source payloads are combined in compliance with the applicable YANG model to create the target data payload.

4. The TMA injects the individualized target data into the payload, replacing variables with corresponding values from the Target Database.
5. The data payload of the derived template is written into the Repository.

The product of the rendering procedure is the target payload, which can be in the form of a derived template or a fully instantiated Configuration Data Payload. Next, the TMA validates the product, the target configuration payload against the YANG model and custom validation rules.

The combined source payloads typically form different branches of YANG instance data tree in the target's payload. However, the rendering process can also combine partial datasets from source template payloads that are part of the same branch.

A derived template can inherit selected variables from its source templates. Other variables can be replaced with actual values from the Target Database record associated with the target template. The TOC System decides whether a variable is replaced or inherited by examining the content of the Target Database record for the target. When the Target Database record contains a value for the variable, the variable is exchanged for the value. Otherwise, the variable is inherited by the target in the same form as in the source template.

Similarly, selected expressions can be evaluated during rendering of the source templates while other expressions are inherited by the Derived Template in the same form as present in the source template.

The rendering process can operate in multiple iterations. A Derived Configuration Template created because of rendering, can later become a source template in another iteration of the rendering process. The iterative process is particularly useful in creation of multi-level hierarchies of configuration data from simpler, more manageable, and “flat” templates. For example, the current FMA MAC-NE YANG model places many configuration attributes as high as at the fourth or even the fifth level of the YANG schema tree.

In the example shown on Figure 7, two source templates, named T1 and T2 are rendered into a derived template, named T3. The data payloads of T1 and T2 are combined in compliance with the YANG model. Next, Variable-1 of source template T1 and Variable-2 of source template T2 are replaced with Value-7 and Value-6 respectively. Variable-3 is inherited by derived template T3 from source template T2.

Note, that the payload from source template T1 is inserted at the same level as data in Container Z from source template T2 based on the T1's schema root.

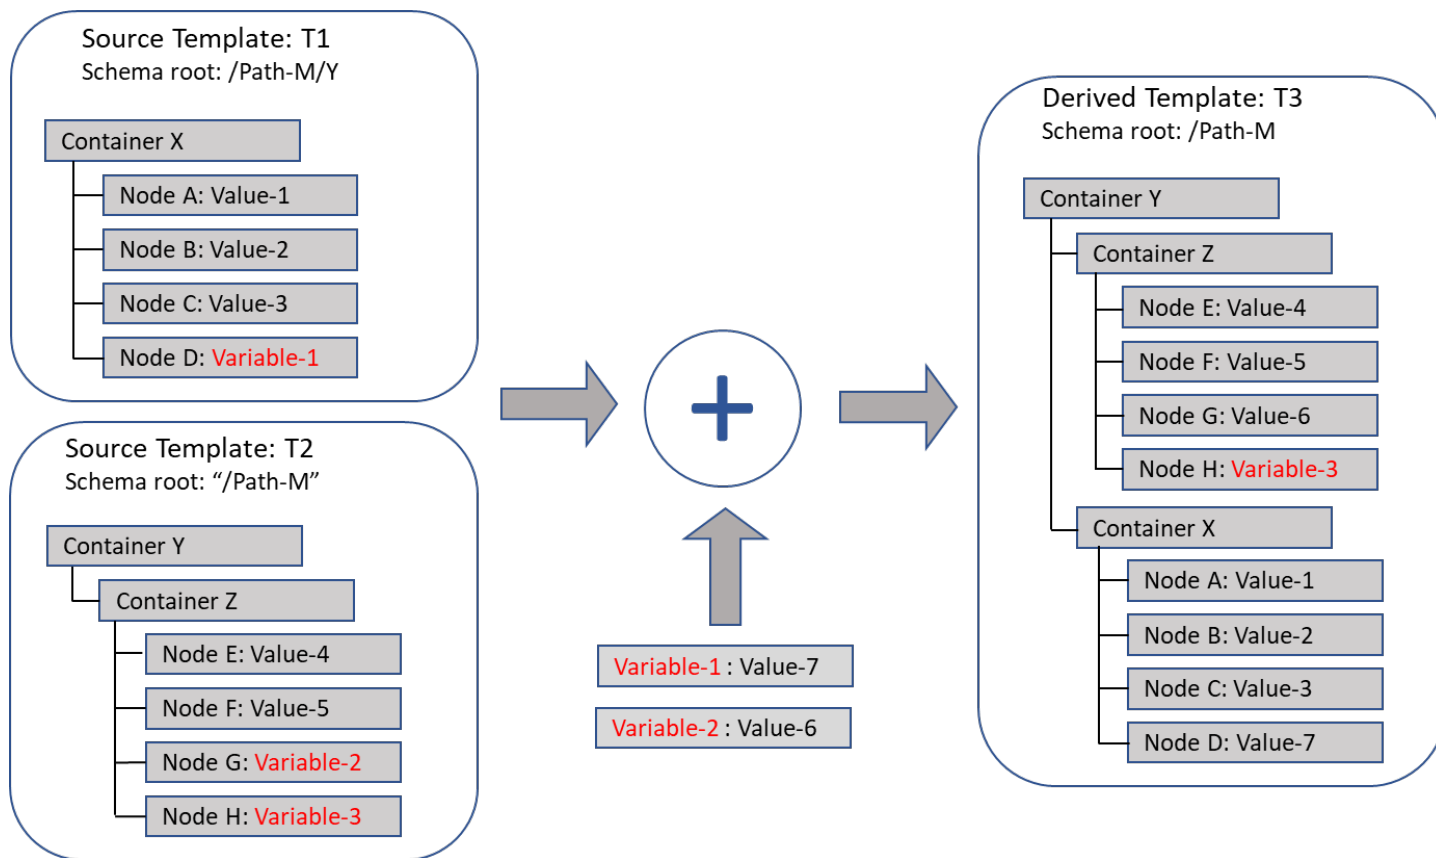

Figure 7 – Template Rendering Example

The instantiated data held in the template payloads, as well as the rules for transforming templates are driven by the YANG model to which the data is compliant. The limitations of the YANG modelling language also limit the TOC System's ability to transform the modelled data in certain, rather rare cases. For example, the data for a user-ordered list cannot be rendered from multiple source templates. The YANG models simply do not contain sufficient information to determine the order of data.

6. Discussion of Selected Use Cases

The following section provides examples of use cases to illustrate and highlight selected aspects of the proposed framework and benefits to Cable Operators.

6.1. Modular Data Design

One of the key advantages offered by the proposed templating methodology is the enablement of modular data design. The YANG-based data model of a MAC-NE can be divided into a set of small-scale segments, where each such segment corresponds to an integral functional area of the MAC-NE. The model break-up naturally follows the hierarchy of the MAC-NE YANG schema tree.

How might this work in practice?

The Cable Operator creates as many templates for each segment of the model as practically necessary to cover all variations of configurations needed for deployment and ongoing management. Several templates

providing configuration prototypes for defined deployment cases in a certain functional area can form a library of fundamental templates. An appropriately crafted set of fundamental template libraries can cover the entire data model of a device.

Figure 8 illustrates how such approach operates with an example based on three libraries of fundamental templates: the RF Subsystem, the Cable Bundle and the PTP Subsystem. Only three fundamental libraries are included in the example for brevity.

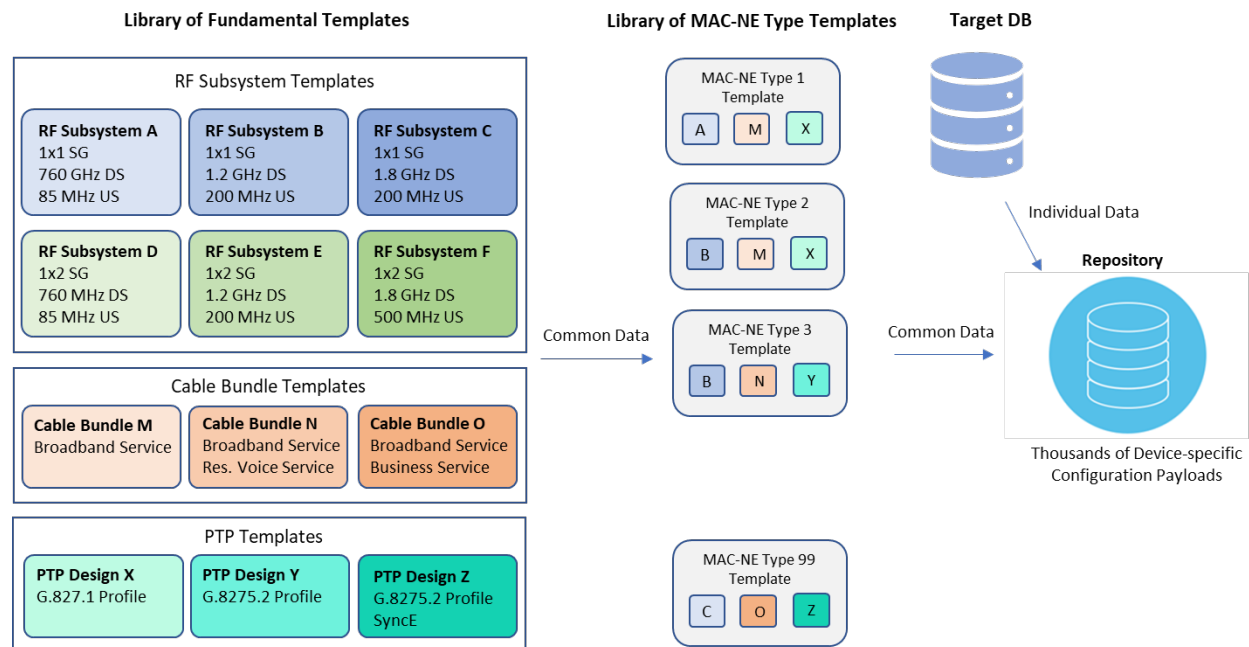

Figure 8 - Libraries of Fundamental Templates

The RF Subsystem template library includes templates for six designs of the HFC Plant. The PTP Subsystem template library includes three templates for commonly deployed PTP profiles. The Cable Bundle template library provides three templates for end-user IP service deployment options.

Next, from the library of fundamental templates, the TOC System renders a larger number of derived templates corresponding to as many variations of MAC-NEs as required. The intermediate library of MAC-NE Type templates is shown in the center of the diagram. Each MAC-NE Type template payload consists of selected payloads from the fundamental libraries.

In the subsequent step, the TOC System injects individual data into a selected MAC-NE Type template to create as many device-specific configuration payloads as needed. The device Configuration Data Payloads are made available to the MAC Manager to load onto the deployed RMDs.

6.2. Subdivision of Responsibilities within the Organization

Dividing work tasks between organizational teams is an essential part of running any business. This is particularly important for Cable Operators' organizations where separate operations sub-departments are often responsible for management of service and equipment lifecycle in functional areas under their jurisdiction. The examples of such functional areas include the DOCSIS[®] Subsystem, the MPEG Video Subsystem, Voice Services, Timing Operations or Subscriber Services.

The proposed framework, through the modularity in configuration data design, also enables the division of responsibilities between sub-departments within the Cable Operator's organization. The personnel of any department can maintain the sole ownership of the set of templates that correspond to the departmental responsibilities. These assignments can be enforced by effective access controls. For example, only the personnel of the department responsible for MPEG video service can be given the ability to modify (write-access to) the templates with configuration of MPEG video channels, DSG and out-of-band services.

6.3. Configuration Lifecycle Management

The flexibility and modularity offered by the Template-Oriented Configuration Management System simplifies many configuration lifecycle management tasks. One specific such task is the process of configuration modification within the template-oriented CMS.

Any changes to the configuration of a device due to network design changes, a software upgrade or service changes are typically contained within a small portion of the devices' configuration set. With proper template design, most configuration modifications typically affect only a single template, or a limited set of target variable values kept in the Target Database.

An administrator can modify a template by one of three methods.

1. The desired modifications are made directly to the payload of the affected template, resulting in a new revision of the template.
2. If the Repository already maintains a template with the desired configuration set, the name of the new template replaces the "old template" name in those Target Database records that need to be affected by the change.
3. The administrator creates the new template with a new name, often by cloning and modifying the previously used template. Then, the administrator modifies the Target Database as in Step 2 above.

After necessary modification to the templates and committing the changes to the Repository, the iterative rendering process predictably propagates the changes to the set of templates derived from the modified template and finally to the set of device Configuration Data Payloads.

7. Conclusion

In recent years the cable industry has embraced Distribute Access Architecture (DAA) including Flexible MAC Architecture (FMA) for innovation and significant investments. The paper augments these cable architecture transition efforts by examining the configuration aspects of DAA deployments and demonstrating how Cable Operators can effectively leverage YANG-based Configuration Template Methodology to scale, simplify and automate system configuration tasks within their back-office systems. The business outcomes are in the form of modular, automated, and streamlined provisioning systems and processes with increased agility and reduced OPEX.

1. Introduction

The ‘speed’ of internet is typically conceived as the main indicator of the quality of our internet connection. Operators have been using the available top speed as a selling argument. For good reasons because cable could deliver a lot.

As usage grew the race for higher speeds was on. The race could be fueled by adding more and more capacity. But there are limits as spectrum is not free and expansion needs time and investment. Fiber can provide the next order of magnitude but doesn’t come for free as well and over time will also require upgrades.

This paper focuses on the question how we can optimize the capacity we deploy in relation to the growing traffic and speed promise.

A simple formula is proposed, tying capacity together with traffic and speed performance. It is an evolution on the k-factor (re. Tom Cloonan, CommScope). This formula is translated into practical applications to plan into the future and to (virtually) measure the actuals of today.

The aim is to support an optimized business balance of the three corners in a measurable way using only the tools we typically already have.

Possible caveats and the current perception of (avoiding) congestion will be discussed as well as practical proof of the results.

Finally, the formula will be applied to possible futures with extreme speeds on DOCSIS or XGS-PON.

2. The 'ks' formula

The proposed formula is essence a combination of two classical methods to determine the amount of capacity needed in a service group (called 'capacity').

- 50% rule; capacity > the highest speed sold / 50%
- k-factor; capacity > utilization + k * the highest speed sold

The 50% rule is extremely simple to use and can be standardize throughout a network, but it discards the actual traffic. As a result, on busy service groups the speed performance is suboptimal. Even up to the point where congestion occurs. In practice an additional planning rule is needed to avoid this. In service groups that are quiet there is more capacity than needed which means inefficiency.

The k-factor must be applied considering the utilization of each service group individually but only provides a factor to the speed. Analyses of the statistical distribution of traffic revealed however that the chance of having sufficient available capacity for a burst of speed is a function of the utilization and not of the planned speed. This means the formula needed an additional factor to modulate the utilization which has been called the 's'. This stands for service level or safety. The result is the ks formula:

$$\text{capacity} = \text{utilization} * s + \text{speed} * k$$

Table 1 – ks formula definitions

capacity:	the amount of capacity that is minimally needed [Mbps]
utilization:	the average utilization during the interval that the speed should be reached (e.g. 8-10 pm) [Mbps]
s:	the service level factor to use
speed:	the top speed that is desired [Mbps]
k:	the factor that defines how much of the top speed we want to enable

3. The expectation of ‘speed’

The customer perception of speed is influenced by many factors of which some subjective. For network planning a translation into objective parameters is required. In some markets regulators have defined measures to adhere to. Operators may also have defined some themselves. For example:

- *at least 50% of customers at peak time need to achieve headline speed*
- *all customers need to achieve 50% of headline speed at peak*

This in turn requires a definition of the interval for which the rules apply. For example

- Between 8 and 10 pm
- During the busiest hour of the week

It also needs a translation of achievable speed into a network parameter. What a customer would see from a speed test depends on for example:

- The available or unused network capacity during the test interval (typically 10-20 sec)
- Limitations in the customer equipment
- The speed test mechanism

This leads to a basic definition of what ‘speed room’ is from a network perspective:

- **The amount of capacity in a service group that is available for a burst of traffic**
 - At any given time during the busy hours between 8 and 10 pm
 - For the duration of ten seconds

It is recommended to define ‘speed’ in this perspective with care since it directly relates to desired performance.

A limited increase of the factor ‘k’ in the formula can be used to compensate for other factors such as:

- Chance of overlapping speed tests from different users at the same time
- The provisioned speed. Typically, modems are provisioned 5-15% higher than the sold speed. This allows a limited amount of ‘catching up’ when during a moment in the ten second test there is not enough capacity available.

4. Utilization in a statistical perspective

4.1. Definition

The speed room is defined by the capacity of a service group minus the actual utilization. While the capacity is a constant, the actual utilization in a service group is varying from moment to moment. This calls for a deep dive into this fluctuation.

When utilization is measured it is typically:

the total amount of bits transported during a sample and expressed in Megabits per second [Mbps]

In regular measurement tools the sample time varies from five minutes to one week. For an entire network this yields a vast amount of data. Normally this data is aggregated to averages over a certain amount of time and 'peak' levels.

But if the aim is to measure ten second intervals for speed room calculations the challenge will become soon just to handle this data. Since traffic appears to be generated in a semi-random pattern, the working assumption is that it can be described as a bell curve.

Figure 1 – theoretical distribution of momentary utilization

With this assumption only a few parameters are sufficient to determine the utilization during the interval and the chances of having sufficient speed room.

- Average utilization
- Median utilization (50th percentile)
- Width of the curve (measured at 20th, 80th percentiles)

In this example the average utilization is 60%. Because the bell curve is symmetrical, 50% of the samples have a higher utilization, the other 50% lower. The symmetry of the curve implies that:

median utilization = average utilization

4.2. The width of the bell curve

In practice the expected bell curve may be differing between service groups and can also change over time. It may be narrow when many users are active and wider in more relaxed service groups.

Figure 2 – examples of busy and quiet service groups

The duration of the samples has an impact on the width of the curve. Short samples will give a wider curve. The longer the sample are, the narrower the curve will be. However,

for the median speed room, it is not relevant how wide a symmetrical distribution is

4.3. The symmetry of the bell curve

So far it has been assumed that the curve is symmetrical. What if it is not?

These two examples of a skewed distribution visualize a non-symmetric distribution.

Figure 3 – examples of asymmetrical distribution

Calculations on extreme examples have revealed that the median utilization can differ up to 10% from the average utilization. In terms of the formula this means that the median speed is reached when

$$0.9 < s < 1.1$$

This brings in uncertainty in the result. In the left example, the median will be 8% lower than the average. This means the results will be worse than expected if $s=1$ is used. In the right situation we the median is 6% higher than the average. This can be compensated by using $s' = 1.08$ (left) / 0.94 (right).

The uncertainty caused by the translation of average utilization into median can be overcome by:

- Measuring the median utilization in ten second samples which may give additional complexity
- Use a default $s' = 1.1$ and accept a possible overestimation of the traffic
- Calibrate with actual speed test results

4.4. The bell curve in reality

Conversion of actual utilization metrics into a distribution chart can be quite challenging. Part of the challenge is the fact that besides the randomness there are also diurnal, seasonal and long-term trends. On top there are single events such as big downloads from software releases, video events and even the pandemic.

The working assumption has been tested in various set-ups. Regardless of the sample time, network and time of day, a histogram yields a bell-type curve.

In this example of a long period of two years where the busiest hour of each week is shown, the distribution is narrow. The median is very close to the average (0.3% difference).

Figure 4 – long term utilization distribution of an entire network

The following example shows the correlation between ten second- and fifteen-minute samples. Both yield a bell-curve which follows the diurnal and weekly trend and correlate strongly. Because it is measured over two weeks, the results include busy and quiet times.

Figure 5 – short-term utilization of a service group

4.5. The cumulative curve

The distribution from figure 1 can be shown as a cumulative curve. This shows for each level of relative utilization which percentage of time the actuals will be lower. If we depict a speed as a percentage of the service group capacity (e.g. 1 Gbps in a 2Gbps service group is $\frac{1}{2} = 50\%$) we can read the percentage of time the utilization samples will be lower and a speed test would be successful.

Figure 6 –cumulative momentary utilization

In this example the average utilization is 60%. It is a symmetrical distribution, so the median utilization is the same. If this is a 2Gbps service group, the chance of a successful speed test for 1Gbps is only 20%. This is an example that the traditional planning with a 50% rule will give a relatively low performance in a busy service group.

Through mathematical manipulation using the ks formula, any distribution (measured or assumed) can be altered to show which percentage of time success belongs to which s if we measure or calculate it.

Figure 7 –s and the percentage of success

Following the example above, the 1Gbps top speed has an $s = (2 - 1 \text{ Gbps}) / (60\% * 2 \text{ Gbps}) = 0.83$. The corresponding % of time success is 20% as is also found in figure 5.

Note that this is just another representation of the same distribution data. It is useful for:

- Determination of other percentiles than the median
- Sensitivity analyses (what if the growth is higher than expected)
- Reconstruction of the distribution from actual speed test data

5. Planning capacity

5.1. Basic calculation

Calculation of required capacity in a service group to obtain a certain speed room has become simple.

$$\text{capacity} = \text{utilization} * s + \text{speed} * k$$

Example 1: for a service group with an average utilization of 400 Mbps during peak hours and a top speed of 500 Mbps, the minimum capacity = $400 * 1 + 500 * 1 = 900$ Mbps. In that case the median speed room will be the top speed.

Example 2: for a service group with an average utilization of 250 Mbps during peak hours and a top speed of 300 Mbps, 80% of speed tests must be successful. To achieve an 80th percentile of success, $s = 1.25$ must be used. This value is obtained from the cumulative distribution in the previous chapter. The minimum capacity = $250 * 1.25 + 300 * 1 = 625$ Mbps. In that case the 80th percentile of speed tests will be equal to the top speed.

5.2. Calculating a speed upgrade

When the top speed of a network is upgraded the capacity must be expanded accordingly.

As an example, the top speed is upgraded from 1Gbps to 2Gbps. In the traditional calculation with a 50% rule this would require $1\text{Gbps} / 50\% = 2\text{Gbps}$ of additional capacity. The ks approach requires the addition of $k * 1\text{Gbps}$ of capacity. Supposed that $k = 1.2$ this is 1.2Gbps of additional capacity. Since the term $s * \text{utilization}$ remains does not change, the performance of the 2Gbps product after the upgrade will

be the same as the 1Gbps product before. Instead of 2Gbps additional capacity, only 1.2Gbps is added with the same performance as before the upgrade!

5.3. No standard capacity across the network

In essence the required capacity is different for every service group because the utilization is different. This could pose an operational challenge. In practice it will be desirable to have some degree of standardization. A method can be to classify all service groups on their utilization and/or spectrum availability. Then plan for the busiest in each group. This ensures sufficient capacity while avoiding too much idle capacity, unnecessary spectrum occupation or node splits.

5.4. Efficiency gain

Compared to a standardized capacity across all service groups, a deployment based on the ks-formula gives an efficiency gain. The amount depends of course on the distribution of busy and quiet areas and the already used standard capacity. In an example busy network the actuals were compared with the requirements following the ks formula. In the quieter areas 17.5% less capacity was needed. In the busiest areas (4.4% of service groups) the standard capacity was insufficient. To reach the median speed as defined 0.2% of additional capacity would be needed. This would give a net gain of ~ 17%, provided there is spectrum available. If this is not available this should drive segmentations and cost 4.4% more capacity. Still a net gain of ~13% and ensured speed performance across the network.

6. Virtual measurement

The formula has a mathematical form and can be altered to virtually measure both s and k from real life data. This can be used to verify the calculation or even manage the actual operation of a network.

There are two reporting options which are explained here:

- Customers reaching the defined speed
- Median available speed room

6.1. Customers reaching the median speed

In essence this is counting the customers that are on service groups with $s \geq 1$.

In an existing network the capacity, utilization and sold top speed are known. This means if $k=1$ (or another value of k that is desired) s can be calculated for each service group. The ks formula is transformed into:

$$s = \frac{\text{capacity} - \text{speed} * k}{\text{utilization}}$$

The resulting dimensionless s provides information on the propensity of reaching the top speed for a random speed test as explained. For $s = 1$ this is the median result.

When all customers are counted that are connected to a service group that has $s \geq 1$ and divided by the total customer count we have an indication of the percentage of customers that have sufficient speed room.

6.2. Customers reaching the minimum speed

When there is a minimum speed guarantee the calculation can be repeated with a different s . In the example the rule applies for the busiest hour. This means a second s_{\max} must be calculated for the utilization at the busiest hour which of course must be available.

A 100% guarantee is not possible, in the example 95% is chosen. So 95% of random tests must have a minimum of 50% of speed room available. The graph in figure 6 shows that the related $s = 1.7$

Again, the customers are counted. This time from service groups with $s_{\max} \geq 1.7$.

6.3. Median speed room

To calculate the median speed room the s in the formula is fixed: $s = 1$. Another transformation of the k s formula yields:

$$k = \frac{\text{capacity} - \text{utilization} * s}{\text{top speed}}$$

The resulting k gives the speed room / top speed ratio. The actual median speed room is then the found with $k * \text{top speed}$. This value is not directly usable to report on a customer level because CPE are provisioned for a certain top speed. Normally 5-15% more than the sold top speed. This means the median top speed from network perspective must be limited to this value to obtain a value that is achievable for customers. If the overprovisioning is 10%, all results above 110% must be capped at this level before calculating the average for a network.

6.4. Median speed in real life

The virtual measurement of the median speed has been put to the test in a multi-million homes network with several thousands of SamKnows' probes. The virtual measurement theory dictates that if $k \geq 1$, the median speed room equals the top speed. With $k < 1$, the median speed goes proportionally down.

The results from hourly tests from ~1.500 probes are compared here with the results from the virtual measurement with network data as described in section 6.3. The expected relation is clearly visible and the found k to meet the median speed in practice is ~ 1.2 for downstream and ~ 1 for upstream.

Figure 8 –virtually measured speed compared with actual test results

7. Congestion

Network congestion is a thing operators want to avoid. The classical approach is to provide sufficient capacity to keep the utilization under a certain percentage. The knowledge from the ks approach can be used to create a different view on congestion and discover opportunities for improvement.

7.1. What is traffic congestion

First step is to define what congestion is and what should be avoided. For this general road traffic theory is used which defines three stages of traffic flow:

1. Free flow of traffic. There are no obstacles to reduce the speed.
2. Viscous flow of traffic. It is busy and the speed reduces on occasions but still flowing.
3. Jammed traffic. Speeds drop to zero on occasions. This leads to a build-up of even more traffic and longer stand-stills

7.2. Congestion versus ks

The three stages of traffic flow can be defined as speed rules. For example:

1. Free flow: the median speed room is achieved at evening peak hours
2. Viscous: at the busiest hour at least 50% of the top speed must be available in 95% of cases
3. Jammed: the speed room is < 10% for > 1% of time

The cumulative traffic curve(s) in use can be used to find the related s for each stage. These values of s can be put in the formula to add additional rules for planning. At the same time the actual network data can be virtually measured to determine the percentage of customers in each stage.

7.3. Never 100%

The stochastic behavior of traffic predicts that at any time short peaks of traffic will utilize the full capacity, even in quiet service groups. If the samples are short enough, we will 'hit the ceiling' sometimes. This is not a problem as there are buffers and IP has ways of resolving lost packets. Customer impact is expected however when the ceiling is hit too long or often. This is exactly what the cumulative distribution curve can be used for to detect.

8. Traffic events

The ks formula works from the assumption that traffic has a semi-random character. The practical tests have confirmed this but in recent years we have seen an increasing number of events that can change the traffic volume suddenly.

The graph below shows the surges of the combined Liberty Global network. The percentage is relative to the expected volume and compensated for normal growth and seasonal fluctuation. In other words, a sudden spike in traffic for one or more hours.

Figure 9 –growing traffic surges

Qualitative analysis showed that the surges are mainly caused by:

- Video broadcast over IP of popular games
- Releases of large software updates Upstream surges from:
- Work and school from home

Because the events are not always plannable, may last short and data collection is complex there is to date insufficient data to determine the impact on the cumulative distribution. A desk examination on two examples can give some hints on what to expect.

8.1. Many video streams

If many customers are watching a video stream, the traffic per customer is relatively low but the number of users is high. For game events the beginning and end are approximately the same for every user. This means a constant amount of traffic is added during the event with little variation. Note that a significant amount of the video traffic will replace regular traffic so the net addition will be less than calculated by the number of users * traffic per user. This ‘replacement’ is estimated at ~50% of the calculated amount.

If viewed from a ten second sample perspective, the distribution curve shifts to the right during the event. Average and median will also shift with the same amount. To maintain the performance this traffic must be included in the planned capacity as discussed.

If it is not included, the performance will go down. This is shown in the graphs below. The s-curve shows the chance of success according to the initially planned traffic. If we planned for an s=1 and temporarily include 20% of traffic, the percentage of successful speed tests will drop from 50% (median) to 25%.

Figure 10 –impact of video event

8.2. Big downloads

An example is used from an observed surge of 25% linked to a game update of 40 GB. The amount of data corresponds with ~1.3% of all customers downloading the update in the same hour.

A 1Gbps customer would be able to download the update in ~5.3 minutes, a 500Mbps customer 11 minutes and for 100Mbps it would take 53 minutes. If these downloads start at the same time, for the first five minutes the traffic surges +78% after which the surge drops in size. If all customers would have a top speed of 1Gbps, for five minutes the traffic would increase by 281%.

The graph shows the hypothetical traffic increase if all downloads start at the same time and customers have a top speed as they are normally distributed.

Figure 11 –impact of simultaneous software download

In reality traffic increased with 25% for the full hour and beyond.

- downloads do not start at the same time (planned)
- peering or IP network capacity is limited
- access capacity is temporarily at its limit

Chances are that the limit of capacity in terms of this document is reached for some time during the downloading. As a result, the speed room reduces to zero during those times.

Simply adding 25% of traffic in the formula (multiply s with 1.25) may not be sufficient to cater for these events. The reason is that the surge would become higher but still the ceiling would still be hit for some time, only shorter. It is a matter of choice to what extent the speed room must be available during these releases. Managing the release times may be more effective and cheaper option. Or accepting that the performance is not compliant for the short duration of these events.

8.3. Speed tests

Performing actual speed tests from the customer's equipment is of course the ultimate proof of speed performance. For testing the network speed SamKnows probes in modems are available. This test rules out any limitation in the customer equipment and wiring. One could argue to use these systematically to have a reliable indicator of the network performance. But performing tests has an impact on the utilization of the network and in the end influences the performance for regular traffic.

Based on the average provisioned speeds an estimation of the additional traffic at peak hours can be made if all would perform a scheduled hourly test of ten seconds. For downstream the addition would be 19%, for upstream 30%. This means that just because of the proofing of the speed room, the capacity must be increased by these amounts to actually achieve the speed room.

If tests are performed randomly during the hour there is a chance they overlap. In case two top speed tests overlap it is likely both will fail as they compete for the same speed headroom. This chance of failure is the highest for the top speeds but can also happen with other speeds or if more than two overlap. In the example the chances of overlap are:

Table 2 - overlap and failure of random speed tests

speedtest for	overlaps with another for	overlap	failure
1000 Mbps	1000 Mbps	2%	4%
1000 Mbps	500 Mbps	13%	24%
all	all	53%	78%

The percentages indicate that a significant amount of speed tests would be impaired just because of the fact that the tests are performed. Similar percentages occur in the upstream direction.

This self-inflicted performance reduction can be mitigated by scheduling the tests so that they do not overlap. The feasibility of this scheduling is not investigated but assumed possible (SamKnows is supposed to avoid multiple tests at the same time on one node). In the example during 46 minutes of every hour there would be a downstream speed test going on (38 in upstream).

Implementing scheduled speed tests means adding capacity to the network to carry the added amount of traffic. If this is added following the ks formula, the statistical availability of speed room would still be as expected because both consider 10 second samples.

There could be however an impact on the customer perception for normal traffic since this is built up from much shorter bursts. To understand the impact in detail, the utilization distribution of shorter samples would be needed. This is not available to date.

9. Long term outlook

The ks formula works from metrics that are familiar from the DOCSIS world. In essence the metrics relate to properties of the aggregated internet traffic from customers, regardless of the technology. This implies that the same method can be used for other means of internet access.

9.1. XGS-PON

As an exercise the calculations are done for hypothetical DOCSIS4.0 and XGS-PON networks.

Table 3 - DOCSIS4.0 and XGS-PON example calculations

	D4.0 1.8/204		XGS-PON	
	Down	Up	Down	Up
capacity	12280	1228	10000	10000
traffic/customer	10	1	10	1
customers/service group	180		24	
traffic/service group	1800	180	240	24
for median (s = 1)				
speed room (k * top speed)	10480	1048	9760	9976
for k = 1.2				
ensured median top speed	8733	873	8133	8313
for an 8Gbps call out, s =	1.4	1.5	0.7	6.7
speed test success	81%	89%	20%	~100%
utilization	15%	15%	2%	0%

The expected traffic is subtracted from the available capacity to obtain the speed room. When divided by the k of choice (here k = 1.2), the ensured median speed room is obtained. In case the market call-out is 8Gbps (0.8 for upstream in DOCSIS), the resulting s is calculated ($s = (\text{capacity} - k * \text{speed}) / \text{utilization}$). With the sample s-curve from figure 2, the speed test success ratio is determined.

9.2. Service group size

Over time the traffic per customer grows and as a result the number of customers per service group reduces. Metcalfe's law predicts that with less users, the volatility of traffic increases. Investigations have confirmed this in practice. As a result, the cumulative distribution and s-curve will get steeper. This means that smaller variations in traffic or s will result in changed speed room results. For the median it is not relevant how wide the distribution is. But for a guaranteed minimum (95% of time minimum 50%

speed room) a higher s is needed, leading to more capacity. For long-term planning it is recommended to include this in the long term s factor.

10. Conclusions

The capacity that a network needs depends on the traffic and desired speed room. The semi-random behavior of traffic can be modelled with a certain accuracy with a simple formula:

$$\text{capacity} = \text{utilization} * s + \text{speed} * k$$

The formula is most accurate and easiest to implement when the performance is defined for the median speed room. It can be enhanced with multiple planning rules to suit the business or market regulations.

Application of the formula for planning provides the option to diversify the capacity and with that save ~15% of capacity.

The same model provides a measurement tool for speed performance based on regular network metrics. Refinement of the k and s variables can be performed with these virtual measurements or with actual speed test results when available.

Congestion avoidance can be refined because the formula can be used predictively and divide congestion in phases, like in road traffic theory.

Traffic events can disturb the traffic distribution for a short period of time. Video events can be predicted and modelled with the formula or accepted with a reported temporary lower speed room. Big downloads can have a significant and prolonged impact on the performance.

Speed tests are useful to verify the planning and virtual measurement but testing in high volumes should be avoided since the tests influence the result and increase the need for capacity.

The ks formula is a general tool, independent of technology or time. It is recommended for short- and long-term planning and quick speed performance evaluation.

Abbreviations and Definitions

service group	aggregation of channels to serve several customers
Capacity [Mbps]	Total capacity in a service group in Megabits per second
Megabits per second [Mbps]	Megabits per second [Mbps]
GB	Gigabyte

1. Introduction

In this changing business environment, it is crucial to take a proactive stance to be more agile and collaborative. One of the development teams in Comcast Cybersecurity adopted a waterfall methodology for their product development. They committed to understanding requirements, designing to those requirements, and asking teams to develop them once the requirement was signed off.

Agile is a popular methodology for developing products and services, but it hasn't been fully adopted in many organizations. More than ever, Agile has shown to be an effective way to create products and services with proper implementation. It is a culture that changes how teams work together, communicate with each other, and manage their work. It's more than just a new way of doing things. It is a whole new way of thinking about how to do things.

This paper and presentation will talk about the challenges faced by the team, provide a description of Agile, including the planning, implementation and benefits of using this approach. It will show how a transition to Agile delivered significant benefits to our customers.

2. Challenges

The cyber security landscape has been changing rapidly over the last few years, and it has become a constant challenge for organizations to keep up with these changes. There are often delays in the process of analysing customer requirements, often to the point of having them become obsolete before they are addressed. Market conditions often create changes to an initial requirement, which, if not addressed immediately will lead to dissatisfaction of the requesting party. Without an effective communication and feedback cycle, stakeholders are not included in initial discussions or informed of changes leading to a gap in development, stakeholder awareness, and further dissatisfaction. After development and during Testing or User Acceptance Testing can generate minor requirement changes; changes that can take a long time to implement, which might cause the real purpose of the requirement to be lost over time.

3. What Is Agile Management?

Figure 1 – Agile methodology workflow

Agile is an iterative approach to developing software products. It emphasizes the importance of early and continuous delivery of working software, which can be obtained through frequent releases, demonstrating progress early and frequently to stakeholders, and responding quickly to feedback (Figure 1 and Figure 2).

3.1. The Pillars of Agile

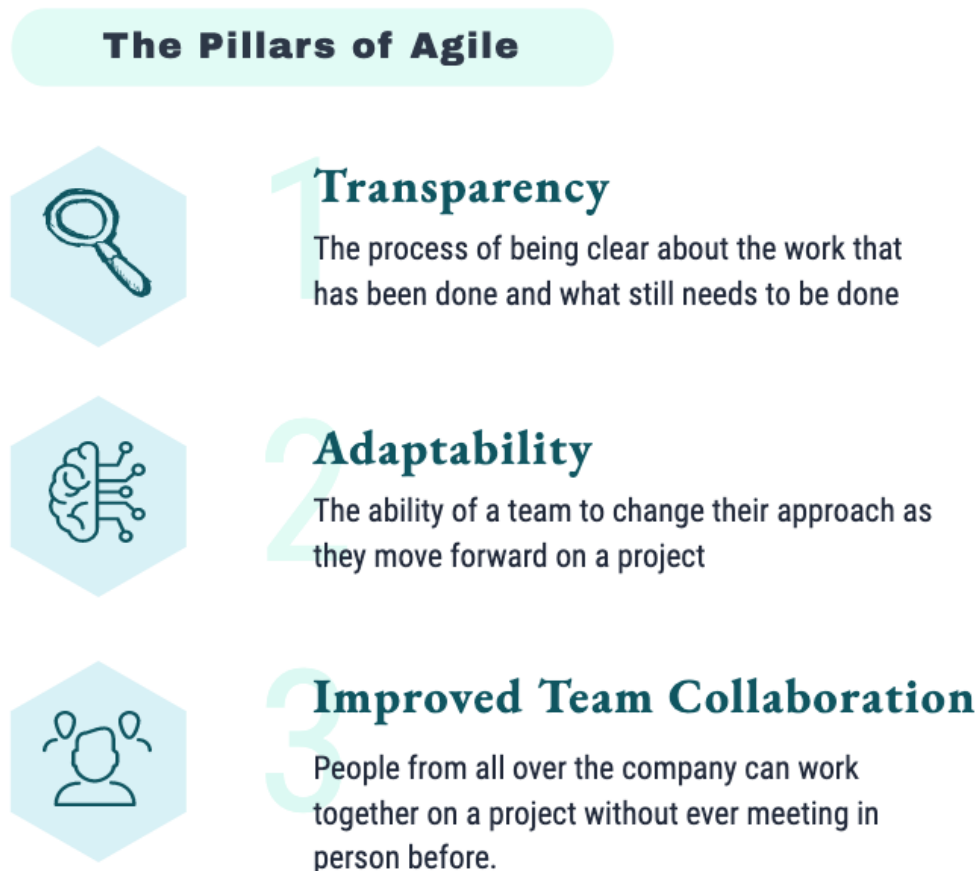

Figure 2 – Pillars of Agile

3.2. Agile mindset

To succeed with Agile methodology, teams must cultivate an Agile mindset. The Agile mindset is a thought process that involves understanding, collaborating, learning, and staying flexible to achieve high-performing results. [3] By combining the Agile mindset with methods and tools, teams can adapt to change and deliver incremental value to their customers. [3] Imagine a concert where each musician plays separate notes without coordination. This is not an impressive performance, and you will be disappointed by the end of the event. Take this case and apply the same scenario to your work environment. Concerts depend on melody, harmony, and rhythm to create a piece of soulful music. Similarly, software teams can successfully deliver the final product when they collaborate, help, share information, and work flexibly.

An Agile mindset (Figure 3) focuses on "being agile" as a foundation for success in "doing Agile." [3] It is defined by the four values and described by the twelve principles of the Agile Manifesto and then manifested through an unlimited number of practices and diverse ways of working. [3]

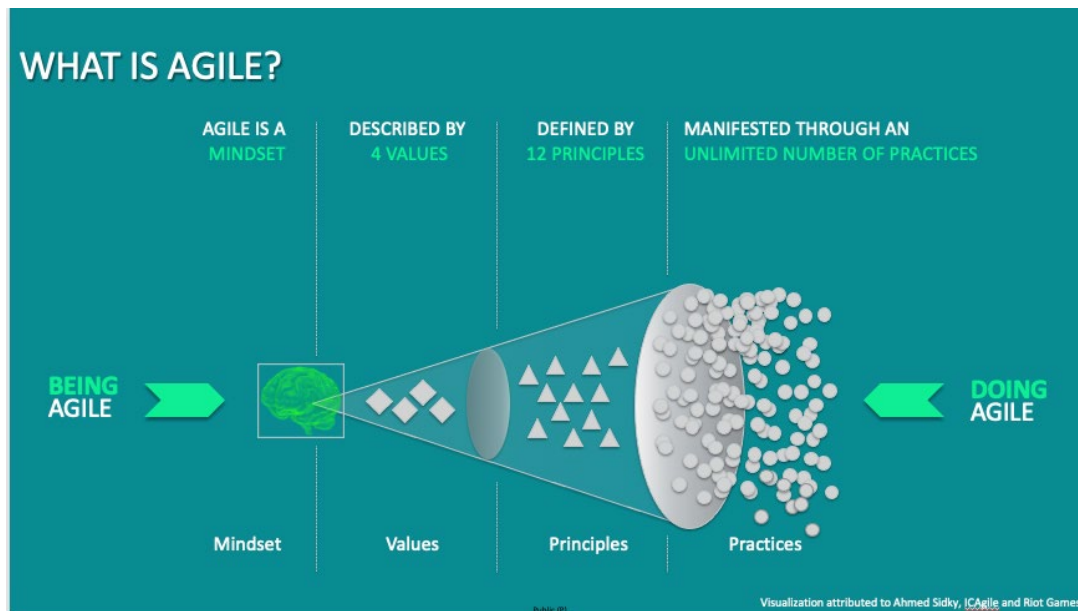

Figure 3 – What is Agile

3.3. Agile Values [10]

We are uncovering better ways of developing software by doing it and helping others do it. Through this work we have come to value:

- **Individuals and interactions** over processes and tools
- **Working software** over comprehensive documentation
- **Customer collaboration** over contract negotiation
- **Responding to change** over following a plan

3.4. Agile Principles [9]

- 1) Satisfy Customers Through Early & Continuous Delivery
- 2) Welcome Changing Requirements Even Late in the Project
- 3) Deliver Value Frequently
- 4) Break the Silos of Your Project
- 5) Build Projects Around Motivated Individuals
- 6) The Most Effective Way of Communication is Face-to-face
- 7) Working Software is the Primary Measure of Progress
- 8) Maintain a Sustainable Working Pace
- 9) Continuous Excellence Enhances Agility
- 10) Simplicity is Essential
- 11) Self-organizing Teams Generate Most Value
- 12) Regularly Reflect and Adjust Your Way of Work to Boost Effectiveness

4. Planning Agile Implementation

“Planning is everything, Plans are nothing”

-Prussian Field Marshal Helmuth Graf von Moltke

Estimating and planning are critical to the success of any software development project of any size or consequences (Figure 4). Plans guide our investment decision. A plan helps us know who needs to be available to work on a project during a given period. [13]

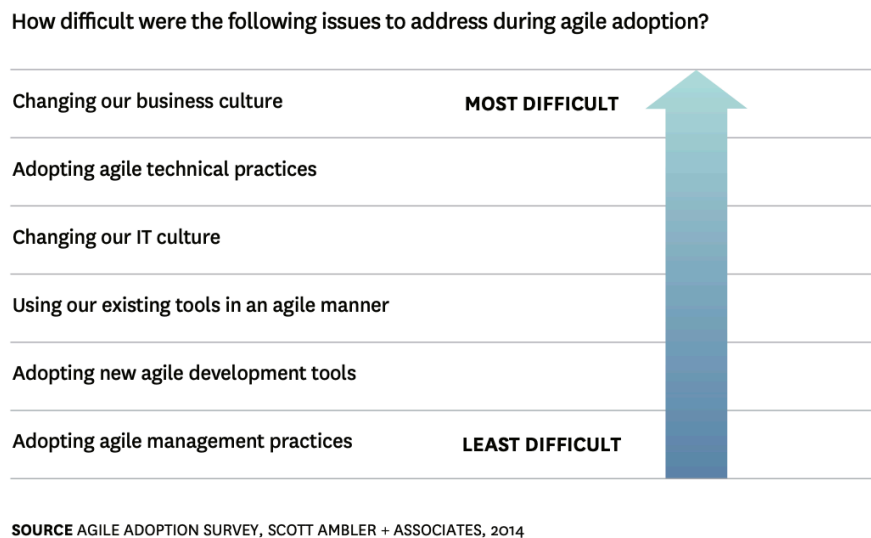

Figure 4 – Difficulty of Agile adoption

Plans are documents or figures; they are snapshots of how we believe a project might unfold over an uncertain future. Planning is an activity. Agile planning shifts the emphasis from the plan to the planning.

Planning for Agile balances work and expense, ensuring we will change the plan throughout our project to improve the outcome. An Agile method is one in which we're not only willing to but are very keen to alter. We want to be flexible because change indicates we've learned something or avoided making an error. We might have discovered that customers want more or less of a specific feature, have determined it is more crucial to have usability than anticipated, or that programming in the new language takes longer than expected. As part of project planning, the team's Agile implementation, we identified and prioritized the requirements, created an initial design, and determined how we'll measure success.

The following are some of the critical steps taken in the planning for Agile implementation in the Cybersecurity team:

4.1.1. Understand the culture and needs of the organization.

Figure 5 – Understand organization culture

Understanding the culture and needs of the team/organization is the key to success in Agile implementation (Figure 5). We realized that change and transformation are not easy. There will be some resistance, but it can be overcome with a proper understanding of the culture, needs, and goals.

The first step we took in understanding the culture of this was to learn about the different modules of their work on an elevated level (what they do), how they do their requirement gathering, design, development, testing (how they do it), identify their end customers, (for whom they do it), and why this development is needed (why do they do it). This helped all parties understand how Agile can fit into their existing framework.

The next step was to listen. Top management was open to hearing other perspectives, and they listened to what others wanted with agility and understood the impact. Once an Agile approach was approved, we identified points of leverage by asking how Agile could serve this project as effectively as possible.

4.1.2. Identify what needs to be changed and what is not changing.

For an organization/team to successfully transition from traditional project management techniques to Agile, it is essential to understand the difference between a change and a non-change, and how these factors affect how Agile implementation should be approached. The answer to this question is dependent on a few distinct factors.

In general, teams like ours which are not Agile need to make fundamental changes to their structure and how they work. We identified what processes need changing and how these processes will be improved.

Some of the key factors we considered when determining if the team needed to change its approach were the goals of the team, the percentage of available time the team spent on projects, and the number of people on the team.

It is essential to understand the different stakeholders' perspectives to communicate with stakeholders about the changes and challenges in Agile implementation. We began by identifying what our stakeholders wanted and expected from us. We then worked specifically on what they wanted, not what they didn't, and then began a process of open and continuous communication so they knew how their ideas were being implemented. This last item, communication, had been identified in our previous development model as an area that could be improved so it was important for us to address.

To ensure that we could identify all the stakeholders and involve them in the process, we created a plan to define the problem/opportunity and to identify the key stakeholders.

There are four main categories of people whom we involved in the change process:

1. those whom the change will directly impact
2. those who need to support the change
3. those who will have a stake in the success of the change
4. those who must manage or implement it

The plan for involving them included getting their buy-in and commitment to participate, identifying what they will do and when they will do it, and identifying what resources they need.

We then developed a strategy for integrating Agile practices into existing organizational processes, policies, and procedures. This allowed us to efficiently integrate these behaviors into all levels of the organization while still preserving those aspects of the existing organizational culture that remain valuable or important to success.

5. Plan for Agile Implementation in a non-Agile Organization

We decided to go with the most popular Agile methodology, which is Scrum. Before planning for an Agile project, we needed the following details (Figure 6).

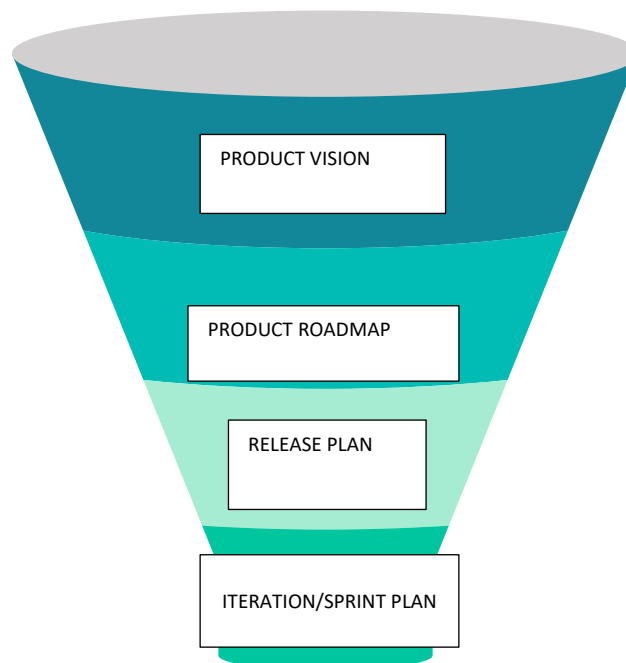

Figure 6 – Steps in Agile planning

5.1. Product Vision

Product vision is the product idea communicated to the team and stakeholders and is the driving force behind a product. We tried to answer the following questions in our product vision document.

1. What is the problem that this product solves?
2. What are we trying to achieve with this product?
3. Who will use this product, and what benefits will they get from it?
4. How does this product make people's lives better or easier?
5. How do we want users to feel when they use our product?
6. What are we going to build, why, and how are we going to do it?

5.2. Product Roadmap

Product roadmaps are a visual representation of a product's future. Creating a product roadmap allowed our teams to visualize the progress of their work and adjust as needed. We used the roadmap to track progress, identify risks, and adjust according to sprint feedback. A product roadmap also helped us set expectations with our customers about what they can expect from our team in the future, which led to increased customer satisfaction and loyalty.

5.3. Create a Release Plan

Figure 7 – Create a release plan

As we did our requirement gathering, we evaluated the time needed for the project along with the constraints of technology, materials, and other considerations. We determined what would be accomplished through technological means or manual labour (Figure 7).

5.3.1. Prioritize Requirements

Agile projects are a way of working that helps teams focus on the priority requirements and deliver the most critical features first. Prioritizing requirements benefited us by allowing our teams to focus on what was essential, allowing us to not get bogged down in less significant details. Prioritization helped us reduce risk as we were able to focus on delivering value quickly, and it encouraged collaboration as we provided a transparent prioritization process.

Prioritizing requirements in our Agile project was a challenging task, and it required our teams to clearly understand the business, product, and product vision. The team also identified the essential requirements to be satisfied first. We prioritized requirements in an agile project using a Moscow (Must Have, Should Have, Could Have, Won't have) analysis.

5.3.2. Create an Initial Design

We developed a design that was easy to understand, aesthetically pleasing, and within the budget. The team worked together to include customers, stakeholders, and Agile team members in building the design.

strategy. We had different perspectives on the problem and did not depend on documentation to express our ideas.

5.3.3. Determine the Success Factor

The success of our project was measured by how well we met our customer's and team's needs during the planning phase. To measure our success, we used criteria such as having a clear understanding of what needs to be delivered to meet customer expectations, a clear understanding of who is going to do each task and how this task will help in achieving the goal. We relied on excellent quality requirements, specification documents, and understood clearly how much time and money it will take to deliver each requirement.

5.4. Who Was Involved in the Plan?

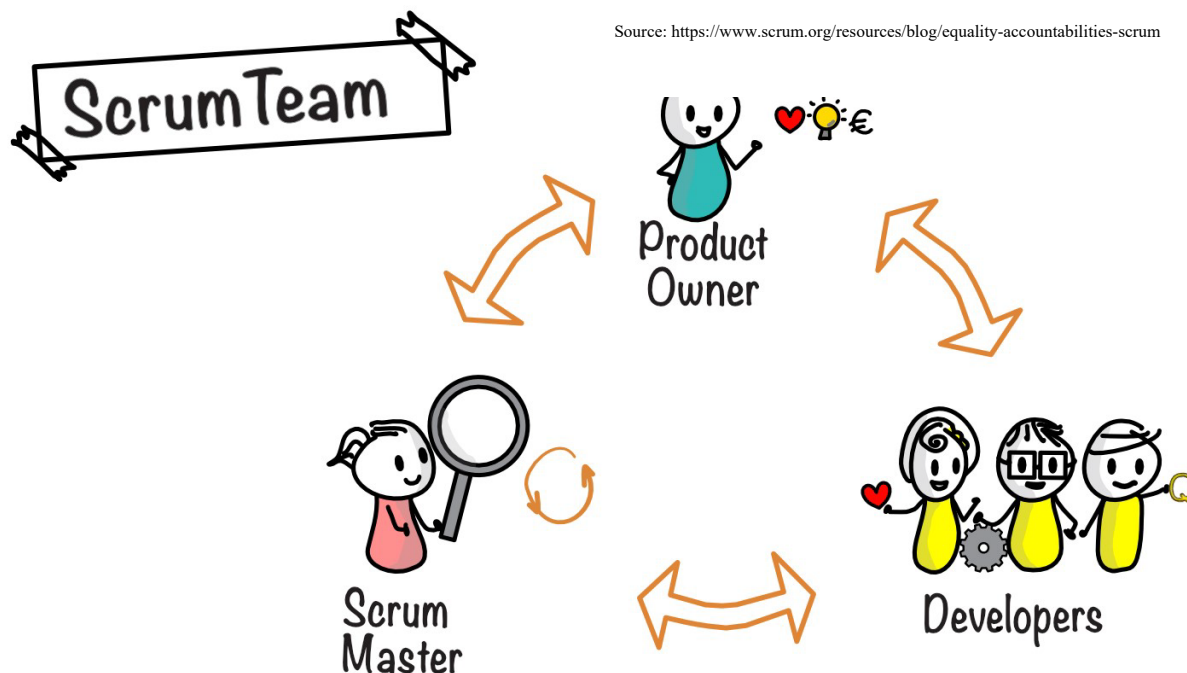

Figure 8 – Scrum team

The Scrum Master is a leader for the team and a facilities provider. He assists the team members in adopting Agile practices to ensure they fulfil their obligations and meet customers' needs. The Product owner provides a full view of the backlog of product requirements and the criteria for acceptance, while the Development Team defines the roles and carries out the work (Figure 8).

5.5. Prerequisites for Iteration Planning

Before we started the Iteration planning, we did the following:

- Ensured that the items in the backlog of the product were sizeable

- Ranked the epics created. Epics are large bodies of work that can be broken down into a number of smaller tasks (called stories) [11]
- Documented the acceptance criteria for each user story. User Stories are short requirements or requests written from the perspective of an end user [11]
- Calculated the number of user stories that could be accommodated into an iteration
- Broke these user stories down into tasks [4] and assigned each to an owner
- Assigned each task an approximate duration

The team members were assigned tasks based on their capacity or speed to ensure that the team member was not overwhelmed.

5.6. Iteration Planning Steps

Iterations are the basic building block of Agile development. Each iteration is a standard, fixed-length timebox, where Agile teams deliver incremental value in the form of working, tested software and systems. [12]

The Product Owner for our product picked up the top item in the existing backlog of items. The team members within explained the tasks needed to complete each user story as they were picked up and were accountable for tasks assigned to them.

The planning poker method was used to determine the complexity of each user story. Those with more story points required more time to develop and test compared to others. Team members were given the flexibility to determine the amount of time it would take them to complete each task.

These steps were then repeated for each item in the iteration process. If any team member was overloaded with work, duties could be re-allocated to others.

6. How To Implement Agile in An Organization That Is Not Agile

The fundamentals of Scrum are simple. To tackle an opportunity, the organization forms and empowers a small team, usually three to nine people, most of whom are assigned full-time. [5] The team is cross-functional and includes all the skills necessary to complete its tasks, and it manages itself and is strictly accountable for every aspect of the work. It is essential to train the team on the Agile framework if they have not previously worked in an Agile environment (Figure 9).

6.1. Design Sprint (Sprint 0)

The design process in an Agile project is iterative, and the process of designing in an Agile project is a continuous cycle of user feedback and design iteration. One of the best practices in Agile Design is to plan for a design sprint.

We started the design sprint by broadly exploring the problem, understanding its scope, and identifying potential solutions. Then, we generated ideas for solutions before focusing on one or two ideas to test initially. Finally, we presented our findings to stakeholders and then chose which idea would be implemented in more detail.

6.2. Project Charter

We kick-started the project by creating a project charter with the team's participation, which included a definition of what "done" meant. This way, when anyone in the team states that they are done with their task, everyone had the same understanding and meaning. We then defined the rules the team would adhere to and be accountable for.

6.3. Scrum Ceremonies

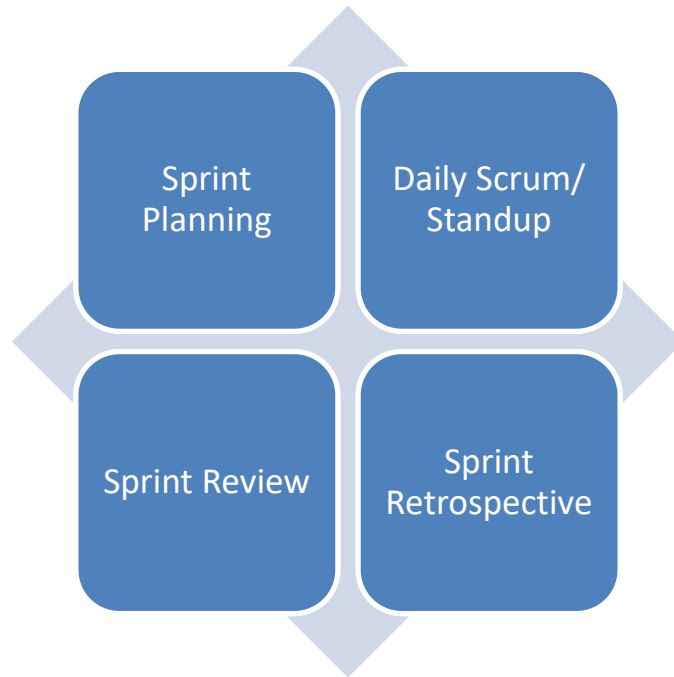

Figure 9 – Scrum ceremonies

6.3.1. Sprint Planning

Stories are committed to developers until they can fill the team's needs and are in line with the priorities of the owner of the product/stakeholders. In the following sprint, the team will utilize average velocity to help them determine the amount they should commit to in any given sprint.

The process began by finding the capacity based on the hours of each team member and subtracting the amount of time required to hold the celebrations during the sprint. For instance, four developers work 40 hours weekly, equal to 80 hours for each 2-week sprint. We subtracted hours for the daily stand-ups and backlog grooming, sprint planning reviews, sprint planning, and the time for sprint retrospectives to calculate the actual hours required to finish stories. Subtract 12 hours for the ceremony from each developer. Thus, their current availability is just 68. Multiplying 68 by 4, the capacity total is 272.

6.3.2. Daily Scrum/Stand up

Four days a week, team members met virtually via a team call and discussed what they accomplished the previous day and the next thing they planned to do the following day. These meetings were less about status and were utilized more for collaboration in the event of dependence and coordination within the team. We also ensured that no one was telling others how to proceed and that all are self-organized to complete the user story at the end of the sprint.

6.3.3. Sprint Review

At the end of the sprint, we conducted a sprint review meeting where the team reviewed/ demonstrated the stories to the product owners. We documented feedback from the product owners and evaluated its

impact on the development process. We used the test environment to highlight the demo where we created records using dummy data instead of actual production data to explain the feature.

6.3.4. Sprint Retrospective

In the sprint retrospective calls, the team reviewed the tasks and efforts they contributed during the sprint. We recorded what went well, what could have gone better, and what did not go well for the duration of the sprint. This allowed us to determine what we would like to put aside, begin doing, and then continue to do. Retrospection at the end of every sprint offered us opportunities for continuous improvement. An enormous improvement in quality, management, and performance happened within just a few sprints (as short as four to six weeks).

As an example, in one of our sprint retrospectives, we discussed that lack of technical documentation led to extended development time as the developers had to spend significant time going through the code to understand and then pick up the enhancement. We started creating technical documentation as, and when, team members had additional time within the sprint which helped us increase the turnaround time. In another example, each team member created their own test framework for testing which led to inconsistencies. We decided to have a common framework on which team members will write their test cases. This helped us have uniformity across testing and test results.

As much feedback as possible was highly appreciated and played a significant role in the overall success of the entire team.

6.4. Metrics for Agile

We categorized Agile metrics into productivity, progress, and quality types.

6.4.1. Productivity metrics

Productivity is a measure of how much work was completed. We used the Agile metrics below to understand how productive the team was.

- **Velocity** measured how much work was completed each time, which can be expressed as story points per day. We calculated sprint velocity based on the story points completed in the first few of sprints.
- **Lead time** measured how long it takes a team to complete their work from start to finish. [6] The team should always aim for short lead times because it's more efficient and cost-effective. [7] <https://kanbanize.com/kanban-resources/kanban-software/kanban-lead-cycle-time>
- We calculated the **average time** it took each team member to start and complete each task over the first four sprints. As an example, we found that Engineer 2 had a slightly longer lead time than Engineer 4 as they spent additional time finding solutions for some challenging problems. We used these metrics and conducted a brainstorming session to identify what we could do as a team to decrease the lead time.
- **Cycle time** is a measure that captures the time taken for the team to complete the sprint, i.e., time taken from In Development to Ready for testing.

6.4.2. Progress metrics

Progress metrics are a measure of how much work is completed.

The sprint burndown (Figure 10) represents actual scrum activities completed compared to the estimates of scrum-related tasks to assess a team's performance throughout a sprint.

Figure 10 – Sprint burndown

Epic and release burndowns are similar to sprint burndowns but epic burndown and release follow the progress across a more significant work body. These metrics are helpful when working with milestones. Also, the burndowns of releases monitor work progress when work is committed to a specific release.

6.4.3. Quality metrics

Quality metrics measure the degree to which the product meets its requirements. There are many quality metrics in an Agile scrum project, but the most important ones include the Quality of Backlog Items which determine how good the items in the backlog are. If they have high quality, they can be easily implemented, and their implementation will not take much effort. On the other hand, if they have low quality, they need more work, or they have a defect or deficiency.

A cumulative flow diagram (CFD) was used to see the status of various tasks - backlog, in-progress review, completed, and in-progress. The metric provided teams with an overview of all the activities in the workflow and the overall progression of the entire project.

The Quality of Team metric determined how good the team was. If they had high performance, the team quickly finished their tasks without much effort. On the other hand, if they had low performance, the team needed more time and effort to finish their tasks.

Escaped Defects allowed us to determine the quality of products received. This measure helped track the number of bugs discovered before a release is put into production.

Throughput measured the team's effectiveness by measuring the amount of work completed and handed over to the client within the period specified. This measure assisted us to determine the duration needed for the creation of software, and it let our end customers evaluate the team's degree of consistency.

The Quality of Product metric determined how good the product was in terms of value delivered (which uses value points to determine the quality of the work delivered to the client).

A control chart was linked to the cycle duration and was used to measure the cycle time of specific issues to assess the method's reliability, predictability, and stability. The control chart is a way to determine the success or failure of various processes within the project and is used to determine if there are any flaws.

7. The Benefits of Agile Methodology

1. Adopting Agile in our project involved teams creating and testing more frequently and delivering improvements to products and services more quickly to customers. Our customer satisfaction increased by 14% in 3 months since implementing this change.
2. The Agile development methodology allowed us to provide top-quality software in shorter release cycles that are more aligned with users' requirements.
3. Agile methodology helped us increase efficiency through more practical communication and was highly flexible to the ever-changing requests of customers. Our overall development-to-testing effort was reduced by over 30%. The number of back-and-forth communications using user acceptance testing decreased from around 5 - 6 rounds to no more than 2.
4. The ever-changing business environment of those customers requires flexibility and innovation on our part. As a team, we wanted to shift toward alignment between IT and business by ensuring that the process could be improved while considering the infrastructure and the technology.
5. We also focused on reducing time, efforts, costs, and expenditures in developing, documenting, testing, and deployment.
6. After Agile implementation in our project, developers and quality assurance (QA) teams were more prepared to work well together, allowing them to create software quickly while working closely with the client.
7. With an Agile approach to software delivery that focused on the set of measurements and metrics, teams were able to organize, plan, and deliver with sufficient certainty and a release-level commitment.
8. Measuring and tracking efficiency improvements cannot be accessed without transparency in the project. Teams responsible for software development and delivery understood the direction they were heading. Further development, testing, and operations teams were made aware of the present state of the project, its performance, and the goals of the project and the company.

8. Conclusion

Agile is a methodology of software development that focuses on the process of iterative and incremental delivery. It is a software development approach that emphasizes collaboration, simplicity, and communication. It also focuses on continuous testing and feedback to achieve higher quality products.

The Agile methodology has been gaining ground in various industries such as healthcare, finance, defence, education, etc. The ability to quickly adapt to changing requirements has made it popular among customers for its flexibility and ability to deliver results faster than traditional methods of project management.

1. Introduction

Spectrum in cable networks is often statically configured to support a mix of DOCSIS[®] 3.0 (D3.0), single carrier-quadrature amplitude modulation (SC-QAM), and DOCSIS 3.1 (D3.1) Orthogonal Frequency Division Multiplexing (OFDM) channels. Generally, more spectrum is allocated to D3.0 based on infrequent adjustments to add additional channels, when possible, informed by utilization and modem technology trends as part of long-range capacity and capital planning processes. These capacity management processes consider many business and policy elements including supply chain, procurement, warehousing and inventory, construction permitting, and work order management for node segmentations and cable modem termination system (CMTS) configuration. These important elements can be made even more effective when enabled through software-defined virtual network functions (VNF) that remove many of the manual procedures via automation and deferral of other procedures and capital investment based on real-time channel and spectrum optimization. Automating these solutions also leads to fewer instances of human error, reduces service interruption, and increases availability.

In one illustrative example, the downstream (DS) configuration consists of 44 D3.0 channels (264 MHz) and 1 OFDM (96 MHz) channel in a node that supports 750 MHz of total hybrid fiber coax (HFC) infrastructure spectrum. A configuration that favors D3.0 from a spectrum perspective is counter-intuitive since OFDM supports higher modulation efficiencies (up to 4096-QAM) and a superior low-density parity check (LDPC) error correction algorithm. Using our Profile Management Application (PMA) VNF [1-2], which adjusts physical layer capacity in real time, Comcast is able to improve DS Mbps/MHz by > 44% on average using D3.1 technology. Yet, conventional wisdom states that expansion of the OFDM spectrum is limited by the D3.1 device penetration. Multi-Gbps products, which are enabled only by OFDM/OFDMA, can help drive this device penetration based on consumer demand.

This paper introduces a fresh perspective on optimizing the spectrum to achieve desired outcomes for product speeds, capacity, node segmentation, and cost effectiveness. The goal of the optimization exercise is to maximize spectral efficiency via reallocation of DS D3.0 channels to OFDM while accounting for any increase in utilization, which may lead to costly node augments. We show that the current configuration and CMTS load balancing place a higher burden on the OFDM spectrum, thus making the conditions ripe for spectral reallocation. This reallocation creates a material positive benefit in support of multi-Gbps products. Lastly, we present a VNF concept to farm the D3.0 spectrum and manage load balancing in an automated fashion.

2. How Downstream Spectrum is Utilized

A common spectrum configuration assigns 44 SC-QAM channels for D3.0 and a single 96 MHz D3.1 OFDM channel (equivalent spectrum to 16 SC-QAM channels). Historically, before D3.1 device penetration accelerated, the OFDM channel was thought of as a “bonus” that offers some relief to the D3.0 spectrum and allows the D3.1 cable modem (CM) devices access to exclusive speed tiers (e.g., 1 Gbps and higher). However, D3.1 device penetration has been steadily increasing, mostly by organic means (i.e., new customers opting for the “latest and greatest” cable modems with the best Wi-Fi capability). The distribution of D3.1 CM penetration across all service groups (equivalent to a downstream port on a CMTS) and hardware platforms at Comcast is shown in Figure 1. The median D3.1 penetration has recently crossed a critical level with the consequence that the traffic loads on D3.0 and D3.1 technologies in the spectrum are now comparable on average (but vary per service group). This balance means that a more thoughtful spectrum allocation strategy is now required. Such a strategy may be tailored to the specific characteristics of a service group and considers aspects that include D3.0 and OFDM channel utilization, traffic forecast, projected growth in D3.1 device penetration, and plant

configuration, as well as all the nuances of the current spectrum configuration (location of video, video-on-demand, tones, local inserts, etc.).

Figure 1 - Histogram of D3.1 device penetration across the network. Service group counts omitted from the y-axis on purpose as they do not inform the discussion.

Additional D3.0 distributions of interest are shown in Figure 2. Panel 1(left) confirms that a 44 SC-QAM configuration is the most common, though other variations exist (namely, 40, 36, 32, 24). Panel 2 shows the distribution of the number of DOCSIS devices per service group. Panel 3 is the distribution of service group utilization for the D3.0 part of the spectrum. Service group utilization was calculated by first averaging the point-in-time utilization (sampled at 5-min intervals) across all D3.0 channels in the service group then taking the 98th percentile sample within a 30-day period as representative of the utilization. Typically, service groups that fall above the 80% utilization level are considered to be highly utilized and may require some form of remediation (it could involve, for example, “splitting the node” to create two service groups out of the original one). Finally, Panel 4 (right) shows the D3.0 channel utilization variation range (max – min) within a service group. This metric is a gauge of the CMTS internal load balancing function within the D3.0 spectrum given that each device is allocated a subset of the 44 channels to use (each unique subset is referred to as a downstream bonding group). Though not shown here, we found a large discrepancy between our primary hardware platforms in terms of D3.0 load balancing ability, with some achieving much tighter utilization spread among the SC-QAM channels than others.

Figure 2 - Distributions of (1) number of D3.0 channels per service group, (2) number of devices per service group, (3) D3.0 service group utilization, and (4) D3.0 utilization range across channels within the service group.

What is more important for the concept of spectrum allocation is the load balancing between the D3.0 and the OFDM parts of the spectrum. The CMTS will tend to shift traffic for D3.1-capable devices heavily in favor of OFDM on some of our hardware platforms. For example, on our virtual CMTS (vCMTS) we can influence the load balancing through other VNF and micro-service opportunities. This is beneficial as it allows us to be maximally spectrally efficient, but the higher utilization of D3.1 should be anticipated and accounted for as part of the capacity planning process and policy described in the introduction. To further investigate this feature of CMTS functionality, consider the joint distribution for D3.0 and OFDM service group utilizations shown as scatter plot in Figure 3. In the ideal scenario, with evenly balanced D3.0 and OFDM, the distribution would be centered around the 45° bisector line (shown as black line). Instead, the joint distribution reveals higher OFDM utilization compared to D3.0 (orange line-of-best-fit rotated counterclockwise (CCW) relative to the 45° line). A few points regarding how this data is interpreted:

- At the current median D3.1 penetration level, balancing the D3.0 and OFDM utilizations is challenging for the CMTS owing to the limited spectrum allocated to OFDM. The imbalance is further affected by the fact that the highest speed tiers can only be accessed using D3.1-capable devices.
- More heavily used service groups are driven in large part by the OFDM portion of the spectrum, implying that the D3.0 part has excess bandwidth to yield.
- The joint distribution will continue to rotate counterclockwise (CCW) as D3.1 device penetration continues its organic growth and as CMTS scheduler management is improved, causing more service groups to cross the high utilization threshold due to high OFDM utilization.

Given all of the above, shifting some spectrum from D3.0 to OFDM is a win-win opportunity:

1. It relieves service groups that are heavily utilized in the OFDM spectrum.
2. It adds capacity to the network enabling even higher speed offerings.

Yet, this is not a one-size-fits-all situation and must be targeted within a well-considered spectrum reallocation program.

Figure 3 - Joint D3.0 and OFDM distribution shown as a scatter plot. The black line is the bisector (45 deg. angle) and the orange line is line-of-best-fit for the scatter.

3. D3.0 Spectrum Farming Approaches

This section explores two D3.0 spectrum farming approaches and estimates their impact on service group utilization and capacity. First, presented below are some guiding principles that apply across all analyses:

- It is understood that farming D3.0 spectrum presents a trade-off: overall capacity is increased because of the higher OFDM efficiency compared to SC-QAM, but the D3.0 service group utilization may also increase because of the lost D3.0 spectrum and the fact that not every device in the service groups is D3.1-capable.
- Utilization is assumed to scale linearly with the amount of added/removed spectrum, which is a reasonable assumption that applies to both SC-QAM and OFDM. Thus, this assumption is used as a recipe to project the impact of adding/removing spectrum on utilization.
- For the time being, we ignore second order effects. For example, the fact that increased capacity will enable higher speed tiers, which will in turn lead to higher traffic and increased service group utilization. We also ignore that the load balancing function may adjust given the re-allocation of available capacity between technologies. Note that such changes in speed offerings and customer behavior are tackled within the traffic forecasting and capacity planning functions.

The first approach considers farming the same number of SC-QAM channels across the entire footprint. While such an approach is not favorable from the perspective of the ultimate optimization, it is appealing from the perspective of its simplicity: maintaining a single standard configuration and avoiding development of what could be a complex spectrum management system. Estimating the impact of network wide reallocation of spectrum is straightforward. At any given number of converted SC-QAM channels, the utilizations of the D3.0 and OFDM components of a given service group are scaled proportionally to the lost or added spectrum. The efficiency assumptions of the D3.1 channel are based on years of PMA [1,2] experience across tens of millions of modems.

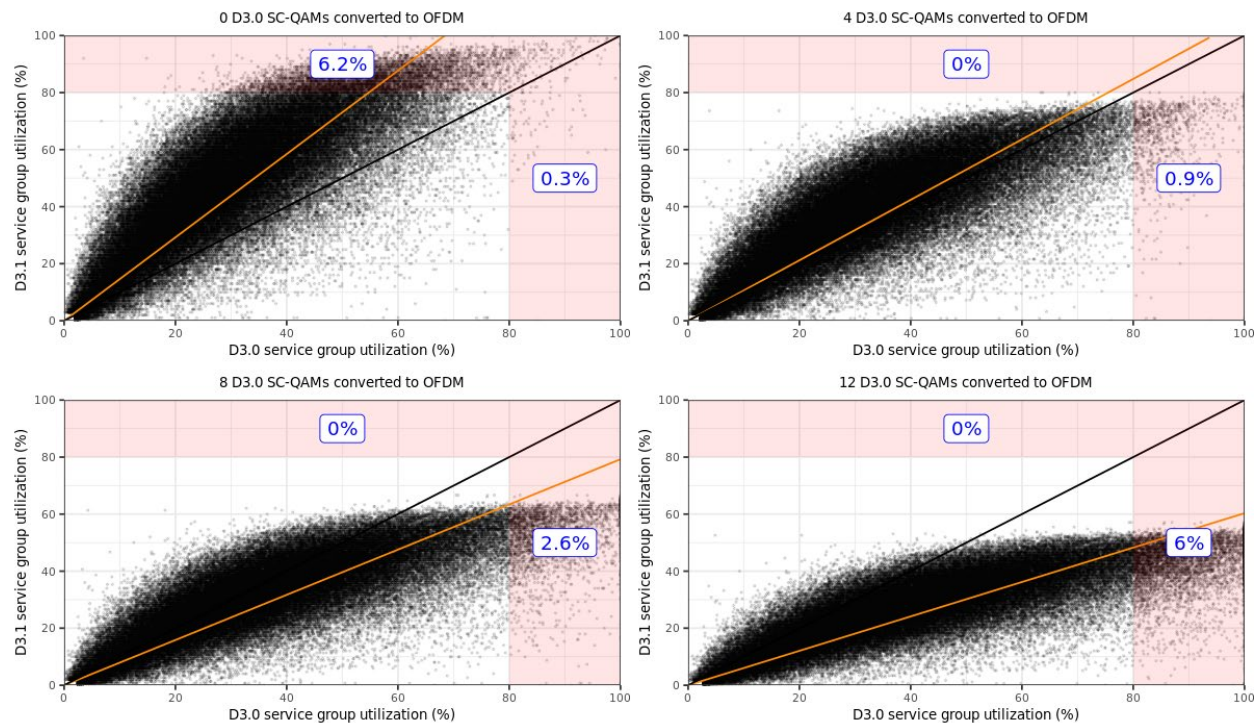

Figure 4 - Joint D3.0 and OFDM distributions at different number of SC-QAM channels converted to OFDM. (Top left) 0 channels converted—representing the baseline, (top right) 4 channels converted, (bottom left) 8 channels converted, and (bottom right) 12 channels converted.

Results of the impact analysis are shown in Figure 4. Each of the panels explores the impact of converting n SC-QAM channels to OFDM, with n being 0 (baseline), 4, 8, and 12. Highlighted on the plots are service groups that are heavily utilized (>80% utilization) falling in the shaded pink area with the percent figure annotated. It is evident that as more SC-QAM channels are converted, the joint distribution rotates clockwise (CW) as expected. At the highest level of converting 12 channels, we end up at roughly the same ratio of service groups that are heavily utilized (~6%) yet these are now driven by the D3.0 utilization rather than OFDM. Under this scenario, no relief is gained in terms of the number of service groups that require remediation as a proxy for equipment and labor capital for adding network capacity. However, ~200 Mbps of capacity was added to each service group in the network (OFDM is estimated to be 16.6 Mbps more efficient than D3.0 per converted 6 MHz channel—this estimate is based on current PMA performance where OFDM is deployed). Also, based on the results in Figure 4, one can argue that converting 4 SC-QAM channels is an easy decision: it alleviates almost all utilization issues while adding a modest ~66 Mbps of capacity to each service group in the network.

To support multi-Gbps downstream product speeds, additional Mbps are needed than can be accommodated with the baseline configuration scenario. This speed requirement is particularly challenging with HFC design spectrum limits such as 750 MHz or 860 MHz node deployments. The only way to accommodate the capacity needed by a multi-Gbps product speed is to re-allocate more OFDM spectrum by reducing D3.0 spectrum in these nodes or via a labor-intensive spectrum upgrade.

The second approach manages spectrum on an individualized service group level. The idea is to convert any number of channels such that:

- The SC-QAM block is not reduced beyond 24 channels as this number corresponds to the maximum number of D3.0 channels to which a D3.0 device is able to bond. Thus, a 44 SC-QAM block will have a maximum of 16 channels to convert.
- The projected D3.0 service group utilization does not exceed 60%, which is a level that allows a safety buffer of several years compounded annual growth rate (CAGR) of 20% before exceeding 85%. Similar models have been developed based on peak period available bandwidth targets.

The analysis shown in Figure 5 explores this approach when applied to service groups that are currently configured with 44 SC-QAM channels. It can be seen from Panel 1 (left) that most service groups are able to release 16 channels for conversion without driving D3.0 utilization above the 60% level. For those service groups that are already utilized above 60%, no channels are converted. Other service groups fall between the 2 extreme cases and are able to convert some number of channels between 0 and 16. Comparison between the current D3.0 utilization (Panel 2) and the projected D3.0 utilization (Panel 3) shows a stark difference. The projected distribution does not exhibit a normal shape as it is artificially constructed from different sub-populations; most notable, the sub-population that was driven to the 60% limit. Lastly, Panel 4 reveals the extent of added capacity: most service groups increased their capacity from just under 2.5 Gbps to above 2.8 Gbps.

Figure 5 - Analysis exploring converting up to 16 SC-QAM channels to OFDM. The number of converted channels is specific to each service group and selected such that projected D3.0 service group utilization does not exceed 60%.

4. View of the State of the Spectrum

The concepts discussed so far present the problem of spectrum farming in an idealized fashion whether the approach is based on a completely dynamic policy optimizing capital investment lifetime or is based on policy constraints. It sufficiently covers the core dimensions pertaining to D3.1 CM penetration, service group utilization, and service group capacity. However, it ignores some important practical aspects to spectrum farming. One of these foundational pragmatic requirements is the challenge around having high confidence visibility into current spectrum allocations on every node. For instance, the Comcast network includes a variety of different hardware platforms, different plant configurations, and different spectrum allocations across localities – e.g., placement and number of video quadrature amplitude modulation (QAM) channels, DOCSIS channels, local video insertions, amplifier automatic gain control (AGC) signals, leakage markers, etc. In a 1 GHz plant, it might not be required to convert SC-QAM channels as the configuration is expected to contain enough vacant spectrum to deploy multiple increased bandwidth OFDM channels. Yet, even in this scenario, it is necessary to understand how the spectrum is currently utilized and the kind of housekeeping that is needed to free up contiguous spectrum blocks. More importantly, striving for a standardized spectrum configuration is a goal in its own because standardization simplifies both day-to-day operations before software management can take over and

deployment of future technologies (e.g., full duplex (FDX), and high split). Given these dynamics, it becomes obvious that automation is a prerequisite to any effort directed towards:

- Optimizing capacity in HFC network segments with limited spectrum by converting D3.0 channels to OFDM.
- Freeing up contiguous blocks of spectrum to deploy OFDM where plant configuration allows it.
- Relocating specific channels in order to move towards a steady state with a few standardized configurations across the network.

Presented in this section are early explorations into concepts that are foundational to the spectrum management tool. The first exercise involved gaining a complete picture of the state of the spectrum configuration across the network. The initial phase of data collection was limited to the vCMTS platform. Data from various sources were merged to provide a unified view on the downstream configuration for every remote PHY device (RPD), which is used in this paper as synonymous to a node, managed by the vCMTS platform. This data analysis task confirmed the lack of standardized configuration as it revealed that ~700 distinct permutations exist for the tens of thousands deployed RPDs. Figure 6 shows three example configurations that represent a small part of the diversity of what is deployed in the field. These examples fall within the top 25 configurations, which covers most of the nodes, creating a “long tail” in the distribution of custom DS channel configurations. Notice the sharp contrast between the three configurations. The first (Rank 1 in RPD count) has a block of vacant spectrum above 750 MHz ready to be used for OFDM expansion. The second (Rank 2) has a lot of vacant spectra but in a more fragmented way, with 2 SC-QAM blocks surrounding the OFDM channel. The third (Rank 21) has vacant spectrum in the expansion region as well but except for a 6 MHz “local insert” channel at ~850 MHz. The local insert could be thought of as a video channel combined locally with the cable signal to serve a specific use (e.g., a security camera system within a hospital or a housing development). This type of spectrum use presents a problem for OFDM expansion. Yet it is often the case that these types of exceptions are not easy to trace since the configuration found in the data is registered for an entire site (large set of RPDs) even if the insert is physically available only on a single RPD or on a node leg. This situation highlights the importance of adding a validation layer on top of the picture that was constructed solely from various configuration data sources.

Figure 6 - Example of three common downstream spectrum configurations.

A validation methodology was adopted that is based on using the full band spectral capture from CM gateways to infer whether a range of spectrum is occupied or vacant. Briefly:

- Raw spectra (117 KHz resolution bandwidth) are captured from every DOCSIS device on the to-be-validated nodes.
- Channel power is calculated from raw spectra for the standardized 6 MHz EIA channel plan.

- A threshold is adopted for determining whether the channel is in use or vacant. For the results presented here, the threshold was set to -40 dBmV.
- Device-channel level data is aggregated to the RPD-channel level and to the configuration-channel level.

The outcome of the vacancy detection process is shown in Figure 7 in the form of a dark gray band overlaid on the configuration map. It is seen that the vacancies detection algorithm performs well as the spectrum gaps neatly correspond with documented vacancies. There are few exceptions. Tones for amplifier AGC, local modulator, or leakage usually overlap with inferred vacancies since these are much narrower than the 6 MHz channel. Furthermore, leakage tones are allowed to be placed within a DOCSIS block, so they should be ignored. What is more interesting is the overlap between the local insert at 850 MHz (Configuration 21) and the inferred vacancy. Since this configuration is shared by 378 RPDs, the local insert may be present in only a small subset of these or even just a single smaller multi-dwelling unit (MDU) on a node that also serves other customers. A deep dive into the device and RPD level data reveals 2 interesting findings shown in Figure 8:

- The local insert was confirmed on one RPD out of the 378 that share the same configuration. 100% of devices on the RPD exhibited energy above the noise level on that RPD.
- Energy was picked up by 50% of devices on a different RPD on a channel that does not correspond to any known use in the configuration (at 885 MHz). Further investigation revealed that the signal represented ingress from a recently installed police repeater.

The first case requires field work to move the inserted channel to a different location and certify that the RPD can proceed with OFDM expansion. The second case does not require any further action since ingress is more appropriately handled by customized OFDM profiles within the PMA system along with plant maintenance dispatch for downstream ingress remediation.

Figure 7 - The same configuration shows in the previous figure with the outcome of vacancy detection overlaid as dark gray band.

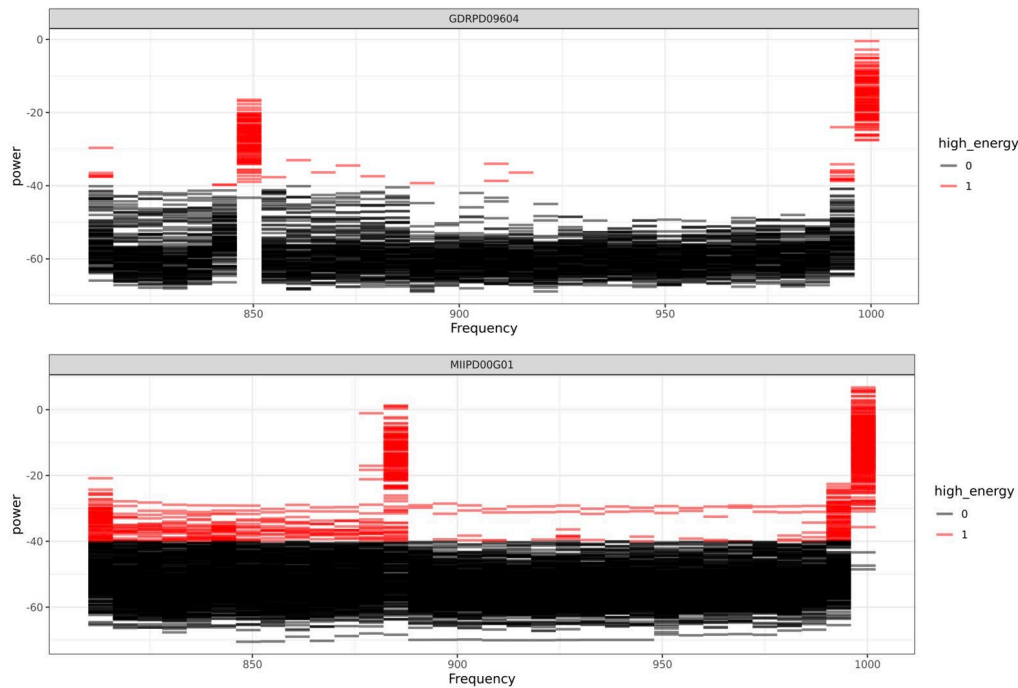

Figure 8 - Example of two “conflicts” picked up by the vacancy detection algorithm: (1) a local insert was confirmed at 850 MHz, and (2) ingress due to police repeater was picked up at 885 MHz on a different RPD.

These early explorations show that we now have a methodology for capturing and validating the state of the spectrum configuration. The subsequent steps involve:

1. Automating the pipeline for building and validating the spectrum configuration for every node in the network (both integrated CMTS (iCMTS) and vCMTS platforms).
2. Implementing an algorithm for moving spectrum around to free up contiguous spectrum blocks for OFDM expansion.
3. Implementing the algorithm for farming D3.0 spectrum where plant configuration restricts use above 750 MHz.
4. Developing a layer that translates the output from both algorithms into the CMTS-specific configuration.
5. Ensuring visibility into real-time spectrum allocations and the technology used in that spectrum is available to all stakeholders. This includes the capacity planning tools and process to ensure optimized investment in network expansion only where and when it is needed.

5. 2 Gpbs Testing

In this section, we introduce some of the preliminary speed test results for a 2 Gbps downstream service to demonstrate how additional OFDM spectrum could be used for higher broadband product speeds. The potential of higher speeds is one of the primary motivations behind the D3.0 farming development. The downstream spectrum configuration for these experiments was 28 SC-QAM channels & a single 192 MHz OFDM on the iCMTS and 44 SC-QAM channels and a single 192 MHz OFDM on the vCMTS.

Figure 9 shows that a single D3.1 cable modem can reach 2.3-2.4 Gbps data throughput over iCMTS and vCMTS systems when there are no congestion or radio frequency (RF) noise issues.

Figure 9 - The data throughput over iCMTS (top 2 panels) and vCMTS (bottom 2 panels) for a single D3.1 cable modem demonstrating speeds in the 2.3-2.4 Gbps range. The different colors indicate different TCP flows utilized by the speed test.

The serving group utilization and RF noise issues may affect the maximum achievable rate at any given time. Figure 10 displays an example for a D3.1 cable modem in a service group with different utilization levels measured within a 15 second window. The results are used to analyze the average and peak utilization levels of the service group to confirm the service group availability for the 2 Gbps speed tier and to drive service group upgrade strategy accordingly. The graphs on the left correspond to relatively high utilization levels and correspondingly impact 2 Gbps speed test results compared to the graphs on the right in which the service group utilization is low. This is analyzed further in this section with more examples to show the impact of utilization burstiness and transmission control protocol (TCP) behavior on supporting higher downstream rates.

Figure 10 - Speed test results for a 2 Gbps speed tier. There are no RF issues observed for this cable modem and corresponding node. However, utilization levels during the speed test have an impact on the results. Purple lines are total octets at service group level while yellow lines are total octets for the OFDM channel. The load telemetry data is displayed with a delay compared to speed test timing displayed in the bottom of each graph and indicated by a red arrow.

With the increased speed tiers and emerging applications, new characteristics have been observed for the ratio of peak-to-average traffic load and peak duration per subscriber and per serving group. As discussed in [3], the higher service tiers have higher burst rates. Although traffic load averaged over longer time periods such as 5 minutes may be low, bursts observed within smaller time windows in the order of seconds can be 10-20 times higher for the current pre-FDX rates. For Gbps rates, microbursts can be observed within windows on the order of microseconds. Microbursts may happen due to service characteristics, network segments with different rates and classic TCP protocol response during congestion [4,5].

Traditionally, utilization in each channel at a CMTS is reported per 5-minute interval. New telemetry models can provide utilization values at 15 second intervals. Measuring traffic utilization and burstiness at smaller window sizes may not be feasible for large scale systems. However, this information is crucial in network analysis. As discussed in [6], bursts and their overlap by multiple users can be infrequent and these short-term bursts may have little impact on aggregate values, but the spikes may have a significant impact on services like gaming, videoconferencing, and augmented reality/ virtual

reality (AR/VR) applications. Internet service providers (ISPs) must develop effective measurement and prediction systems to project granular measurements at small scales to aggregated scales.

An example is shown for an iCMTS with the same settings described for Figure 9. A speed test is performed for a subscriber with 2 Gbps DS speed tier rate, between 7 and 22 seconds as shown in Figure 11. Initially, the serving group load is close to 0.9 Gbps before the speed test starts. After the speed test starts, a set of bursts occurs between 12 and 18 seconds and affects the speed test outcome as the service group is highly utilized during this timeframe. Figure 12 displays the total average load measured at iCMTS. The measurements are collected via a command line interface (CLI) command to get the bit rates for each DS channel. One set of the measurements provides the load averaged over a 30 second window while the other set provides the load averaged over a 1 second window, which is a more accurate representation of the burst that impacts the speed test as shown in Figure 13.

Figure 11 - Total data load computed at the traffic generator's customer premises equipment (CPE) ports connected to the CMs in the serving group. The speed test runs between 7-22 seconds.

Figure 12 - Total average load measured at the iCMTS by summing 30 sec and 1 sec channel loads in the serving group.

Figure 13 - Speed test result from the traffic generator GUI.

This example shows that utilization and other metrics must be analyzed at more granular levels with increased speed tier rates. Burst level analysis is crucial in network planning, cost analysis, quality of experience (QoE), and speed assurance as well as optimization of network functionalities for efficiency and fairness.

6. Conclusion

We presented our perspective on reallocating D3.0 spectrum to OFDM, motivated by the need to increase service group capacity to support higher speed tier offerings. We conclude that:

- The growth in D3.1 device penetration has now reached a level where reconsidering how downstream spectrum is allocated between D3.0 and OFDM is necessary.
- The objective of reallocation is twofold: increase service group capacity to enable higher speed offering and provide relief to a currently highly utilized OFDM spectrum.

- To this end, two approaches were presented: a one-size fits all farming of D3.0 channels, vs. a customized recommendation that considers service group characteristics.
- The latter, due to its dynamic nature, requires building a spectrum management tool; a cornerstone of such a tool is building a unified source of truth for the current state of the spectrum configuration.
- Such a tool also feeds into additional spectrum housekeeping efforts that are targeted towards freeing up space for expanded OFDM region in support of enabling 2 Gbps and higher downstream speeds.
- These spectrum management and farming VNFs will be critical to managing spectrum effectively as the future evolves towards DOCSIS 4.0 and multi-Gbps symmetrical services.
- Initial speed test results reveal the importance of increasing service group capacity via an approach that considers the speed test result sensitivity to utilization and the impact on TCP flow control behavior when testing for these very high speed tiers.

1. Introduction

This paper will discuss the top-5 things an operator should know about operating a virtual cable modem termination system (vCMTS). Specifically, five key aspects will be discussed including deployment, scalability, capacity, troubleshooting, multitasking, power, and space needed for operating the vCMTS. The reader will understand that legacy CMTSs and vCMTSs are similar in most cases, especially from an operational and deployment standpoint. This means that if a user is familiar with operating a legacy CMTS then they should be comfortable migrating to a vCMTS. Further, the paper will explore some advantages that may make vCMTSs attractive to cable operators over legacy CMTSs. By the end of the paper the reader should have confidence in understanding that vCMTSs are quite like legacy CMTSs from a features and performance standpoint, while adding other valuable benefits and functionality that the reader may not have considered prior to reading this paper. Sit back and enjoy the read.

2. DOCSIS Primer

Data-Over-Cable Service Interface Specifications (DOCSIS[®]) technology is effectively a transparent Ethernet bridge over a hybrid fiber/coax (HFC) network. There are two functional components in a DOCSIS network, the cable modem (CM) on the subscriber side and the CMTS in the headend or hub site. The CMTS communicates with the CMs on one or more single carrier quadrature amplitude modulation (SC-QAM) channel(s) and/or orthogonal frequency division multiplexed (OFDM) channel(s). Data on these channels is digitally encoded on radio frequency (RF) signals on the downstream path of an HFC network between 108 and 1.2 gigahertz (GHz). The CMs communicate with the CMTS using one or more SC-QAM and/or orthogonal frequency division multiple access (OFDMA) digitally encoded RF channels, transmitted on an upstream HFC frequency between 5 to 204 MHz (note these frequencies will change with DOCSIS 4.0). The digital data contains DOCSIS management information in addition to subscriber traffic. The CMTS is the system scheduler which coordinates the power level, frequency, transmit time, and pre-equalization of all CM signals on the DOCSIS network.

3. CMTS Overview

In any CMTS you have the hardware, the operating system software, the application software, and switching equipment. A vCMTS is made up of these same components by integrating the operating system, management software, and application software on a commercially available server.

What is a legacy CMTS as defined in the introduction of this paper? A legacy CMTS is a chassis based CMTS containing downstream and upstream RF cards utilizing on-board software and/or firmware for system operation. In DOCSIS 3.1, legacy CMTSs may be augmented to support distributed access architecture (DAA). In this scenario, the legacy CMTS may not have on board RF cards, but instead the RF and physical layer (PHY) portion will extend to a remote PHY (R-PHY) node, but the medium access control (MAC) processing is still performed in the legacy CMTS.

A virtual CMTS or vCMTS on the other hand, is software that is purpose built to run on commodity servers. Proprietary vCMTS software is installed on the server that converts the server into a vCMTS platform. A network interface card (NIC) attached to a switch connects the server to an R-PHY node or shelf and a DAA architecture is created, like the DAA architecture described with the legacy CMTS.

Figure 1 shows a high-level architecture of the cable access network showing both a converged cable access platform (CCAP) and a vCMTS with DAA deployments.

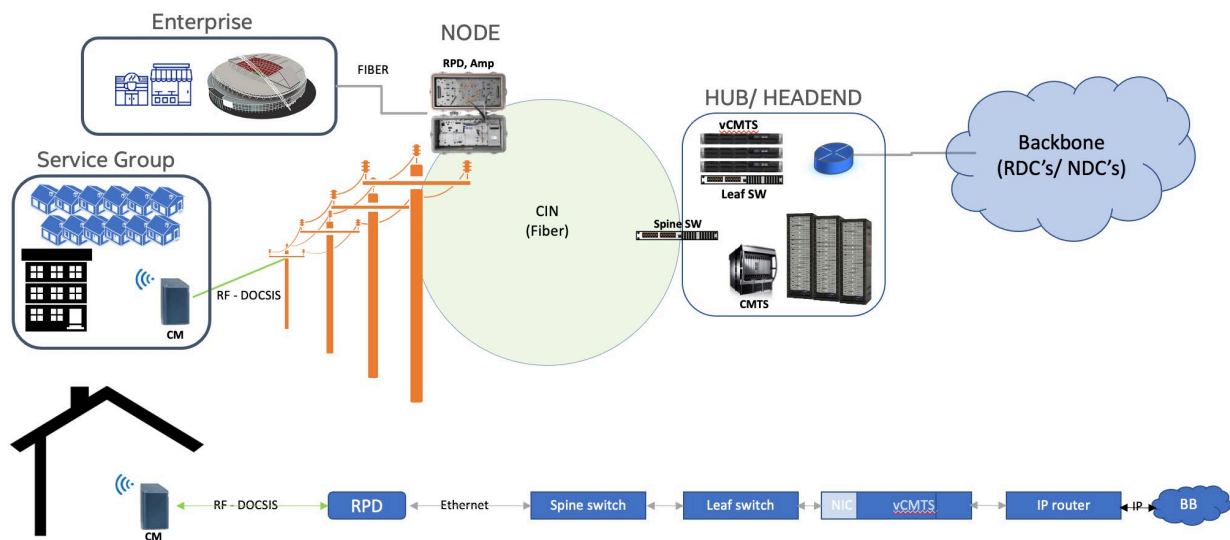

Figure 1 - Cable Access Network Diagram

4. How do I deploy?

The first aspect of turning up any DOCSIS HFC plant, be it legacy CMTS or vCMTS will be the initial deployment. While some aspects differ, particularly when comparing a legacy CMTS to a vCMTS initial deployment, many of the same setup procedures will be the same, just taking different forms. This makes sense because the functionality of a CMTS is just reproduced through virtualization of the CMTS. One area that greatly differs, is the amount of physical setup required for each device since legacy CMTS products require a large amount of either coax (analog) or fiber (digital) for the data ports, along with a much larger physical weight needing to be racked, as can be seen in Table 1.

Table 1 - Physical attribute comparison of different CMTS systems

	I-CCAP	D-CCAP	vCMTS
Data Cables	186 (RF) + 4 (Fiber)	68 (Fiber)	12 (Fiber)
Weight	429 lbs	429 lbs	36 lbs/server (3 servers = 108 lbs)
Power Cables	20 terminal cables	20 terminal cables	6 pluggable cables

Note:

- Weight is inclusive of the equipment such as chassis, line cards, power supplies, etc. Items such as optics, combiners, cables, are excluded from the weight calculations.
- D-CCAP may be several pounds lighter due to PHY modules being removed.

4.1. Legacy CMTS Deployment

Initial deployment of a legacy CMTS begins after the gear has been rack mounted, all linecards and physical NICs installed, and the devices are cabled up. Once the device is up and running, a console terminal is opened, and the management interface, security, host information, and secure shell host (SSH) access are configured through Command Line Interface (CLI). The software and firmware are then upgraded to the proper versions. Networking is then configured with wide area network (WAN) interfaces, loopback interfaces, and routing all being configured for the CMTS to communicate with the network elements (NE). Connectivity, routing, and networking are then verified, completing the initial setup.

DOCSIS configuration can now begin after the initial deployment is completed. There are multiple items that will need to be configured through CLI for the system before service group (SG) provisioning can occur. The first item to be configured is the quadrature amplitude modulation (QAM) profiles; an example of this is shown in Figure 2.

```
Router(config)#cable downstream qam-profile 13

```

Figure 3 - DS controller configuration

This process is repeated for the upstream (US) side with modulation and OFDMA profiles being configured.

With the profiles now created, the controllers can then be configured by applying the profiles to them. With the controllers configured, the Cable, DS Cable, and US Cable interfaces are configured by associating the controllers to them, configuring the MAC-Domains as the channels get bound to it. Configuring SGs continues by creating a Fiber Node by assigning the US and DS cables to it, which creates and associates the US SG and DS SG to the MAC Domain. The CMTS's RF output is checked at the head end to ensure it falls within specified values, and the system is connected to the RF passive equipment. To monitor the system, simple network management protocol (SNMP) is configured and connected to an external software source.

4.2. vCMTS Deployment¹

Initial deployments of a vCMTS cluster consist of a few steps. The server hardware, networking equipment (routers, switches) need to be racked and cabled up, with their management and baseboard management controller (BMC) IP addresses configured, along with the required network configurations so that access is allowed. From there, an external computer, or virtual machine with network access to the devices can be connected and loaded with an automation tool such as Ansible to act as a deployer. The vCMTS software images, operating systems and Ansible playbooks get loaded on to the deployer. A configuration yet another markup language (YAML)² file is created containing all the host information and passwords that are required for the vCMTS cluster deployment. A playbook is then executed, deploying the operating systems, vCMTS software packages, and containers which are automatically deployed and synced for the cluster. After the cluster is deployed, they are connected but unconfigured to talk to the rest of

¹ Much of this section, and its figures, are specific to Cisco's cloud Native Broadband Router (cNBR) but has been generalized where available.

² YAML is a human-readable data-serialization language. It is commonly used for configuration files and in applications where data is being stored or transmitted. YAML targets many of the same communications applications as Extensible Markup Language but has a minimal syntax which intentionally differs from SGML. (source: <https://en.wikipedia.org/wiki/YAML>)

the network elements. This configuration can occur through applying a pre-made JavaScript Object Notation (JSON) configuration files, or directly configuring the NE and networking addresses in a graphical user interface (GUI). These will include all the core addressing, precision time protocol (PTP) information, routing information, etc. for all interface elements, an example is shown below in Figure 4.

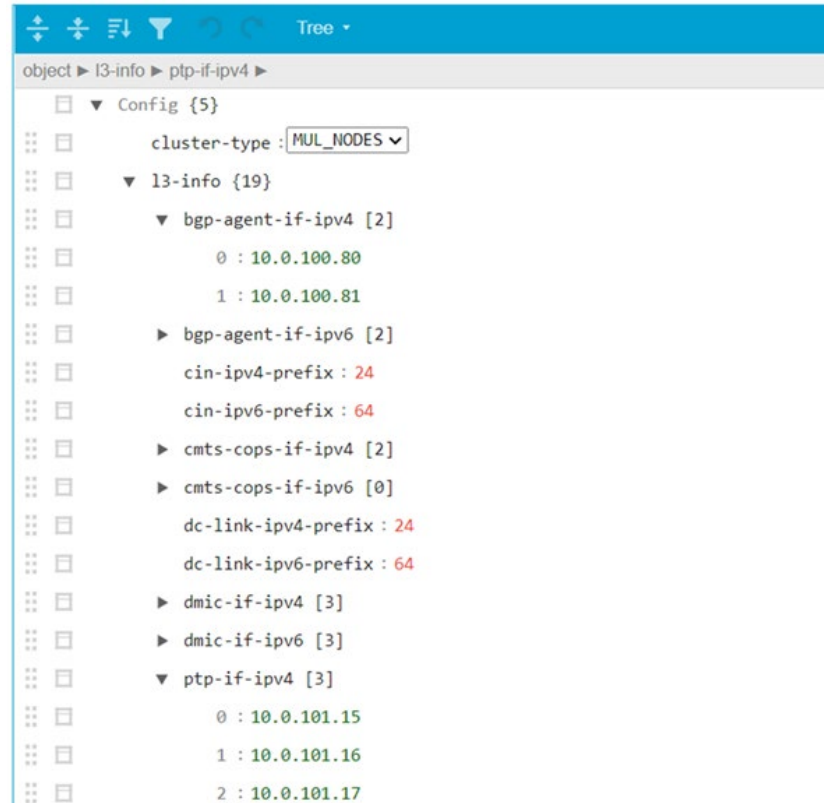

Figure 4 - GUI configuration example of interfaces

Once all the prerequisite day zero configurations are completed, and the vCMTS core cluster is talking to the NE, the basic network setup is completed, and it should be verified that all the NEs can talk to each other, and the systems' PTP clock is locked. This can be accomplished through various means, from ensuring ping capability, checking border gateway protocol (BGP) neighbors and routing tables.

DOCSIS configuration can begin after verification of connectivity. This is once again very similar to a legacy CMTS deployment, and all the elements that would go into configuring a CMTS SG. Profiles for the various elements, the DS channels, US channels, remote PHY device (RPD) PTP information, etc. will all need to be created. These will contain the same information as in a legacy CMTS, as Figure 5 illustrates. This can again be done through importing JSON files into the system, allowing for automation in the configuration process, or through use of a GUI interface.

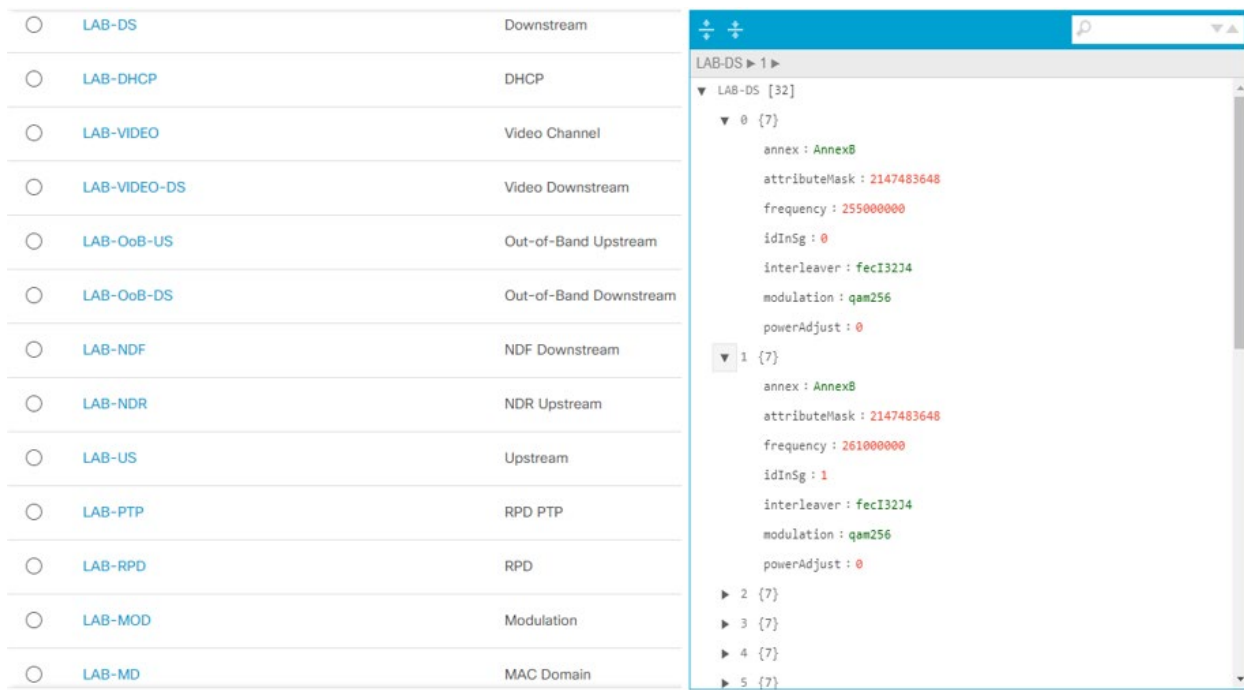

Figure 5 - Profile List (Left) and Sample Downstream GUI profile

Now that all the prerequisite DOCSIS and dynamic host configuration protocol (DHCP) profiles are in the system, SG templates can be created from the profiles, likewise, Layer 3 templates, acting as a cable helper configuration, containing the information for DHCP relay, and BGP peer information, can be created. These are, once again, like a legacy CMTS system and contain all the information required for provisioning.

Unlike previous sections, provisioning SGs in a vCMTS differs from a legacy CMTS. In this case, a separate RPD configuration containing the core information, and DS/US cable information is not needed, as these are configured automatically once a RPD (and consequently a SG) is created. Utilizing a GUI based interface, provisioning is also simplified. Here, the RPD MAC information, names, and the previously created templates provide the necessary information required to provision a SG. As shown in Figure 6, the vCMTS software then checks the configuration, creates the required cabling and routing information, then checks the online status before posting a status report.

Figure 6: RPD/SG provisioning process

While this is a convenient and easy way to provision a SG, for ongoing deployments this would be quite tedious. However, since this is a vCMTS, it is an application programming interface (API) driven setup, provisioning a large amount of RPDs can be accomplished using API calls directly to import the configuration files into the system. As was previously stated, the routing and interfaces are configured automatically by the software, these interfaces are the same ones that would be used in legacy CMTS systems, while the routing is the information for the traffic and DHCP relay, and an example is shown in Figure 7.

SG Name	SG ID	VRF	Prefix	NextHop
SG0	0	default	10.0.122.1/32	10.0.100.103

Figure 7 - Routing (Left) and interfaces (Right) created

After the SG for the system has been provisioned, the configured elements need to be verified working as intended. As with legacy CMTS systems, the RF output of the node (RPD) in the field should be checked with probes. With a vCMTS system, however, many of the monitoring systems have been simplified due to the information being pulled from containers and direct information gathering by streaming telemetry viewable through available dashboards, shown in Figure 8.

Figure 8 - Dashboard navigation

A few examples of this can be seen below, with Figure 9 showing the overall summary of the system, and Figure 10 showing information of an individual SG.

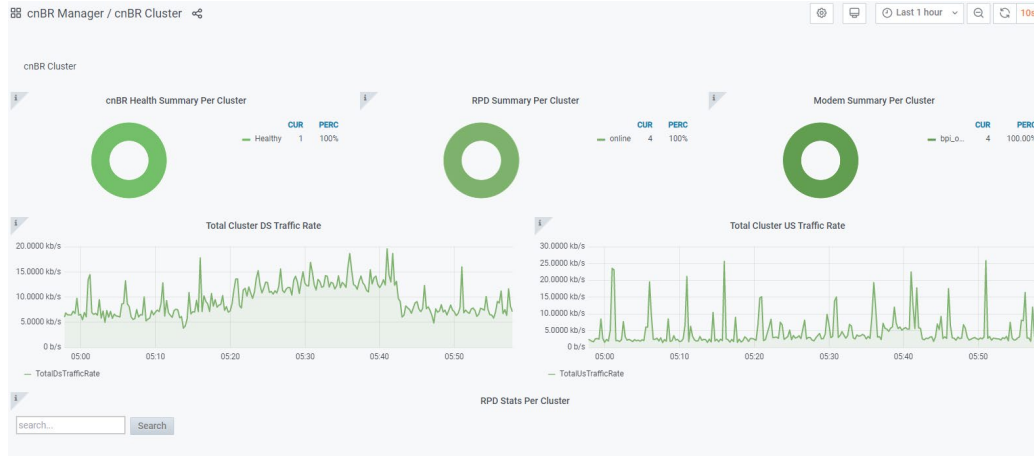

Figure 9 - System Cluster Summary

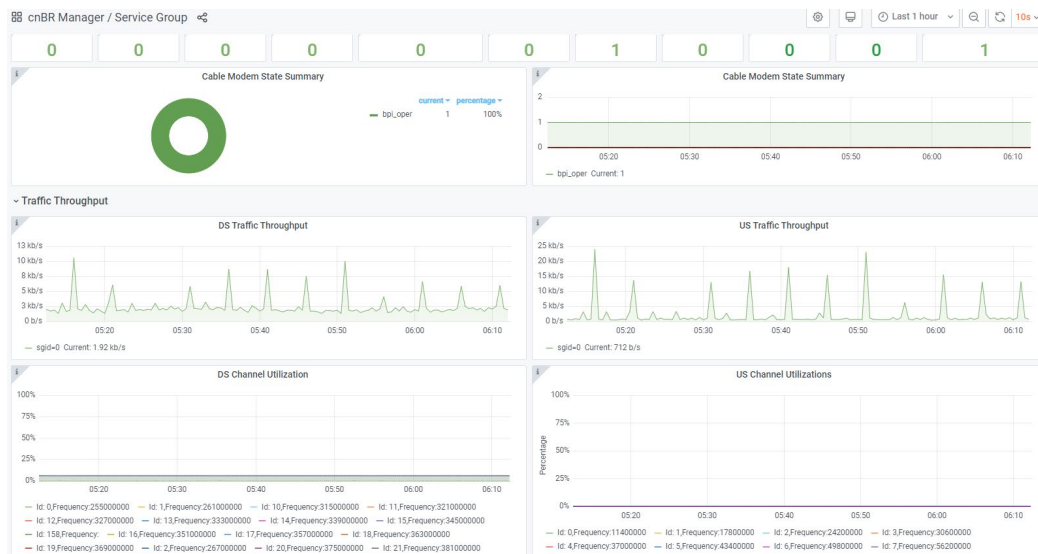

Figure 10 - Service group summary

Virtual CMTS deployments are heavily containerized architectures, with each container acting as an individual application. These containers are orchestrated using the open-source API Kubernetes (often referred to as K8s), or other container management platforms. These containers are applications running the individual components of the overall vCMTS architecture, such as packet processing, packet cable, telemetry, OFDM, SG management, MAC scheduler, etc. While all these containers are running in the background on a vCMTS cluster, they are not needed to be touched or managed by an operator as Kubernetes manages them and their services. So, while a vCMTS does run as all these individual pieces, it operates fundamentally the same as a legacy CMTS. After all, DOCSIS is DOCSIS.

5. How Do I Scale and Add capacity?

A common scenario with any CMTS deployment is increasing capacity. Traditionally, year-over-year growth has been roughly 20% in the downstream and upstream as can be seen in Figure 11. This traffic growth is projected to continue for the foreseeable future. The impact on any CMTS, legacy or virtual, is that the CMTS must be scalable and capable of supporting the continued traffic growth.

Figure 11 - Forecast Downstream Bandwidth Demand 2018-2030 (Source: Strategy Analytics, Inc., CommScope)

5.1. Capacity Expansion Legacy CMTS

Capacity expansion in a legacy CMTS is dependent on the CMTS vendor, though ultimately a well-defined process. Legacy CMTSs will have a finite number of downstream and upstream SC-QAM and OFDM/OFDMA channels. These channels may be combined to create service groups. A SG is defined as a set of downstream channels and upstream channels which are further associated logically in the CMTS as a MAC domain. Downstream and upstream communication over the downstream and upstream RF channels to a specific fiber node will be associated together as traffic. One can think of this as a shared data pipe in the downstream and shared data pipe in the upstream. Similarly, on the CMTS, each individual channel in the downstream is shared or “utilized”, provided the CMTS is properly configured. The same holds true for the upstream.

Consider a downstream with 32 SC-QAM channels at 256-QAM. Assuming a 256-QAM channel supports approximately 38 Mbps after overhead, the total downstream capacity would be:

$$32 \times 38 \text{ Mbps} = 1.216 \text{ Gbps}$$

This is a common CMTS downstream configuration prior to DOCSIS 3.1 OFDM. When subscribers on this fiber node saturate the fiber node in the downstream with continuous traffic during peak hours (which is about 1.2 Gbps) chaos will break out and the CSR phone lines will

start to ring. Subscribers will experience poor quality of experience due to network congestion. This will eventually generate a work order for a node split on that fiber node.

Node splits are expensive and time consuming. One or more new fiber nodes will be installed to reduce the number of subscribers per SG. The CMTS must then be updated to add a new SG(s) for the new fiber node(s). This is a common and ongoing process in most DOCSIS networks. DOCSIS 3.1 has enabled cable operators to delay fiber splits by adding DOCSIS 3.1 OFDM channels in the downstream. These channels can add up to 1.89 Gbps per 192 MHz OFDM block. In either case, the CMTS must support the addition of licensing for more SC-QAM and/or OFDM channels for the SG. It is possible that the CMTS will need additional hardware such as line card(s). The line card(s) provide the conversion of data to RF signals which are referred to as SC-QAM and OFDM channels. If the CMTS is already completely full and no additional slots are available for new line cards, then the cable operator would need to buy a new CMTS chassis and perform the steps mentioned in section 4.1.

Once the CMTS has been licensed and upgraded with hardware, someone with knowledge of the CMTS and required SG update must program the CMTS. The programming is similar to that in section 4.1. CLI programming is not consistent across CMTS vendors. But in general, the concept is the same, driven by DOCSIS specifications. Some cable operators have automated the process to the point where a SG can be created by a script. These scripts may need to be updated as networks evolve and CMTS code changes.

5.2. Capacity Expansion vCMTS

One of the benefits of migrating from a traditional hardware-based legacy CMTS appliance to a software-based containerized vCMTS solution is the agility and time required to add capacity. Also, a legacy CMTS requires more rack space than a vCMTS. If a legacy CMTS is fully populated, then to add capacity, it may require an additional legacy CMTS chassis. A vCMTS on the other hand, that runs on common off the shelf (COTS) servers and may need as little as 1 rack unit (RU) of rack space to add new SGs. This is a significant space savings.

Kubernetes has gained popularity over the years and has now arguably become the de-facto standard for container orchestration and its lifecycle management. Most, if not all, vCMTS core offerings from independent software vendors (ISVs) are orchestrated and managed using Kubernetes APIs. As the existing Kubernetes cluster starts to run at maximum capacity and resources start to run out, to add more SGs, new K8s worker nodes can be added to an existing cluster that runs vCMTS applications. A single K8s cluster can run several hundred worker nodes though officially K8s claim to support up to 5000 worker nodes.

Adding new worker nodes in the headend is relatively easier if the management network and simple IT infrastructure are properly set up for remote access. When a new server with desired hardware specifications is acquired, it is mounted in the rack and connected to the management and data plane networks. An out-of-band management interface can be used to update basic input/output system (BIOS) and enable required hardware features (e.g., Hyperthreading), single root input/output (I/O) virtualization (SRIOV) etc. The new server can either have a pre-installed operating system (OS) with custom configurations (IP, ssh keys, etc.) before it's racked up, or the

OS can be installed remotely after the server is mounted in the rack. This paper presents one example of how a new server with no pre-installed OS can be provisioned in the virtualized cable headend which has a DHCP and preboot execution environment (PXE) boot server with desired OS image already setup. As the new server boots up for the first time it can be booted from the network using a PXE enabled NIC. This will let the OS image be downloaded from the PXE boot server (trivial file transfer protocol [TFTP] server) and install the OS on the newly provisioned server. The OS image can be customized beforehand to enable remote ssh access before its uploaded on to the TFTP server. Once the initial OS is installed using PXE, the server can then be accessed remotely and ready to be added as a new worker node to an existing vCMTS K8s cluster.

There could be multiple ways to add new nodes to a Kubernetes cluster but broadly it can be divided into two different approaches 1) manual 2) automated.

A manual installation approach would require all K8s node software components to be installed and configured individually. This could be a tedious task and prone to errors and doesn't reap the real benefits of virtualizing a cable headend.

A better approach is to adopt automation which significantly reduces time and effort to deploy and scale, while improving quality by preventing human errors. One popular automation tool adopted widely today is Ansible. Ansible is an agentless automation tool that runs Ansible “playbooks” from a remote Ansible controller to perform cluster provisioning, configuration management and performs various actions on remote machines. Ansible controller communicates with remote/host machines over SSH protocol. Ansible playbooks are configuration files that define tasks to be performed on host machines and let users customize multiple parameters to fit their installation needs. Playbooks can be used to deploy new K8s clusters and add new K8s nodes to a running cluster. The whole process of adding new vCMTS nodes takes a few hours if playbooks are configured properly.

Another automation tool widely used today with K8s is Helm. Helm is a package manager tool that runs on top of K8s to automate the installation process of plugins and K8s capabilities and used to deploy and manage applications like vCMTS applications. As the new K8s node is added, Helm can be used to deploy new vCMTS service groups to the newly provisioned K8s node. Scaling out new SGs to a new node consists of running a few K8s CLI commands that spins up new vCMTS SGs. The rest of the SG configurations are the same as previously explained in section 4.2.

6. How do I Troubleshoot the CMTS?

An important aspect of any CMTS is ensuring that subscribers continue to send and receive high speed data without interruption. Being able to identify if the CMTS is having a hardware and/or software issue or if there is an impairment in the plant impacting subscribers is critical. Troubleshooting the CMTS is a feature which must not be overlooked in any purchasing decision of a CMTS. If one is unable to quickly troubleshoot the CMTS and network, then the CMTS is failing at its main mission of delivering data to and from the subscriber.

6.1. Troubleshooting a Legacy CMTS

Legacy CMTSs have had over 20 years for vendors to harden the CMTS, identify internal bugs and resolve them. However, over the past 20 years the DOCSIS specification has continued to evolve meaning more complexity, features, higher density, and increased power use. Problems can and do occur in the CMTS hardware as hardware degrades over time. Legacy CMTS vendors include CLI and SNMP commands that allow one to continuously monitor all aspects of the CMTS for hardware failures.

6.1.1. Hardware Failures

As an example, a typical scenario may be the failure of a power supply. Using simple CLI commands one can see the status of all power supplies and the total power consumed by the CMTS. Figure 12 shows that the current CMTS supporting roughly 5k subscribers with 42 service groups is consuming about 4.4kW of power.

Figure 13 - Example of Detailed Powering and Temperature Statistics on Legacy CMTS

In Figure 13 it is evident that much greater detail is available on legacy CMTSs. This data can be extracted from the CMTS and stored in a database, then plotted over time. Trends which would indicate the CMTS is failing giving the cable operator time to replace the failing element or the entire CMTS if necessary. Further, nearly every element of a legacy CMTS is redundant. These include power supplies, processing cards, NICs, and even the RF cards (if desired). It is standard for legacy CMTSs to operate in high availability (HA) mode, such that if any single component or element fails, there is a backup to take over. This generally makes legacy CMTSs very reliable.

6.1.2. Software Failures

Because legacy CMTSs runs on proprietary code, which for most vendors has been built on years of development, software failures are uncommon. This does not mean that there are not compatibility issues between CMTSs and cable modems. It does happen and more frequently it has occurred in new standards, such as with DOCSIS 3.1 OFDMA. These are not so much software failures as they are software “issues”.

6.1.3. Subscriber Impairments

Troubleshooting subscriber impairments is a key feature for any legacy CMTS. Because legacy CMTSs are standards-based, they support standard management information base (MIBs) providing rich access to SNMP data. This SNMP data is used by reactive and proactive monitoring systems which provide the health and key performance indicator (KPI) metrics of each subscriber as well as the aggregate metrics of the network. Reactive and proactive monitoring systems give cable operators the visibility to know when subscribers are having problems or will have problems in the future. The aggregated view also enables cable operators to have visibility into the total traffic consumption on any given fiber node or an entire CMTS. This is important information to monitor and trend over time so that capacity expansion may be planned, as discussed in section 5.1.

SNMP can create a load on legacy CMTSs. Reactive and proactive systems need a lot of data from CMTSs to do their job. At the same time, legacy CMTSs have finite processing power, of which most is dedicated towards managing subscriber traffic. SNMP queries to the CMTS will impact the legacy CMTS processor. If there is too much strain on the CMTS from subscriber traffic, excessive SNMP queries may result in no response to the SNMP queries or even worse, SNMP queries may impact subscriber traffic. If the former, no SNMP data is returned, then the monitoring system will return false data, possibly causing the cable operator to react to bad data. In the latter case, excessive SNMP queries have been known to impede subscriber traffic and even crash a CMTS. This is quite serious and legacy CMTS vendors, monitoring software vendors and cable operators must be aware of these concerns and always ensure their CMTS are not overloaded by either subscriber traffic or SNMP utilization.

6.2. Troubleshooting the vCMTS

One of the benefits of virtualizing a cable headend is that it enables cable operators to collect huge amount of telemetry - much more than what was traditionally exposed by hardware appliance network functions - including hardware, vCMTS software, and environmental equipment. If the telemetry from vCMTS infrastructure is used efficiently it can provide a holistic understanding of infrastructure and services running on top of it. Telemetry makes it possible to achieve closed-loop automation, streamline root cause analysis, perform timely reactive maintenance, effectively plan for proactive maintenance, and much more.

The vCMTS and the platform telemetries are available through open and industry-standardized interfaces, so it can be used to feed a wide range of applications and workflows [3]. There are many telemetry data collection open-source software available that use various plugins to gather metrics from a variety of sources, including COTS servers and software applications like vCMTS. Some common metrics collection software widely used today are Collectd [4], Telegraf [5] and cAdvisor[6]. This telemetry can be integrated with various monitoring solutions that can help remediate platform and vCMTS-related issues quickly. These metrics collection daemon is typically run on non-dataplane central processing unit (CPU) cores so the metric collection processes doesn't interfere with data plane performance. The metrics are collected periodically and stored in a time-series databases like Prometheus [7], InfluxdB [8], etc. These metrics from the hardware and the vCMTS application can be visualized on a single or multiple Grafana dashboards. Grafana alerts can be created in a single and consolidated view based on certain pre-set conditions, and application and platform metrics thresholds, that make headend management easier, enhance recovery time, and reduce service downtime significantly.

Like legacy CMTSs, vCMTSs can also have hardware failure from time to time. Since a vCMTS runs on commodity servers the common hardware failures are related to power supply, memory dual in-line memory modules (DIMMs), NIC port, disk corruption etc. One great benefit of virtualization is that you can have redundancy available at almost all levels with properly configured HW and closed-loop automation. Intel servers provide a great deal of telemetry from different server components and if monitored properly can indicate hardware failures beforehand. This lets cable operators plan maintenance proactively and isolate bad hardware to mitigate downtime significantly. The hardware telemetry can also be used to enhance scheduling decisions in K8s which enables intelligent placement of vCMTS SGs pods based on up-to-date

platform telemetry and vCMTS workload requirements. If one of the K8s nodes reports any bad hardware metrics, the K8s scheduler will automatically cordon off those nodes and de-schedule SGs from that node and move them to a healthy node.

One key consideration for cable operators is to use automation to manage their virtualized headend's network operations. Automation helps to manage growing and changing networks, fix problems faster, and helps adhere to customer service level agreements (SLAs). To perform automation effectively, it requires end-to-end monitoring of software, services, and the hardware on which these services are running within the network. Intel server telemetry spans a vast number of domains including utilization, power consumption, fault detection, and performance. To offer meaningful insights from this information, Intel has created a portfolio of telemetry reports that provides actionable data about the current status of the server [9]. Combining these insights with vCMTS performance data allows for a more holistic view of the vCMTS network function. These reports can be used to help automate orchestration, self-healing, and energy optimization. There are four telemetry reports currently being developed:

- Platform health; covers overall platform health covering compute, memory, storage, and network interfaces
- Utilization; covers platform utilization and capacity indicators
- Congestion; covers CPU overload or network congestion scenarios
- Configuration; covers platform misconfigurations

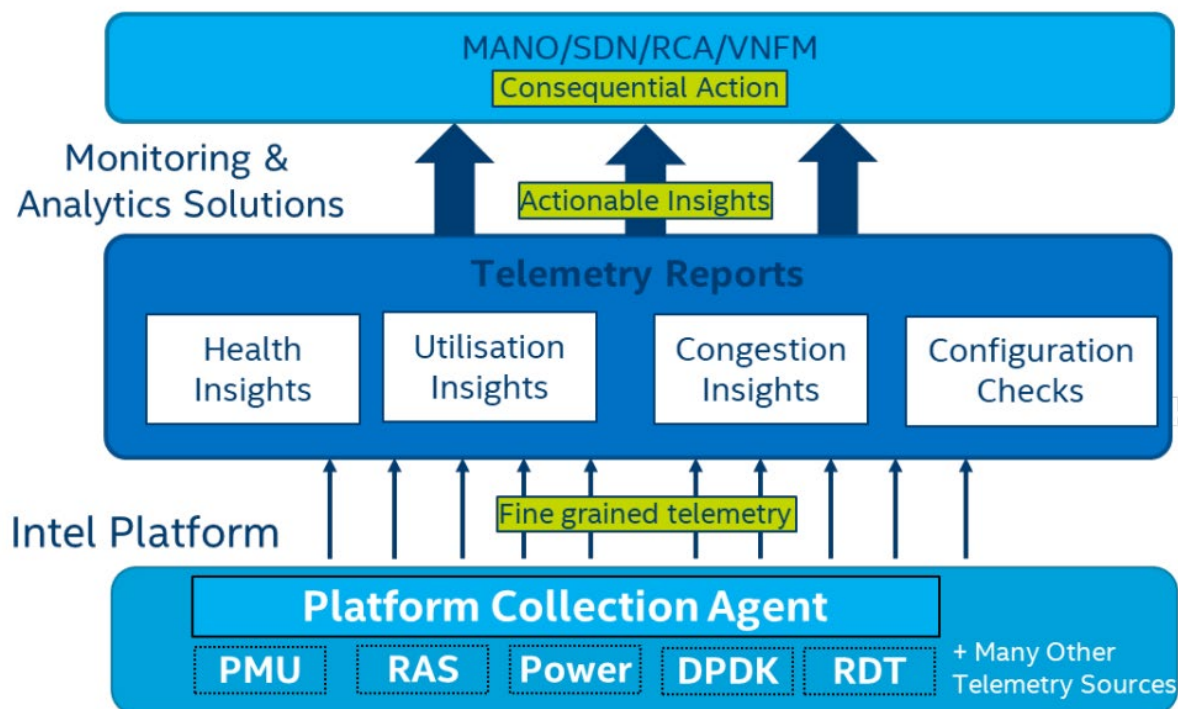

Figure 14 - Telemetry and insights data flow

Figure 14 shows how the telemetry reports use Intel server telemetry provided by Collectd and Telegraf via intel plugins to a monitoring solution that forms the input for the reports. The output

of the reports can be read by an operator or consumed by other management systems. The cable operators can feed these insights generated by the reports into their monitoring systems, which are then processed by online or offline automated systems and can also be used for visualization purposes. Figure 15 (below) illustrates a simple Grafana dashboard visualizing two of the memory health reports, availability and errored seconds. Errors can be documented in this instance and clear indications of these errors can be visualized. [9]

Figure 15 -Grafana dashboard visualizing two memory reports

In addition to the platform metrics in a vCMTS, Grafana dashboards can provide metrics to diagnose and examine subscriber issues. This can be seen in Figure 16 below from a cnBR show cable modem PHY dashboard. This displays the PHY output of the cable modems, just like running the command in CLI on a legacy CMTS.

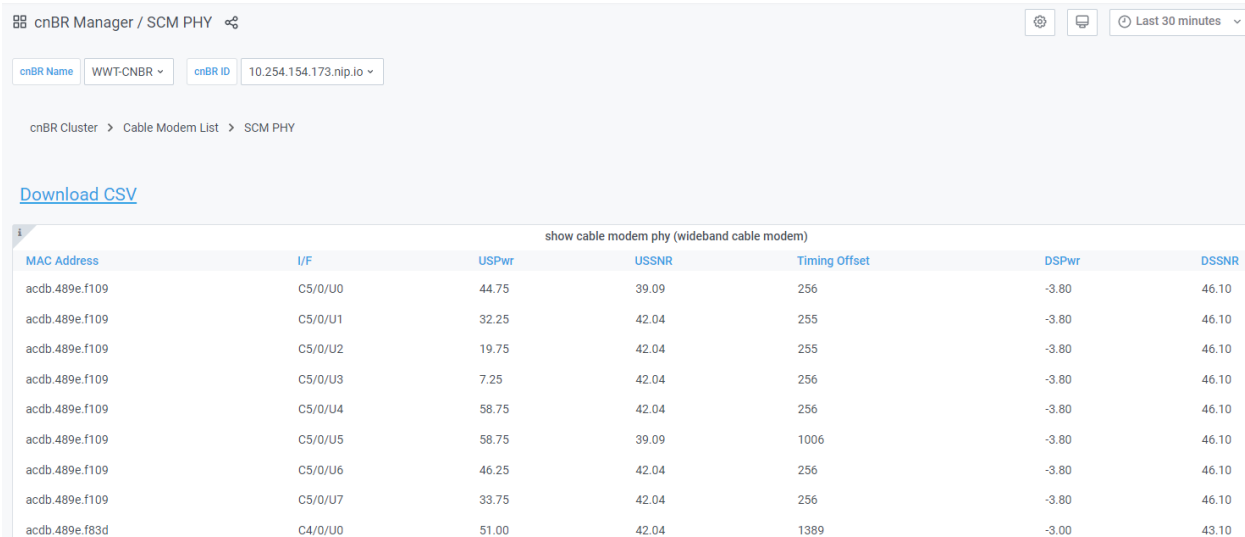

Figure 16 - Show Cable Modem PHY dashboard

Using the metrics collected by the vCMTS software, troubleshooting issues follows the same paths as legacy CMTS systems. The information is provided from the various containers and displaying them in easily navigable outputs. Subscriber impairments can be investigated by examining an individual subscriber and the reported information from the modem. The way this information is presented can vary by vendor, with the subscriber information in Figure 19 being displayed by Harmonic's CableOS, while Figure 20 displaying similar information as reported by Cisco's cnBR. While these software packages come with default dashboards, since these are using Grafana, the operator is able to modify, or completely create new dashboards as needed.

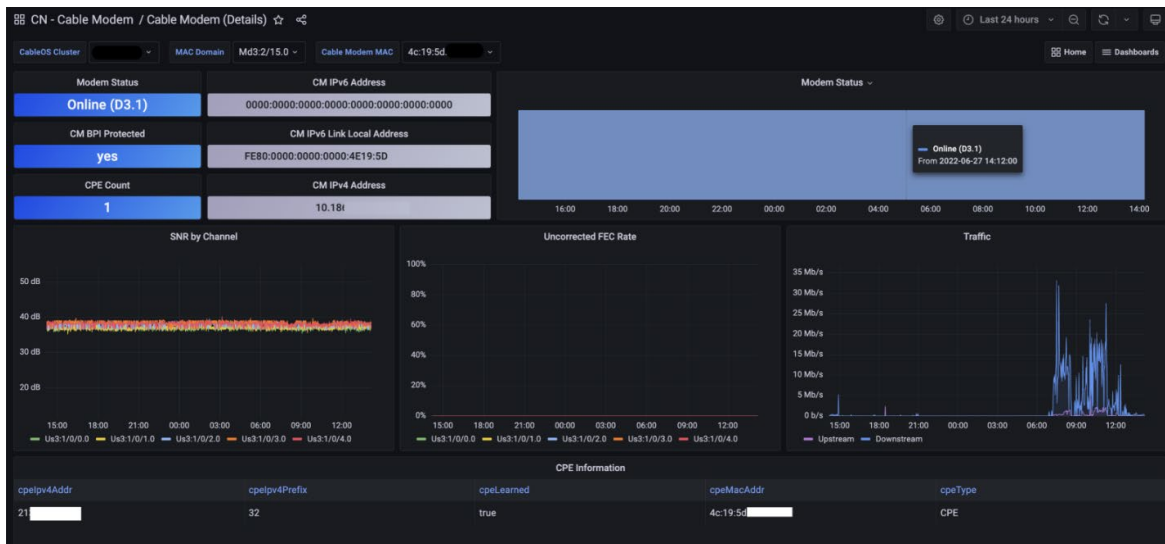

Figure 19 - CableOS dashboard displaying modem detail

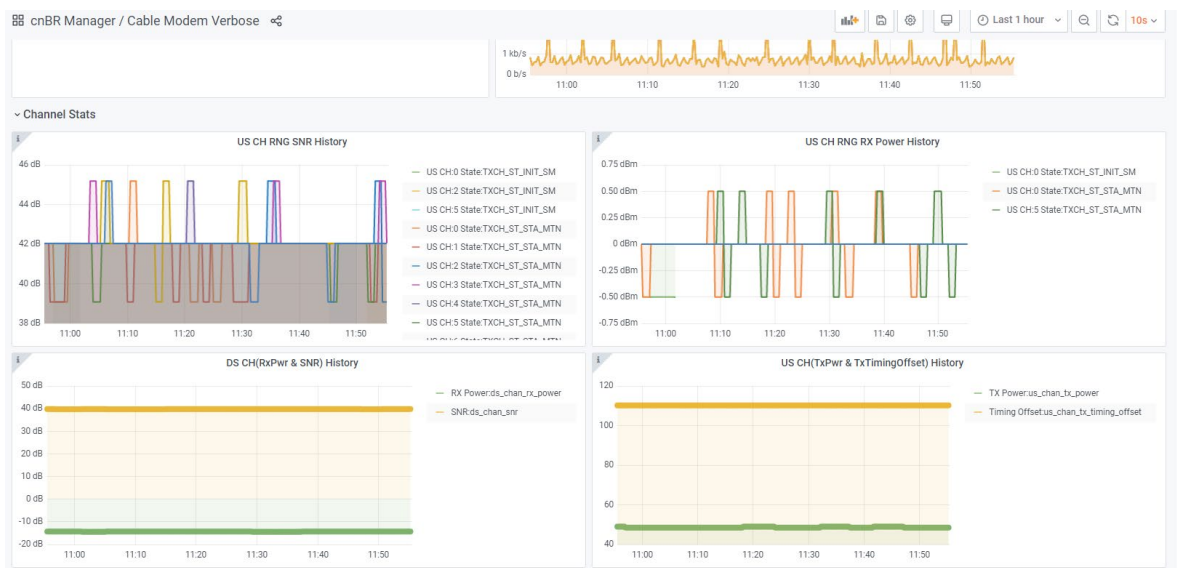

Figure 20 - cnBR dashboard displaying modem detail

A vCMTS ultimately provides the same information that a legacy CMTS provides. As such when diagnosing DOCSIS issues the troubleshooting techniques likewise follow the same steps that are performed in section 6.1. The difference being that the information is provided in an easier to digest form using GUI information, and not requiring SNMP or CLI intervention to obtain the data, thus simplifying operations. However, new telemetry-based tools, such as a Telegraf, InfluxDB and Grafana (TIG) stack, along with a new set of skills and training may be required to take advantage of the improved reporting features available in the vCMTS.

7. How do I Multi-task with a vCMTS?

The disaggregation of the PHY layer-1, MAC layer-2, and IP layer-3 of the CMTS makes it possible for cable operators to scale their access networks - virtually infinitely. As we have seen with the adoption and deployments of DAA, cable operators are reaping the benefits of running the DOCSIS PHY in the field by deploying RPDs. Upstream RF signals are demodulated at the RPD. This means RF signals are transported back digitally to the CMTS. Combining RF signals in racks of RF-combining equipment is no longer required. This has benefits for cable operators looking to reclaim headend space, reduce power and cooling costs in the headend.

The standardization of DAA for DOCSIS and further advancements in the flexible MAC architecture (FMA) standard have enabled the transition to a software-centric cable network infrastructure. [2] One option that the DAA and FMA architectures allows for the DOCSIS MAC software to be deployed as a virtual network function (VNF) on general purpose x86 servers in a cable operator headend as a vCMTS, while the DOCSIS PHY layer is housed in an HFC node near subscribers and business customers.

7.1. What is required to run the DOCSIS workload in software on a general purpose x86 server?

In Figure 17 below, we illustrate the typical components that make up a virtual CMTS deployment. There are hardware and software elements needed to deliver the DOCSIS workload to cable modem users.

The **hardware** required is COTS hardware that is typically found in a data center or server room of companies across all sectors of today's information age such as telecom, media & entertainment, manufacturing, medical & health services, automotive, and financial services. The servers are sold by original equipment manufacturers (OEM) such as HPE, Dell, Cisco, Lenovo, SuperMicro, Intel, and others. The NIC are made by various OEM suppliers such as Intel, Mellanox, Broadcom, Marvell, Cisco, and others. The data center switches are made by OEM vendors such as Arista, Cisco, Dell, Extreme, HPE, Juniper, and others. The hardware comes in various sizes and configurations to meet the compute and networking requirements to serve the workload in that location of the network topology. The benefit of running the DOCSIS workload in software on general purpose servers and switches is the economies-of-scale.

The **software** elements listed in the Figure 17 below vary depending on the vCMTS software selected by the cable operator. Typically, different software is needed for the OS, the container orchestration, management, automation, monitoring, analytics, and the vCMTS VNF. Some of the software to run the server platform and container network function is available in opensource and has been proven to scale to billions of end-users.

Figure 17 - Anatomy of a Virtual CMTS deployment

The advent of SDN and NFV has accelerated innovation for the separation of the data plane function, the control plane function, and the management functions in the delivery of networking applications. Containerization allows further disaggregation of compute, networking, and storage resources needed to move, process, and store packets and data at a much more granular level than previously possible with purpose-built, fixed-function, hardware. An example of this is a CMTS that is built to serve the function of modulating and de-modulating DOCSIS encapsulated packets, processing the packets, and moving them between end-users and the Internet. At the turn of the century, the legacy CMTS platforms were built with shared compute resources to service pre-defined network segments such as an upstream port or a downstream port. In the new world of container networking running on commodity servers, more control and freedom is given to the cable operator to allocate (i.e. orchestrate) compute and networking resources required to service the customer-defined segments. The cable operator can allocate the compute resources down to the granular level of threads in the CPU cores, and the amount of IO on the NIC logical ports at the service group, the upstream, and the downstream level to maximize resource allocation needed per service element. Not all service groups are the same, therefore, the compute and IO resources to serve them can be customizable.

Servers can be purchased as single socket or dual socket systems. Meaning, the server can be configured to have 1 CPU or 2 CPUs in the same system that houses the power supplies, fans, memory, and NIC cards. Each CPU will have multiple CPU cores. A CPU core is a virtual CPU that is a self-contained unit of compute within a CPU. Each CPU core can perform different tasks. Today's servers have CPU sockets, CPU cores and NIC interfaces that do the compute processing and network movements of the data packets. The vCMTS software solution typically has default allocations for CPU sockets, CPU core, threads, and NIC partitions that are pre-defined for ease of operation of the DOCSIS function that cable operators adopt "out of the box."

If desired, an operator could potentially orchestrate the container functions and land a DOCSIS workload on one of the two CPUs in a dual-socket server that services 10 DOCSIS service groups in a small town, while orchestrating the other CPU socket to run a cloud Digital Video Recorder (cDVR) function with some cloud storage resources. Even more granular, an operator may choose to mix the CPU cores in the CPU socket to do different functions. For example, if the operator was running 2 service groups with a few of the CPU cores and decided that there are CPU cores available for running the virtual optical line terminal (OLT) function of the passive optical network (PON) network, or, for terminating the Soft Generic Routing Encapsulation (Soft-GRE) tunnels for the community WiFi service, or for running another service, the operator can do so with flexibility. The x86 CPU cores and NIC cards and ports, coupled with container networking software allows operators much more control, flexibility, and optionality to maximize usage of the computing resources. This flexibility to allocate compute, IO, and storage resources at a much more granular level allows cable operators to scale their networks much more cost-effectively while converging multiple services on commercially available servers.

8. Does a vCMTS Consume More or Less Power Than a Legacy CMTS?

When migrating from legacy CMTS to vCMTS, cable operators will realize significant reductions in power consumption. Depending on the configuration of the vCMTS server clusters, Cable operators will see reductions in power that are 3 to 5 times less than legacy CMTS. Furthermore, coupled with the reduction in vCMTS power consumption and the associated heat being generated, cable operators will see significant reductions in power consumption of the heating, ventilation and air conditioning (HVAC) cooling systems. The reduction in rack space to house vCMTS servers to service the same, or more, service groups will also result in significant cost reductions.

When comparing power consumption of legacy CMTS versus vCMTS, the units of measurements will be normalized down to a cable service group. Below is a chart comparing a legacy CMTS operating in I-CCAP mode, a legacy CMTS performing the DOCSIS MAC functions connected to a remote PHY device, and a vCMTS doing the DOCSIS MAC processing connected to a remote PHY device.

On a per service group per watt comparison, without including the HVAC cooling reductions, a vCMTS uses 2.5 times less power than a distributed converged cable access platform (D-CCAP) and 3.8 times less power than an integrated converged cable access platform (I-CCAP). When comparing the amount of DOCSIS throughput delivered per megabit per second (Mbps) per watt, a vCMTS delivers nearly 10 times as much bandwidth as an I-CCAP.

There are additional power conservation possibilities when running vCMTS software on Intel servers. One example that cable operators can employ is to turn down the CPU clock frequency during off-peak network periods to reduce the power consumption of the vCMTS servers.

Table 2 - Power consumption comparison

	Scenario 1	Scenario 2	Scenario 3
	I-CCAP CBR-8	D-CCAP CBR-8	vCMTS 3 servers + switch + timing server
Power consumed	5,200 watts	5,000 watts	2,635 watts
Service Groups served	56	84	108
Watts per Service Group	92.8	59.5	24.4
Rack space	14 RU	14 RU	8 RU
Aggregate Throughput	100 Gbps	100 Gbps	480 Gbps
Mbps per watt	19.23	20.0	182.2

Notes:

- For this comparison, speed of 3 Gbps downstream and 200 Mbps upstream configurations for each service group were used.
- The RPD power consumption is not included as it will be the same for scenarios 2 and 3. Scenario 1 would have multiple racks of required RF cable combining equipment that are not included in this power consumption analysis of the DOCSIS MAC processing.
- The vCMTS configuration in scenario 3 includes three (3) dual-socket servers powered by Intel 3rd Generation Scalable Processor CPUs, one (1) Cisco Nexus 3232c leaf switch, and one (1) timing server. Each server consumed 635 watts while producing 160 Gbps of aggregate active throughput and powering 36 active service groups and 12 standby service groups.
- Aggregate throughput of I-CCAP and D-CCAP are limited to 100 Gbps due to physical limitations of the I/O cards. Similarly, the aggregate throughput limit of the vCMTS server is the NIC capacity, which is typically 100 Gbps, 200 Gbps, or 400 Gbps per server, as procured today.

9. Conclusion

In conclusion, we hope the readers will appreciate that operating a vCMTS is not much different than operating a legacy CMTS. Some would argue that the web interfaces for managing a vCMTS are easier to navigate than the CLI of legacy CMTSs, similar to the transition from MS DOS to Windows in 1995, which made using a personal computer (PC) much easier.

As the CMTS workload is performed in software, cable operators can run the vCMTS software on commodity servers. These general-purpose servers are used for running a plethora of applications such as DNS, email, video streaming, web services, chat, user authentication services, firewalls, security, billing, monitoring, video encoding, video transcoding, and so many other applications. Thus, millions of servers are purchased and deployed annually by companies, big and small, to run their business services. By running the DOCSIS workload on commodity servers and switches, cable operators can buy the hardware at a fraction of the capital cost of purpose-built hardware. Furthermore, if no longer needed for running DOCSIS, cable operators can repurpose the commodity servers to run other functions such as email, video streaming,

proxy caching, or SD-WAN, or any other software application on the same CPU cores in the servers located at that location in the network.

CMTS hardware has served cable operators well to win market share in the burgeoning broadband market over the past 25 years. Compared to legacy CMTS equipment, vCMTS software running on servers can do the job at a fraction of the hardware cost, consume a fraction of the rack space, use a fraction of the power, and allow cable operators more flexibility to quickly scale and remain competitive.

Abbreviations

API	application programming interface
bps	bits per second
BIOS	basic input output system

1. Introduction

The Internet is based on fundamental design goals that emphasize simplicity and reliability. Early on, the idea was that instead of a centrally controlled network that was a gatekeeper on new features (such as telephony ‘star’ codes) most of the intelligence was decentralized into the edge systems to help enable a tremendous wave of permissionless innovation at the application layer. Any complex network-oriented processing was to be performed by the host devices. A fundamental difference of today’s Internet is ‘predictable service qualities’, which can be achieved only by ‘smart’ components in an end-to-end path. Over the years, applications have adapted as well. A classic success story is Internet streaming. Through maintaining an appropriate size playback buffer and aided with adaptive bitrate control, HTTP-based adaptive streaming (and UDP equivalents) is the dominant application.

As society moves from the information age to the age of the M2M communications, we anticipate further significant changes to the Internet as well as significantly different applications. Machines are making decisions based on data, many times in real-time. There are wired and wireless scenarios to consider. Many of these applications have yet to be invented, but based on early examples such as cloud gaming, enhanced videoconferencing, coordinated autonomous vehicles, drone swarms working in a coordinated manner to carry out missions, multiuser virtual-reality gaming, the Internet needs to be re-examined to determine what must be addressed so that technological breakthroughs in devices and systems are not held-back by Internet performance limitations. These concerns have motivated the key standards bodies to pursue broad initiatives that will enhance their respective technology’s ability to support emerging applications systems that require predictable service qualities.

Cable operators are evaluating Low Latency DOCSIS (LLD) to determine how the new technology might improve subscriber’s perceived quality and how an operator might leverage the technology for new services [1, 2, 3].

In this paper, we first present LLD lab analysis that shows promising results. We then discuss end-to-end factors that are critical in providing predictable end-to-end LL services. We conclude our paper with an architecture including network and service components to deploy an effective LL system.

2. Low Latency DOCSIS: Promising Results

The term Low Latency DOCSIS (LLD) reflects the general Internet and cable community’s efforts to offer an architecture that satisfies the requirements for both non-queue building (NQB) traffic and queue-building (QB) traffic over the same physical network [4, 5, 6]. The core ideas behind LLD are novel and show promising results based on preliminary studies and trials. The goal is to enhance the end-user experience and to allow operators or over-the-top service providers to develop new services.

LLD is compatible and aligned with a new generation of Internet flow control, with Low queuing Latency, Low Loss, and Scalable throughput (L4S) technology [4] which supports end-to-end

latency that manages queuing delays with congestion notifications that will result in flow rate adjustments, thus avoiding the packet drops and retransmission as much as possible for the NQB flows. The goal is to transition to substantially lower queuing delays across the network while coexisting with ‘classic’ congestion controls used widely in the Internet today. This will become important not only to the development of new applications as described here, but also to improve customer experience as sufficient network speeds are now becoming widely available to all Internet users and higher speeds may no longer improve the Internet experience, especially for residential consumers.

LLD aims to support non-queue-building applications that send data quickly and don’t cause latency in the presence of queue-building applications from and to the same subscriber’s modem. The main components are coupled dual-queue with weighted scheduler, proactive grant scheduling and optimized MAP timing and channel settings [6]. The aim is to support ~10ms DOCSIS round-trip-time (RTT) latency for the 99th percentile of LL flows, a ~10X improvement to today’s DOCSIS deployments.

The initial tests show promising results. The following upstream examples are discussed to describe the benefits of LLD in the presence of high home network utilization. The lab tests are carried over an iCMTS with deployment configuration and D3.1 CMs supporting LLD features. A simplified version of the setup is shown in Figure 1.

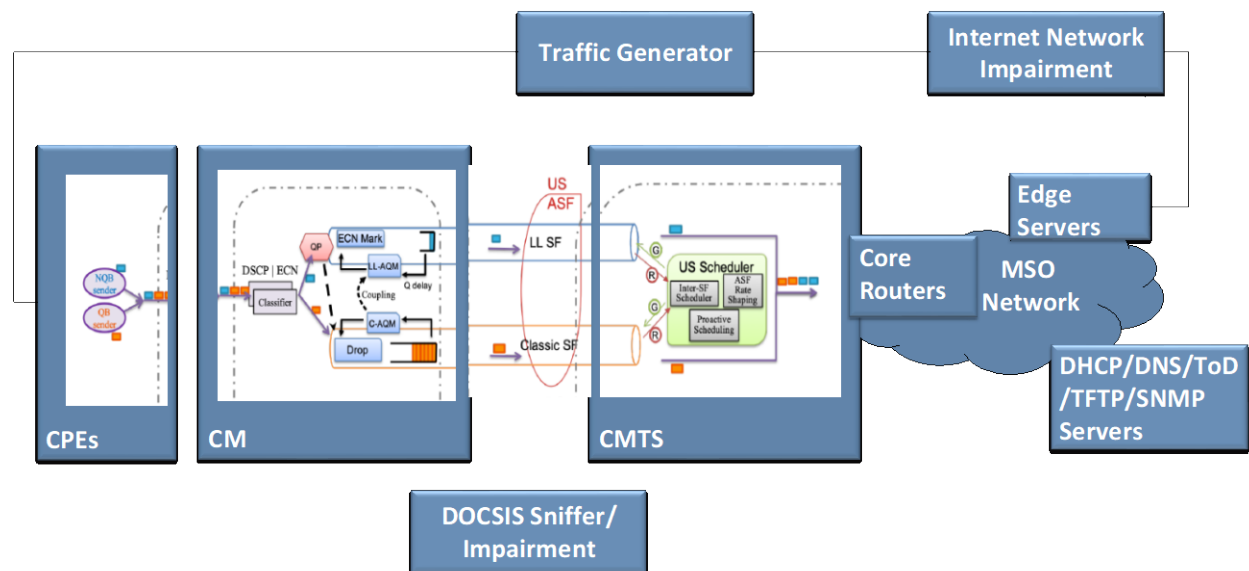

Figure 1 – LLD Lab Setup

The queuing and media access are the major DOCSIS latency sources while propagation, serialization, encoding, and switching also contribute to the latency. Figure 2 displays example idle latency values for a VoIP type traffic in the upstream direction. Idle latency refers to latency when there are no other simultaneous home traffic flows competing with the test traffic for the shared resources. Delays due to propagation, FEC, ATDMA Interleaving/OFDMA Framing,

CM/CMTS MAP processing, queuing (\sim MAP timing/2) and other processing are computed for a total latency estimation as shown in blue line in Figure 2. A traffic generator is used to create VoIP type traffic and measure latency as shown with circles in the same figure. As expected, propagation latency, described by the data point annotation, is the major factor depending on the distances between the CM and the US scheduler as a function of CMTS. Today, most headend-to-CM distances are smaller than 160 km, deployed with typical DOCSIS timings, which provides good latency performance. If better latency bounds are targeted, US scheduler can be deployed closer to the subscriber as a microservice or proactive grant scheduling techniques can be integrated.

Figure 2 – Idle Latency Analysis

The idle latency provides important information on the achievable minimum latency and typical values when LL traffic is not affected by other traffic in the CM. Today in many homes there are many users or sources of traffic that use the network simultaneously with work and school from home that increased dramatically in recent years. As a result, while setting a lower bound on

latency performance, is a less effective metric for user experience. However, LL services require consistent performance values such as jitter.

Latency under load or working latency computed during high home network congestion levels provide upper bounds for latency and jitter a LL service may be subject to, depending on the speed tier rate and conditions of the shared resources. Figure 3 displays an example use case where two audio flows are generated for the same CM, one marked with LL DSCP value and the other one marked with DSCP 0x00. The dual queue LLD features are tested. The top graph displays the latency over time (green line) for unmarked audio flow while the middle graph displays the latency over time for an audio flow marked per LLD specifications. The concurrent TCP flows 'throughput, representing other traffic flows in the home, is displayed in the bottom graph. As the TCP flows fill up the speed tier bandwidth, both audio flows' latency values are affected proportionally to TCP flows' throughput fluctuations as seen in the figure. However, the unmarked audio flow's latency increases proportional to the TCP traffic RTT as it shares the same queuing and scheduling weight while the marked audio flow's latency is bounded with a ~6X improvement. Not only is the absolute delay much lower, but the variation in delay is within a much smaller window which is a critical key improvement for most applications. Note that the MAP time and other physical layer channel settings are not yet optimized for these results set, and will lower latency even further.

Figure 3 – US LLD example showing the impact of QB traffic on NQB traffic latency

In Figure 4, two marked NQB traffic flows share the same LL queue while QB TCP traffic and unmarked NQB traffic is transmitted through the classic queue for the dual queue approach. In [5], suggested unresponsive NQB traffic load is 1 Mbps or a couple of packets per RTT. The marked NQB flows share the resources fairly with bounded latency results (top two graphs), while unmarked NQB traffic (third graph) has inconsistent latency fluctuating depending on the TCP traffic (bottom graph). The latency histograms and Complement Cumulative Distribution Function (CCDF) are shown in Figure 5, with top two graphs for marked NQB flows, third graph for unmarked NQB flow and last graph for CCDF of all three NQB flows. In this example, there were a few packets with latency close to 19 ms and 99%ile of packets have latency smaller than 18 ms. Further optimization of LLD feature parameters and DOCSIS settings can reduce this latency range further. For the same settings, the latency improvement is close to 5X for 99%ile range. The flows in this simulation are longer than those of Figure 3 where TCP flows are ramping up for most of the simulation time. The latency variation for the unmarked NQB traffic can still be observed in Figure 4 during the steady-state TCP conditions as well.

TCP traffic

Figure 6 – US LLD example with two marked NQB traffic flows of different rates in the CM

Figure 7 – Latency statistics for US LLD example with two marked NQB traffic flows of different rates in the CM

For applications requiring tighter latency bounds or less variations due to use cases such as serving group congestions, Proactive Grant Scheduling as defined in [6] may be preferred. Although PGS eliminates the latency due to request-grant cycle in the upstream direction, it may

create network inefficiency if the grants timing and NQB traffic characteristics are not matched well. In this case, unused grants would decrease network efficiency while less grant allocations might increase the latency. However, as shown in Figure 8, the 99th percentile latency and jitter are further improved by an incremental ~65% with this technique increasing the overall improvement to > 13X. Cable operators may apply PGS for certain services or extend the implementation with traffic activity detection.

Figure 8 – Latency statistics for US LLD example with PGS

3. Predictable End-To-End Latency

As discussed in the previous section, LLD improves the latency and jitter for the NQB traffic. Since NQB traffic doesn't share the same queue as QB traffic, packet loss due to aggressive QB traffic is avoided. While DOCSIS network segment can benefit from LL features, the subscriber's QoE depends on the end-to-end latency. In this section, different factors that cable operators must consider for a predictable latency are discussed. Although latency is mentioned as the main metric, in fact, jitter, packet loss and throughput are analyzed concurrently. Reliability, security and service availability are other metrics that operators consider for a complete service assurance.

3.1. E2E Marking

LLD and LL implementations in other network segments depend on marking unresponsive NQB and L4S traffic with LL DSCP and ECT(1) [4,5]. In traditional systems so far, operators have bleached or remarked marked packets entering their network. Wi-Fi gateways and routers in the upstream direction and interconnect routers and CMTSs in the downstream direction bleach or remark these packets.

Operators must assure their network components do not bleach or remark (except CE marking as explained in [4] and DSCP conversions as explained in [5]) LL packets in their network. Queue protection schemes [4,6] and new security features may be applied to detect NQB traffic violation. Negotiations with peering partners and edge servers may be used to avoid the issue with network components in the segments outside of operator's control.

Although, techniques such as mirroring the marking in the downstream per the received marked packet in the upstream may be used, symmetry is not always guaranteed. Application detection should be used only if subscriber has full control and/or a paid service is deployed.

3.2. End-to-End Measurements

Cable operators have been deploying latency, jitter, packet loss and throughput/speed measurements in their network for idle, LUL/working and real customer traffic [1]. Techniques that can measure latency in the access network as well as latency outside of operator's network has been also deployed [1]. These platforms must be upgraded to measure these metrics per LL marked and classic packets and flows.

These measurement techniques must be analyzed with other monitoring features such as utilization levels, device conditions, routing options, channel conditions and many more resource conditions that can affect e2e latency. As latency targets get lower and/or speed tier rates increase, traditional monitoring windows may not be adequate for this analysis. For example, 5 min averages for channel utilization have been widely used in cable operators' networks.

However, bursts (even microbursts) at smaller windows may have a big impact not only on flow control for very high speed tiers, but also on LL services. Traditional monitoring settings may not catch the correlations and causations. An example is shown in Figure 9 for a serving group with highly variable utilization bursts. 5 min values correspond to 98% of utilization measured within 15 sec and reported every 5 min. 15 sec values correspond to 98% of utilization measured and reported every 15 sec. It can be seen that 15 sec values report high burst rates while 5 min values are smoother. The same behavior may be observed for home network utilization and other channel and network conditions.

Figure 9 – Utilization statistics reported with 15 sec and 5 min windows

LL services QoE may correspond to different QoS levels. Although it is not a straightforward process, operators developing platforms to map QoS levels to LL service QoE will be able to program their networks in an optimized way.

3.3. End-to-End Optimizations

A cable operator's network may be approximated as a tandem queuing and servicing. As shown in the literature, in tandem queuing, the arrival rate and distribution in a network segment depends on the previous network's arrival and service processes. Therefore, analyzing the network segments with interdependency can help the operator to estimate the end-to-end latency and find ways to optimize the network features in an end-to-end way.

Mathematical models for complex tandem queuing system with general arrival and service processes may not exist. Operators may use measurement and machine learning techniques to detect the dependencies of network segments.

Edge servers may be deployed for cases where dependency outside of the operator's network creates an obstacle for certain LL services, depending on the cost and latency analysis.

Another factor to consider is how marking is passed based on the next segment's LL support. For example [5] proposes remarking LL DSCP to a lower DSCP value if the next network segment is not ready to support LL services and a higher DSCP may create unfairness or starvation for other services.

3.4. Network Segments with Classic ECN

Although a rare use case, network bottlenecks employing a shared queue that implements an AQM algorithm that provides Explicit Congestion Notification signaling according to RFC3168 may create issues for the L4S deployment [7]. ECT(1) usage for L4S traffic classification are defined in RFC8311 to update RFC3168. If end-to-end path includes network segments with RFC3168 AQMs, having L4S compliant congestion controlled flows instead of all classic congestion controlled flows may cause a lower throughput of classic congestion controlled flows in the same queue. As explained in [7], this problem is rare and significant only if RTTs are long and rates are high for long running flows. [7] proposes preferred and other options, including using edge servers, upgrading AQM implementations, fairness improvement techniques etc. Operators may use end-to-end monitoring and QoE assessment techniques to discover such cases and deploy options defined in [7]. IETF specifications have recommendations for other cases that may be incompatible for L4S deployments during transitioning to a larger ecosystem support.

3.5. Standards Compliance and Larger Ecosystem Support

Although IETF and CableLabs specifications are the main standards cable operators rely on for LL feature implementations, most cable operators support other technologies in their networks, such as PON, 4G/5G, Wi-Fi and wireless IOT technologies. For a predictable E2E latency values, the standards' LL approaches such as marking and congestion notification techniques must converge. For example, IEEE 802.11be (Wi-Fi 7) specifications introduces new Access Categories and mapping for LL services, that comply with LLD features.

In addition, applications (e.g. online and cloud gaming, videoconferencing, interactive real-time streaming, VR/AR), OS (e.g. Windows, MAC, Linux) and API protocols (e.g. WebRTC, Element) providers must also support LL marking, accurate congestion notification and scalable congestion control techniques. LL services may be supported seamlessly and in a predictable way with larger ecosystem support as every party will win with a common goal.

At the IETF 114, sponsored by Comcast, and held in Philadelphia the week beginning July 23, a Hackathon to test interoperability of L4S, ECN and LLD took place.[9]. There were over 30 participants including cable operators and large Internet application and technology providers

including Google, Apple, Meta, Netflix and NVIDIA among others. During this hackathon network infrastructure for DOCSIS, Wi-Fi and 5G were all tested. Results for LLD traffic with an AppleQu8ic implementation are summarized in Table 1.

Table 1: IETF 114 Hackathon results with very compelling improvements in Latency and Jitter.

Upstream	Classic AQM Network	L4S + LLD Network
Upstream Flows	P99 – 30 msec P99.9 - 125 msec	P99 – 9 msec P99.9 - 10 msec
Downstream Flows	P99 – 56 msec P99.9 - 96 msec	P99 – 1.1 msec P99.9 – 7.8 msec

4. Conclusion

LLD promises predictable low latency service support if end-to-end architecture and deployment strategies are well defined. It requires many service and network components to interact in a harmonious way as shown in Figure 10. To support such an architecture requires disruptive changes in traditional cable operators' networks. Operators should support Software Defined Networking (SDN), Network Functionality Virtualization (NFV), Data-driven automation and service agility for the best LL service support.

1. Introduction

Through industry partnerships and customer connects, we have pursued insights on how the pandemic has fundamentally shifted consumer and worker behavior, exploring the increased importance of engagement in a world of remote work, and touchless experiences. We discovered a significant shift in customer expectations and behaviors: customers have moved beyond speed and are looking for a unified and simple experience with channel of choice. In a post-pandemic world, preferences have shifted to more personalized, convenient, and connected experiences.

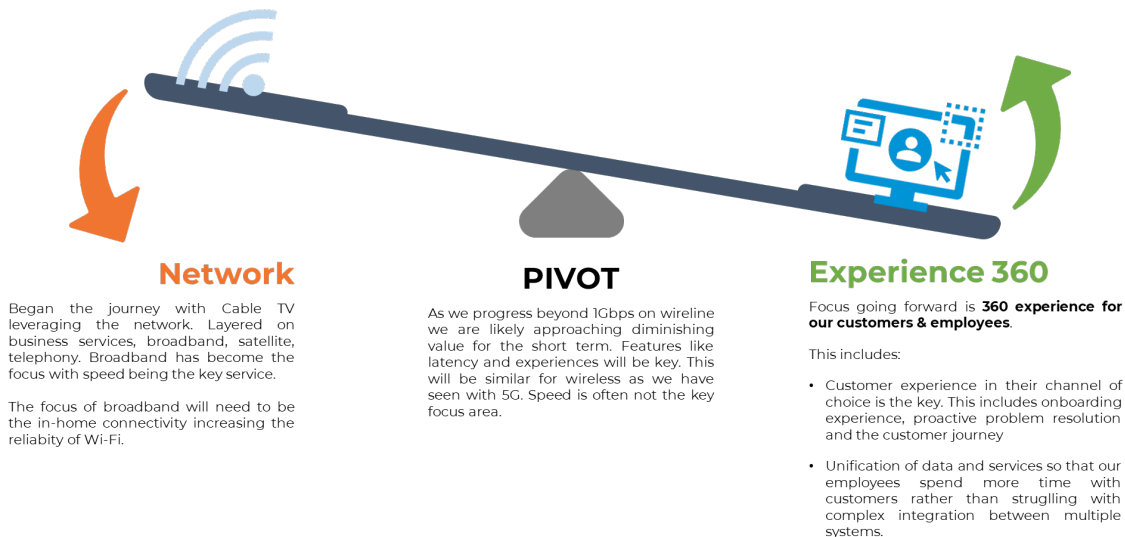

Figure 1 - Pivot in Customer Expectations

A unified channel touchpoint and agent experience is central to providing a connected customer experience. Because agents are behind the various customer interaction channels, their experience is the most crucial factor in meeting these quickly evolving customer expectations. To obtain a 360-degree view of the customer, agents have traditionally needed to access information from multiple systems and applications. However, this “swivel chair” experience was inefficient and impacted call times, wait times and general customer experience. Something had to change.

A Unified Customer Platform (UCP) has since been designed to empower agents through seamless visibility to any Customer in one place – no more swivels. UCP provides an accurate and centralized look at all the services a customer subscribes to, across all lines of business. Available 24/7, UCP visualizes customer and service information (using simple but intuitive UIs and modern search capabilities), allowing sales and support teams to quickly understand the customer is subscribed services. It also serves as the foundation to create customer communications and digital journeys, automated marketing and sales campaigns, enriched customer segmentation and enhanced reporting.

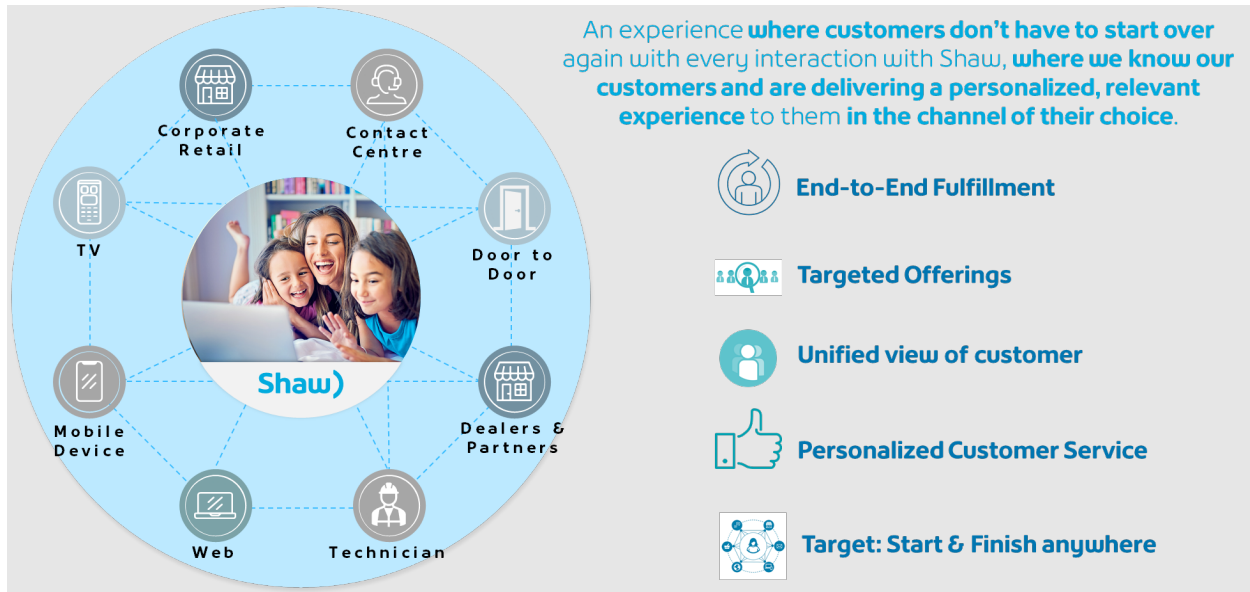

Figure 2 – Shaw's Customer Experience Strategy

In this paper we introduce the Unified Customer Platform (UCP), a modern platform that helps Shaw identify customers who meet eligibility requirements for new product offerings.

Figure 3 - Shaw's Agent Experience Strategy

Eligibility requirements often require taking a 360-degree view of the customer across multiple lines of business to highlight the products and services that are a good fit. This analysis leads to cross sell/upsell opportunities and would typically take place outside of a source system with the data analysis occurring in siloed data sets. Centralizing customer information (account information, subscribed services, history) in

UCP creates a single-entry point for reviewing cross-sell/upsell opportunities. Accessing customer information in UCP via an application programming interfaces (API) or a Google-like search interface was an important design decision. This will be the first time Shaw has had access to a single platform capable of retrieving customer information for all our customers across all lines of business.

Overall, the care teams using UCP are incredibly happy with the platform. The consolidated customer information helps reduce the “swivel-chair” previously required to jump between different billing systems. It provides them with the consolidated account details to best help support the customer base. The key findings that emerged from building and deploying UCP are:

- 1) Customer care teams benefit from platforms that aggregate account data from multiple source billing systems. We saw good adoption from Wireless Care teams who needed to find authorized users listed on a Wireline Internet services account.
- 2) Searching for customer accounts using the Elasticsearch search engine is a comfortable and time saving feature. Expanding customer search to include multiple service addresses and other business-class? options has been collected.
- 3) Modern technology stacks inside public clouds like AWS help reduce the overhead of building a new, common data platform and can deliver extreme performance at reasonable costs.
- 4) The lack of real-time data feeds into UCP was a constraint placed on us because of how data gets batched and scheduled upstream. For key data attributes like upgrades to new services, care teams would like to see an indicator that something is pending rather than no data.

Our intent is to continue to develop the UCP platform as an aggregation platform for a variety of new use cases that reach beyond care teams. Also adding additional account details like pending upgrades and customer interactions would help paint a better picture of our customers. Migrating some of the data loads into event-based streams could also help reduce the data load lag times caused by batched daily loads of data.

This paper will be organized as follows: we begin by introducing some of the drivers that helped ground us on why Shaw pursued building UCP in the first place. We will then present an overview of UCP and how it is being used to improve customer experiences. This is followed by the platform architecture and design challenges. We conclude the paper with a look at UCP’s journey so far, and likely future states.

2. Key Drivers

The key drivers to provide a personalized, convenient, and connected experiences to our customers started with the rebranding of the Shaw wireless product suite. If the Unified Customer Platform helps with selling Shaw Mobile, it could be used for other customer offers in the future. The relatively short project timelines had us looking at ways to modernize the technology stack so that we can focus on building business value without the incumbrance of managing infrastructure at scale.

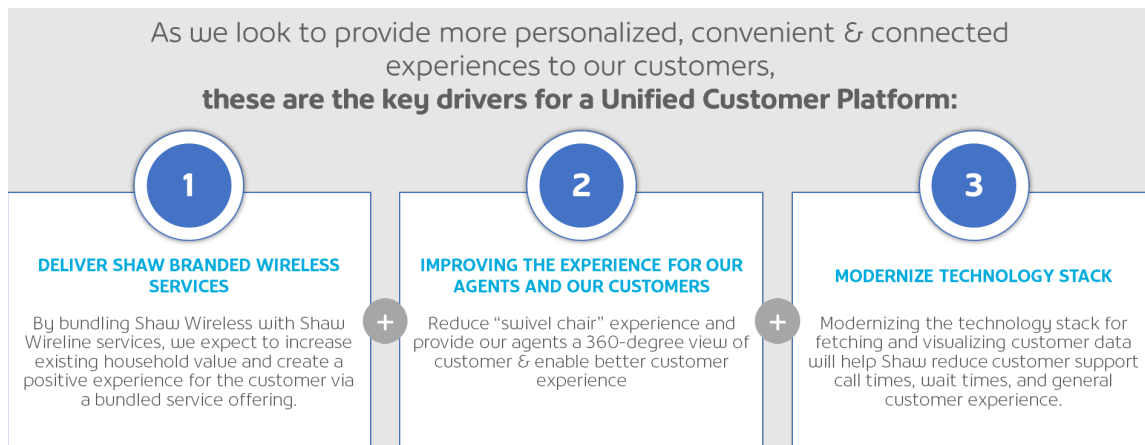

Figure 4 – Key Drivers for UCP

- Shaw wants to deliver a new Shaw-branded wireless product in Western Canada. By bundling Shaw Wireless with Shaw Wireline services, Shaw expects to increase existing household value and create a positive experience for the customer via a bundled service offering.
- Having a complete picture of the customer will provide a better agent experience and improve Shaw’s ability to support the current customer base, improve upsell recommendations, and maximize the effectiveness of marketing campaigns.
- Modernizing the technology stack for fetching and visualizing customer data will help Shaw reduce customer support call times, wait times, and general customer experience. Specifically, we were interested in how a query language for your API (GraphQL, graphql.org) can potentially create a more consumable API when compared to traditional RESTful (REpresentational State Transfer) API’s.

3. Overview of Unified Customer Platform (UCP)

The Unified Customer Platform enables searching for both residential and business customers across all lines of business using a dedicated search engine. Work was done to build data pipelines that aggregated this fragmented data into a single search index. Searching against this index matches your search terms against customer names, account numbers, phone numbers, and email addresses. The search results contain a list of customers, ordered by relevance, that match or partially match the search criteria along with all the associated child accounts for each customer. Why does this matter? UCP provides a single view of the customer instead of an account-centric view that was previously spread across five different source systems. Knowing the customer from an aggregated data perspective provides an enriched customer interaction, creates cross/up sell opportunities, exposes data insights to better serve the customer and allows the right offers to be recommended at the right time.

We felt it necessary to build this complete picture of the customer across three distinct layers. 1) a relational data set that can support reporting and marketing campaigns. 2) An API layer that functions as a data fetching API and gives clients the flexibility to select what data they need with minimal transformations. 3) And because agents need to interact with this data while assisting customers, it was necessary for us to build a new front-end to search and see all the customers data on one screen.

The Unified Customer Platform can be divided up into the following components:

- A front-end user interface that supports customer search and viewing customer details.
- An application programming interface (API) layer that uses the GraphQL to control exactly what data you get back from the API.
- Local data stores that optimize data fetching and retrieval.
- A data transfer layer that handles loading of the local data stores.
- A cloud data warehouse that aggregates customer data.
- A master data management (MDM) platform that uses a set of business rules for linking customer accounts across 5 incongruent billing systems.

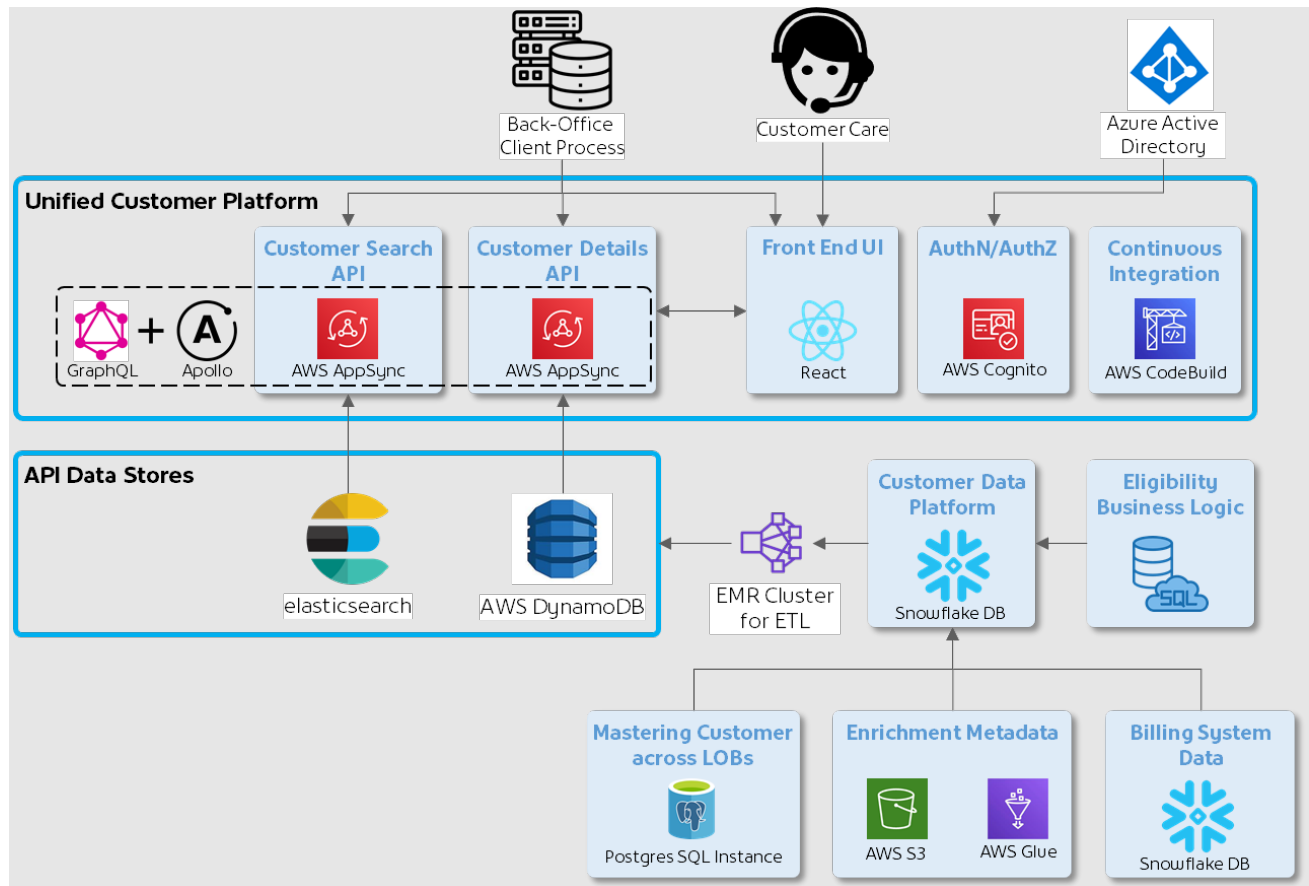

Figure 5 – High Level System Overview

4. Guiding Design Principles

When we sat down to develop this new platform, we were getting several different requirements from different teams. The scope of potential end-users was broad and included Back Office teams, Care teams, Retail support, Marketing, Finance, Revenue Assurance, Technical Operations, and corporate stores across multiple lines of business.

Some teams don't typically interface directly with the customer and have more time to perform troubleshooting steps. Teams like the Back Office, Marketing, and Finance are good examples of teams disconnected from the customer experience. Other teams like the technical operations and retail support provide the necessary support but operate under different expectations for a timelier resolution of issues. And then there are the customer facing teams like the care teams that operate the call centers and the retail store reps. The customer facing teams often need to navigate systems and applications while talking to a customer.

To avoid feature bloat and build a usable product, the design and development teams grounded ourselves on a few key principles. These include:

Basecamp Like Delivery

- Structure work and teams into cycles that last six weeks. We experimented with three, two-week sprints and two, three-week sprints. The number of actual sprints and length of sprints could vary depending on the type of work. But roughly every six weeks we wanted to finish a batch of product work and start preparing for a new batch of work. We were largely influenced by how Basecamp (Cisco, 2018)[1] structures their work.

Right Sizing Teams

- Team sizes are kept small. A team is two or three people that is dedicated to a portion of the product. We had a 2-person team for the UX design, a 2-person team for the AWS infrastructure, a 2-person team for the front-end, and a 2-person team for data engineering work. In a 6-week cycle, team sizes could flex up or down depending on the scope of work that needed to be done.

Prioritize Based on Value

- We could not do everything that we wanted to do and do it well. We did not have the time, resources, people, etc., so we prioritized the features to make the minimal viable product that executes on a few things and does them extremely well. The top requested feature was the ability to view account details for wireless and wireline to see if the account owner or authorized users on the account are eligible for promotions or offers.

API-First Approach

- Employ an API-first approach to building products. An API-first approach means that for any given development project, the API's are treated as "first-class" citizens. The API's can be consumed by both the client applications, other system platforms, or other development teams. Therefore, the API's need to be designed in an intuitive and reusable manner.

5. Minimum Viable Product Scope

The initial set of users for UCP was reduced to the care teams, marketing teams and back-office teams. Having a targeted user base helped us get both timely feedback and a reduced set of requirements plus allowed the development teams to course correct between sprint cycles.

The search feature was limited to customer names, account numbers, phone numbers, and email addresses. Searching by customer name needed to allow for partial matches on either the first name or last name.

Account details needed to include total monthly revenue totals by line of business, identification of the different product subscriptions, how long has this person been a customer, account status, payment status, and any authorized users on the account. Address information for billing and service addresses was also needed.

The unified customer channel needed to include three distinct access patterns for fetching customer data:

- A relational data warehouse that functions as the foundation for data aggregation and enrichment of customer data that can be accessed using Structured Query Language (SQL)
- A GraphQL API that provides some flexibility for the client to choose what data gets returned
- A React Web Application that uses the GraphQL API to efficiently fetch customer data

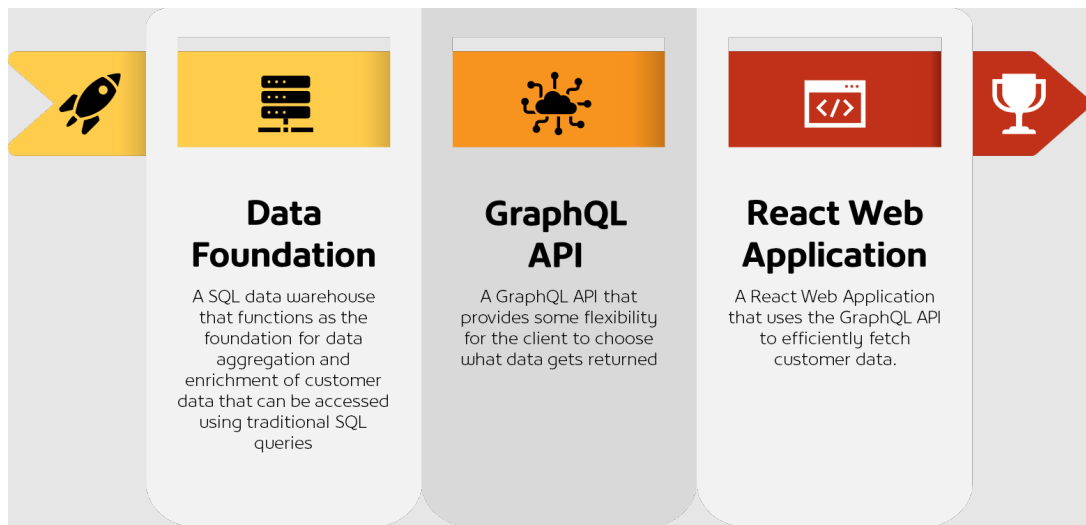

Figure 6 – UCP - Minimum Viable Product Scope

6. Components

6.1. Customer Search

The goal was to develop a single customer search endpoint that would search across the entire customer base in a performant manner. To optimize search performance, we are using Elasticsearch, a distributed search and analytics engine.

Initially, we considered using traditional relational database engines for search, but the search performance that we got from Elasticsearch was far superior to that of a Postgres database. In addition, we also had plans to take advantage of Elasticsearch features for including alternate spellings and nicknames for a customer's first name and addresses. Overall Elasticsearch felt like the best tool for the job.

We wanted searching to be simple, intuitive and with minimal navigation. We evaluated different design options and preferred a single search bar component with some place holder text that tells the user what to enter for search terms.

Figure 7 – Top Search Bar

Searching across residential and business accounts is the default without a need to provide any extra context. We also wanted the search engine to support partial matching of customer names and email addresses.

6.2. Search Results

Search results needs to show the customer, and all their associated linked accounts. (The linking of accounts will be covered later under the Customer Account Linking section.) When accounts are linked, there is one account that gets designated as the primary account. The rest of the linked accounts are considered child accounts. Child accounts can and will span multiple lines of business and be sourced from different billing systems.

4 RESULTS FOR

Customer Name: (John Smith)

Figure 8 – Search Results page variation where “Service Type” is shown with text in the Account # column

By clicking on one of the arrows on the right side of the page, the user will navigate to a customer details view.

6.3. Customer Details View

The customer details page provides a summary of accounts by line of business. Each line of business is reflected in a separate tab and has a summary of services, date connected, total number of accounts, the total revenue for all services, and whether the customer is in the mobile network and is eligible for a wireless bundle.

Below the tabs, there is an account summary section consisting of the account number, authorized users, revenue per account, source billing system, and account status/payment status. Below the summary are the account details that includes billing and service addresses and the details for the distinct types of services.

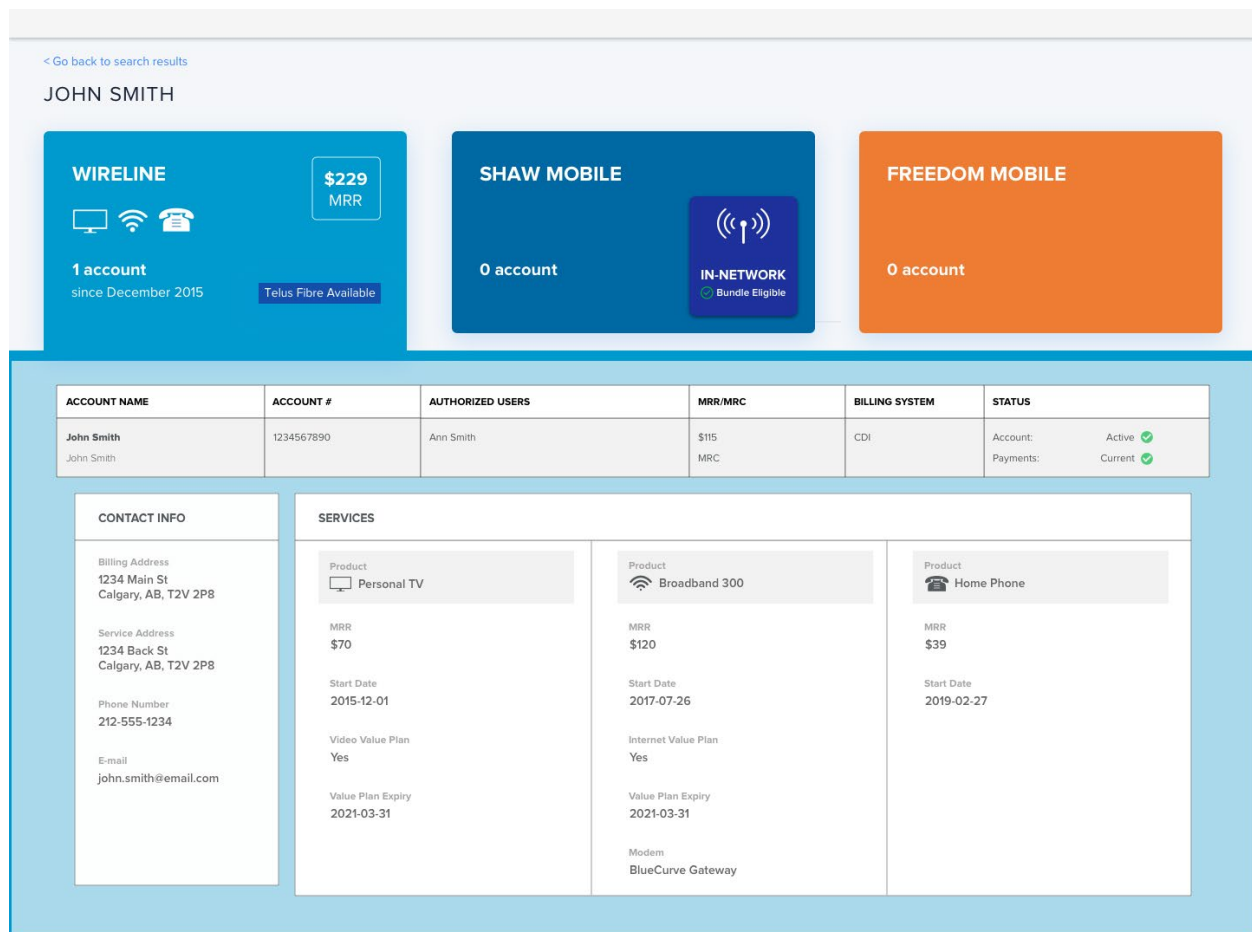

Figure 9 – Wireline, no mobile service (in-network wireless quality & eligible for bundle)

6.4. Data API Considerations

A customer data API needs to be designed in a reusable way to support multiple use cases. The primary use case is to serve as the back-end data fetching API for the new UCP front-end. In addition, we received requests from other platform owners to use this API to enrich customer data by making a simple HTTP request to our API. This type of integration is attractive because we eliminate the need for replicating customer data sets between various systems. Replicating large data sets across disparate systems is expensive, slow, and difficult to maintain.

The decision to use GraphQL over REST was an easy decision from the perspective that by 2020 GraphQL was a proven technology offering many advantages over some of the challenges that faced traditional REST APIs.

For example,, retrieving an aggregated view of accounts using a RESTful API might require making multiple calls to the API to get all the required data for each account. Or, if the data has been aggregated to a centralized landing area, the REST API would most likely be broken up into individual resources that return a set of data specific to a use case and still require a client to make multiple API calls to retrieve all

the required data. Also, the data returned from a REST API call has the potential to return a lot of unnecessary data to the client.

GraphQL is a more modern approach to building API's that gives clients more control over the data that they want to get back from an API request. This quote is from the graphql.org web site [2] which does an excellent job summarizing GraphQL:

“GraphQL is a query language for APIs and a runtime for fulfilling those queries with your existing data. GraphQL provides a complete and understandable description of the data in your API, gives clients the power to ask for exactly what they need and nothing more, makes it easier to evolve APIs over time, and enables powerful developer tools.”

A query language for APIs means that clients can change the shape of data returned by a GraphQL server. Clients will have control to specify different return fields, run multiple queries in a single request, and add aliases to fields to accommodate naming differences across front-end and back-end code. This all helps reduce the amount of data transformations needed on the client to process the data.

In summary, GraphQL is typically served over HTTP/s via a single endpoint with a data schema that informs clients about the shape and types of data that can be returned from the API. This contrasts with REST APIs over HTTP which typically expose a suite of URLs (multiple endpoints), with each URL endpoint exposing a single resource that defines a data format for the return data.

6.5. Snowflake Cloud Data Warehouse

One of the core requirements was to provide a unified customer channel that can be accessed via SQL as well as an API. It seemed logical that the cloud data warehouse would be a landing zone for customer data, so we built a customer data mart for this purpose. This customer data mart was designed as the primary source of data for UCP.

The primary consideration was that we wanted to use a modern data platform that enabled separation of compute and storage so that we can scale compute and storage separately. This requirement had us considering a cloud data warehouse (e.g., Snowflake) or a modern cloud data lake in AWS. We ultimately chose Snowflake because it was an SQL-based cloud data warehouse that allowed us to leverage existing skill sets with the minimum amount of training required to adopt the new platform. Snowflake's user administration was also simpler and more integrated with the product compared to the AWS data lake.

6.6. API Data Stores

The API data stores were needed to meet our performance needs. For the customer search API, we used Elasticsearch in AWS. There is nothing specific about the Elasticsearch configuration that required it to be hosted in AWS, so this decision was made mostly out of convenience.

For the customer details lookup API, we used DynamoDB, a fast, NoSQL Key-Value database. The main consideration was that we needed a database that could manage semi-structured customer data in JSON format. Other NoSQL datastores like MongoDB could be drop-in replacements for DynamoDB.

6.7. Customer Account Linking

Customer account linking is the process of matching accounts by different attributes like name, service addresses, phone numbers, etc. Once a grouping of accounts is known for a customer, one account gets assigned as the primary account and other accounts become child accounts and are linked via a data relationship.

We took a conservative approach to linking customers by building a recommendation engine that only recommends accounts to be linked. Administrators need to accept the recommendation before one account gets assigned the primary account and all the other accounts get linked as child accounts. The recommendation engine factors in a set of rules that helps prioritize which accounts are considered the primary.

This process runs on a separate platform and the results for account linking get replicated into Snowflake for consumption by UCP.

7. Challenges

Building a GraphQL API that returns data for all customer types across all lines of business required defining a customer data type in a GraphQL schema document. Bringing residential and business customers together in a single data type requires some flexibility in the design so that we do not create dependencies for things that are independent.

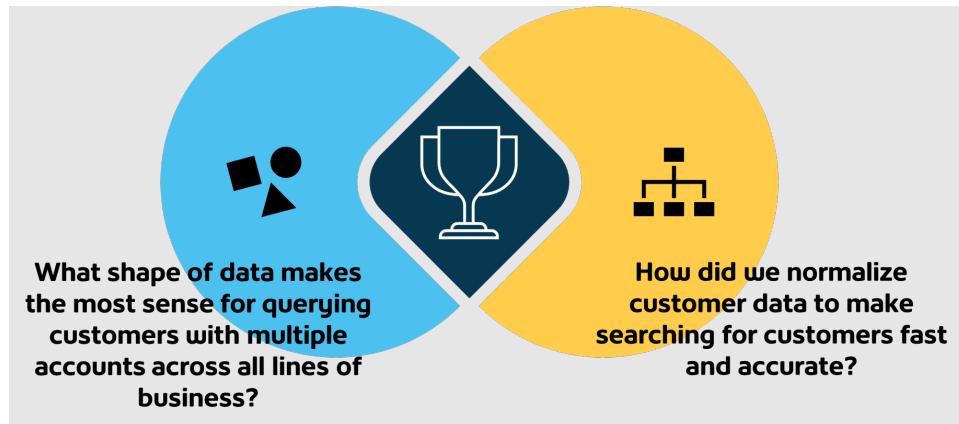

Figure 10 – UCP – Challenges

What shape of data makes the most sense for querying customers with multiple accounts across all lines of business?

The customer API must be flexible and return a range of possible data types depending on the subscribed products and services for each line of business. A customer could be a combination of wireline and wireless services with data coming from different source billing systems. We wanted to future proof the API by not adding any dependencies across billing systems. Billing systems can make changes that are independent of other billing systems and the customer API needs to be able to handle any type of data.

The types of data for a residential customer could differ dramatically from a business customer and the API needs to dynamically handle this. We wanted to remain consistent with GraphQL best practices by having a single API endpoint for all the distinct types of customers and to be able to return all the customer data in one HTTP request. If you only are interested in detail for one type of customer, for example, wireline customer details, the request payload can change to reflect the exact details for a specific customer or even multiple customers.

For the API to handle a range of possible field types, there is a union type that's part of the GraphQL specification.

```
union ServiceProvider = ShawWirelineServiceProvider | ShawMobileServiceProvider | FreedomMobileServiceProvider | AccountNotFound
```

Figure 11 – Union of Customer Types

A query that returns the ServiceProvider type is designed to receive more than one billing account number that could be any one of the ServiceProvider types. If the account lookup fails, the AccountNotFound type gets populated.

In cases where a client is passing in a single account number and already knows the type of service provider, they can build an extremely specific query that reduces the API response to the pieces of data that they care about.

```
query GetInNetworkStatus {
  getAccountsByServiceProvider(getDashboardInput: [{billingAccountId: "TESTESI-11111111"}]) {
    serviceProvider {
      __typename
      ... on ShawWirelineServiceProvider {
        accounts {
          accountName
          billingAccountId
          detailType
        }
        inNetwork
        wirelessCoverageQuality
      }
    }
  }
}
```

Figure 12 – Example of Getting In-Network Status for a Single Account Number

In this example, the client is only interested in finding out whether the customer is in network and has good wireless coverage quality to be able to offer them a Shaw Mobile bundle.

In other cases, we could enter multiple billing accounts for a single customer. In this example, the \$getDashboardInput is an array that accepts multiple billing accounts of type getAccountInput. The account numbers getting passed in could be one of the three different service providers or a failure condition when account number is not found.

```
query getAccountsByServiceProvider($getDashboardInput: [getAccountInput!]!) {
  __typename
  getAccountsByServiceProvider(getDashboardInput: $getDashboardInput) {
    serviceProvider {
      __typename
      ... on ShawWirelineServiceProvider {
        accounts {↔}
        telusFibreAvailable
        inNetwork
        bundleEligible
        minStartDate
      }
      ... on ShawMobileServiceProvider {
        minStartDate
        accounts {↔}
      }
      ... on AccountNotFound {
        __typename
        missingaccounts
      }
      ... on FreedomMobileServiceProvider {
        minStartDate
        accounts {↔}
      }
    }
  }
}
```

Figure 13 – Multiple Account Numbers as Input; Aggregate by Service Provider

How did we normalize customer data to make searching for customers fast and accurate?

As mentioned above, one of the design considerations for search was to use Elasticsearch as the search engine for finding customers by customer name, account number, email address or phone number. Elasticsearch, or one of its derivatives like AWS OpenSearch, typically ranks extremely high in popularity for enterprise search capabilities. DB-Engines ranks Elasticsearch #1 in popularity as of June 2022. [3]

Today, a lot of the undifferentiated heavy lifting for provisioning and scaling an Elasticsearch cluster is handled by third-party cloud providers. We will not go into tremendous detail on the physical infrastructure that is needed to search across millions of customer records. Instead, we will spend more time discussing how the customer data is indexed to achieve fast and efficient searches.

The physical infrastructure for an Elasticsearch cluster in AWS that will support searching across millions of customers could look like the following.

- Use Amazon OpenSearch Service for managing a six-node search cluster running either an Elasticsearch 6.8 cluster or an OpenSearch 1.2 cluster.
- Typically, there would be three master nodes and three data nodes all running on instance types of either c5.xlarge.search (Elasticsearch) or m6g.xlarge.search (OpenSearch).

Indexing data in Elasticsearch is done using analyzers that translate data into tokens that are more suited for search. A token in Elasticsearch contains the string, type, and some positional offsets. In large blocks of unstructured text, the same token could appear in multiple positions. For the examples here, we are dealing with structured data as text or keywords and therefore the positional offsets are not as important.

In Elasticsearch there is a difference between a text field and a keyword field. The text fields get analyzed and broken down into different tokens, whereas a keyword field is typically represented as a single token.

The tokenization of a customer's full name as a keyword field could look like this:

```
1 {
2   "tokens" : [
3     {
4       "token" : "josh smith",
5       "start_offset" : 0,
6       "end_offset" : 10,
7       "type" : "word",
8       "position" : 0
9     }
10  ]
11 }
12
```

Figure 14 – Keyword Field Tokenization Keeps Josh Smith as a Single Token

Whereas the tokenization of a text field for a customer's full name as a text field would look more like this:

```
1 {
2   "tokens" : [
3     {
4       "token" : "josh",
5       "start_offset" : 0,
6       "end_offset" : 4,
7       "type" : "<ALPHANUM>",
8       "position" : 0
9     },
10    {
11      "token" : "smith",
12      "start_offset" : 5,
13      "end_offset" : 10,
14      "type" : "<ALPHANUM>",
15      "position" : 1
16    }
17  ]
18 }
19
```

Figure 15 – Text Field Tokenization Separates Name into Two Tokens

Only text fields can be sent through an analysis process that structures data into tokenized formats that are optimized for search. Elasticsearch ships with built-in [4] and custom analyzers. Custom analyzers will be needed to improve search hits for account numbers and phone numbers.

Normalizers are like analyzers but are performed on keyword fields and only produce a single token. Keyword fields are usually structured data types that are recognizable fields like email addresses, phone numbers, and account numbers that are typically used for filtering and sorting.

Now that there is a better understanding of the difference between keywords and text fields, we can jump into some of the things that we had to do to improve searching by account numbers and phone numbers.

Account numbers defined as keywords will get normalized to make searching against them simpler. Because we are dealing with a handful of different billing systems, we could see variations with how account numbers are formatted. Some accounts are all digits; sometimes accounts include leading zeros, other times they do not; and some accounts have characters that prefix a set of digits that could be capitalized or lower case.

The first step is to deal with the leading zeros, so we do not require this as part of search. The `char_filter` will replace any of the leading zeros with an empty string. For this example, we will just focus on the `customer_account_number.keyword` field. This field uses the keyword normalizer with a custom filter (`char_filter`) that removes the leading zeros and forces the final token to be lowercase.

```
PUT scte_index
{
  "settings": {
    "analysis": {
      "char_filter": {
        "no_leading_zeros": {
          "type": "pattern_replace",
          "pattern": "^(0*)",
          "replacement": ""
        }
      },
      "filter": {},
      "normalizer": {
        "keyword_normalizer": {
          "type": "custom",
          "char_filter": ["no_leading_zeros"],
          "filter": [
            "lowercase"
          ]
        }
      },
      "analyzer": {}
    },
    "mappings": {
      "properties": {
        "customer_account_number": {
          "type": "text",
          "analyzer": "account_number",
          "fields": {
            "keyword": {"type": "keyword", "normalizer": "keyword_normalizer"}
          }
        },
        "customer_name": {}
      }
    }
  }
}
```

Figure 16 – Removing Leading Zeros from Account Number

Using the above settings, searching for a customer using an account number no longer requires specifying leading zeros. The query below uses account number “123456789” as the search term.

```
GET scte_index/_search
{
  "query": {
    "match": {
      "customer_account_number.keyword": {
        "query": "123456789"
      }
    }
  }
}
```

Figure 17 – Account Number Search Query (Leading Zero not Specified)

The query string of “123456789” normally will not match an account number that is indexed with “0123456780” because of the zero prefix. However, if you look at the results below you will notice that the document returned from the query “123456789” matches a document that contains a zero prefix.

```
{
  "took" : 3,
  "timed_out" : false,
  "_shards" : {
    "total" : 5,
    "successful" : 5,
    "skipped" : 0,
    "failed" : 0
  },
  "hits" : {
    "total" : {
      "value" : 1,
      "relation" : "eq"
    },
    "max_score" : 0.2876821,
    "hits" : [
      {
        "_index" : "scte_index",
        "_type" : "_doc",
        "_id" : "-EXVc4EB6ViCQ5dG6p-7",
        "_score" : 0.2876821,
        "_source" : {
          "customer_account_number" : "0123456789",
          "customer_name" : "john smith"
        }
      }
    ]
  }
}
```

Figure 18 – Search Results for Query “123456789”

Normalizing phone numbers required a little more work to get satisfactory results. Phone numbers needed to be only numerical digits, 10 digits minimum, not empty, required removal of all zero prefixes, so that different formats for phone numbers could be handled. In the example below, we use a custom phone number analyzer and search analyzer.

```
{
  "scte_index_03" : {
    "mappings" : {
      "properties" : {
        "customer_phone_numbers" : {
          "type" : "text",
          "analyzer" : "phone_number",
          "search_analyzer" : "phone_number_search"
        }
      }
    }
  }
}
```

Figure 19 – Phone Number Mapping Example

And below you can see how the phone number analyzer is configured. There is a `char_filter` for removal of all non-digit characters from the phone number. The `us_phone_number` is a custom tokenizer that removes any leading 1's from the phone number and preserves the original number.

```
{
  "analyzer": {
    "phone_number": {
      "char_filter": "digits_only",
      "tokenizer": "keyword",
      "filter": [
        "us_phone_number",
        "ten_digits_min"
      ]
    },
    "phone_number_search": {
      "char_filter": "digits_only",
      "tokenizer": "keyword",
      "filter": [
        "not_empty"
      ]
    }
  }
}
```

Figure 20 – Phone Number Analyzer

We can test how the `phone_number` analyzer works by using the `_analyze` feature of Elasticsearch. The `_analyze` feature runs an analyzer with a text string and outputs the generated tokens.

```
GET scte_index_03/_analyze
{
  "analyzer": "phone_number",
  "text": "18005551111"
}

GET scte_index_03/_analyze
{
  "analyzer": "phone_number",
  "text": "1 (800) 555-1111"
}

GET scte_index_03/_analyze
{
  "analyzer": "phone_number",
  "text": "800.555.1111"
}
```

Figure 21 – Examples of How to Test Different Phone Number Formats

The first two _analyze examples resolve to these two tokens [18005551111, 8005551111] while the last example resolves to [8005551111]. The important thing to notice that each example has the 8005551111 as one of its tokens. Actual output from the _analyze command is shown below.

```
{  
  "tokens" : [  
    {  
      "token" : "18005551111",  
      "start_offset" : 0,  
      "end_offset" : 11,  
      "type" : "word",  
      "position" : 0  
    },  
    {  
      "token" : "8005551111",  
      "start_offset" : 0,  
      "end_offset" : 11,  
      "type" : "word",  
      "position" : 0  
    }  
  ]  
}
```

Figure 22 – Results for Analyzing Phone Numbers

Because account numbers, email addresses, and phone numbers are stored in different fields we needed to use what Elasticsearch calls a multi-match query. In a multi-match query, we are running multiple queries with the same search term. Because the search term gets applied to different search fields, we rely on the relevance score to build the search results page.

Search algorithms apply rules and mathematical calculations to derive a relevance score so we then can do a little manipulation of the scores. For example, we boost complete matches against full name and last name higher than a partial match that uses a wild card search. Elasticsearch uses Lucene under the hood so by default it uses the Practical Scoring Function [5]. The details of the scoring function go beyond this paper, but it is worth noting that Elasticsearch does give you the ability to tune the scoring algorithm and change relevance scores.

8. What's next for Unified Customer Portal

There are a lot of opportunities for us to continue development of UCP so that Care agents continue to have better interactions with the customers. Below are three features that we are currently pitching to the UCP product owners.

8.1. Search Improvements

For customer search we would like to add synonyms for both customer first names and alternate spellings for address searches. To accomplish this in Elasticsearch you need to start with a synonyms file that correlates between a name and different nicknames.

```
aaron => erin, ron, Ronnie  
alan => al  
...  
benjamin => ben  
...  
josh => joshua  
...  
william => bela, bell, bill, billy, will, willie, willy
```

Figure 23 – Example Synonym File Provides Alternate Names

Maintaining a synonym list is difficult to do manually so we would like to explore some novel ways on how to automatically push updates to this file. The plan will be to start with an initial list of nicknames that we can eventually compare against actual search logs so that we can measure the synonym list for completeness.

Once a synonym list is added to an Elasticsearch index you can map the synonyms to an analyzer. The example below uses a synonyms field instead of a file, but it is sufficient to prove out how we can take advantage of nicknames. The filter object defined next to number 1 creates the synonyms. The number 2 section tells Elasticsearch to use the name_synonyms analyzer for the name field. And Section 3 configures the analyzer to tokenize text into lowercase and add the synonyms data.

```
PUT scte_index_02
{
  "settings": {
    "analysis": {
      "filter": {
        "name_synonym_filter": {
          "type": "synonym",
          "synonyms": [
            "josh,joshua",
            "ben,benjamin"
          ]
        }
      },
      "analyzer": {
        "original": {
          "type": "custom",
          "tokenizer": "keyword",
          "filter": [ "lowercase" ]
        },
        "partial": {
          "type": "custom",
          "tokenizer": "standard",
          "filter": [ "lowercase" ]
        },
        "name_synonyms": {
          "type": "custom",
          "tokenizer": "standard",
          "filter": [ "lowercase", "name_synonym_filter" ]
        }
      },
      "mappings": {
        "properties": {
          "name": {
            "type": "text",
            "analyzer": "name_synonyms"
          }
        }
      }
    }
  }
}
```

Figure 24 – Mapping Settings that Applies the Name_Synonyms Analyzer

We created three analyzers in the example above and we can use the `_analyze` function to show how text gets tokenized and synonyms are incorporated.

```
GET scte_index_02/_analyze
{
  "analyzer": "original",
  "text": "Josh Smith"
}
```

Figure 25 – Testing the Original Analyzer without Synonyms

The tokenizer named original keeps the text “Josh Smith” as a single token, but it does make it lower case. Take note that these synonyms are not included in this example when using the original tokenizer.

```
1 {
2   "tokens" : [
3     {
4       "token" : "josh smith",
5       "start_offset" : 0,
6       "end_offset" : 10,
7       "type" : "word",
8       "position" : 0
9     }
10  ]
11 }
```

Figure 26 – Results of the Original Analyzer

By changing the analyzer from 'original' to 'name_synonyms' you will see the tokenization of “Josh Smith” look different from the above example.

```
GET scte_index_02/_analyze
{
  "analyzer" : "name_synonyms",
  "text" : "josh Smith"
}
```

Figure 27 – Testing the Name_Synonyms Analyzer

There are now three separate tokens for “Josh Smith” that can be used for searching [“josh”, “joshua”, “smith”]

```
1 {
2   "tokens" : [
3     {
4       "token" : "josh",
5       "start_offset" : 0,
6       "end_offset" : 4,
7       "type" : "<ALPHANUM>",
8       "position" : 0
9     },
10    {
11      "token" : "joshua",
12      "start_offset" : 0,
13      "end_offset" : 4,
14      "type" : "SYNONYM",
15      "position" : 0
16    },
17    {
18      "token" : "smith",
19      "start_offset" : 5,
20      "end_offset" : 10,
21      "type" : "<ALPHANUM>",
22      "position" : 1
23    }
24  ]
25 }
26 }
```

Figure 28 – Tokenization Results of the Name_Synonyms Analyzer

Searching for “Joshua Smith” without synonyms will get a match on “smith” but both “josh smith” and “ben smith” are scored the same.

```
GET scte_index_02/_search
{
  "query": {
    "match": {
      "name": {
        "query": "joshua smith"
      }
    }
  }
}
```

Figure 29 – Searching Names without Synonyms

```
1 {
2   "took" : 2,
3   "timed_out" : false,
4   "_shards" : {
5     "total" : 5,
6     "successful" : 5,
7     "skipped" : 0,
8     "failed" : 0
9   },
10  "hits" : {
11    "total" : {
12      "value" : 2,
13      "relation" : "eq"
14    },
15    "max_score" : 0.2876821,
16    "hits" : [
17      {
18        "_index" : "scte_index_02",
19        "_type" : "_doc",
20        "_id" : "90W8coEB6ViCQ5dGSZ9S",
21        "_score" : 0.2876821,
22        "_source" : {
23          "name" : "benjamin smith"
24        }
25      },
26      {
27        "_index" : "scte_index_02",
28        "_type" : "_doc",
29        "_id" : "Ys08coEBexGa4gSBP-bi",
30        "_score" : 0.2876821,
31        "_source" : {
32          "name" : "josh smith"
33        }
34      }
35    ]
36  }
37 }
38
```

Figure 30 – Both Benjamin Smith and Josh Smith have the Same _Score

After adding synonyms to the search query, you get a good match for a “Joshua Smith” query which will be ranked higher than “ben smith.”

```
GET scte_index_02/_search
{
  "query": {
    "match": {
      "name": {
        "query": "joshua smith",
        "analyzer": "name_synonyms"
      }
    }
  }
}
```

Figure 31 – Searching Names with Synonyms

```
1- {
2  "took" : 17,
3  "timed_out" : false,
4-  "_shards" : {
5    "total" : 5,
6    "successful" : 5,
7    "skipped" : 0,
8    "failed" : 0
9-  },
10- "hits" : {
11-   "total" : {
12     "value" : 2,
13     "relation" : "eq"
14-   },
15   "max_score" : 0.5753642,
16-   "hits" : [
17-    {
18     "_index" : "scte_index_02",
19     "_type" : "_doc",
20     "_id" : "Ys08coEBexGa4gSBP-bi",
21     "_score" : 0.5753642,
22-    "_source" : {
23     "name" : "josh smith"
24-    }
25-   },
26-   {
27     "_index" : "scte_index_02",
28     "_type" : "_doc",
29     "_id" : "90W8coEB6ViCQ5dGSZ9S",
30     "_score" : 0.2876821,
31-    "_source" : {
32     "name" : "benjamin smith"
33-    }
34-   }
35-  ]
36- }
37- }
38
```

Figure 32 – Josh Smith Now has a Higher Score with the Synonyms File

8.2. Customer Device Details

We would like to enhance the customer details by adding device metrics. Device data that is associated with the service line can provide a Care agent more context on how well their mobile plan is working and if changes are needed.

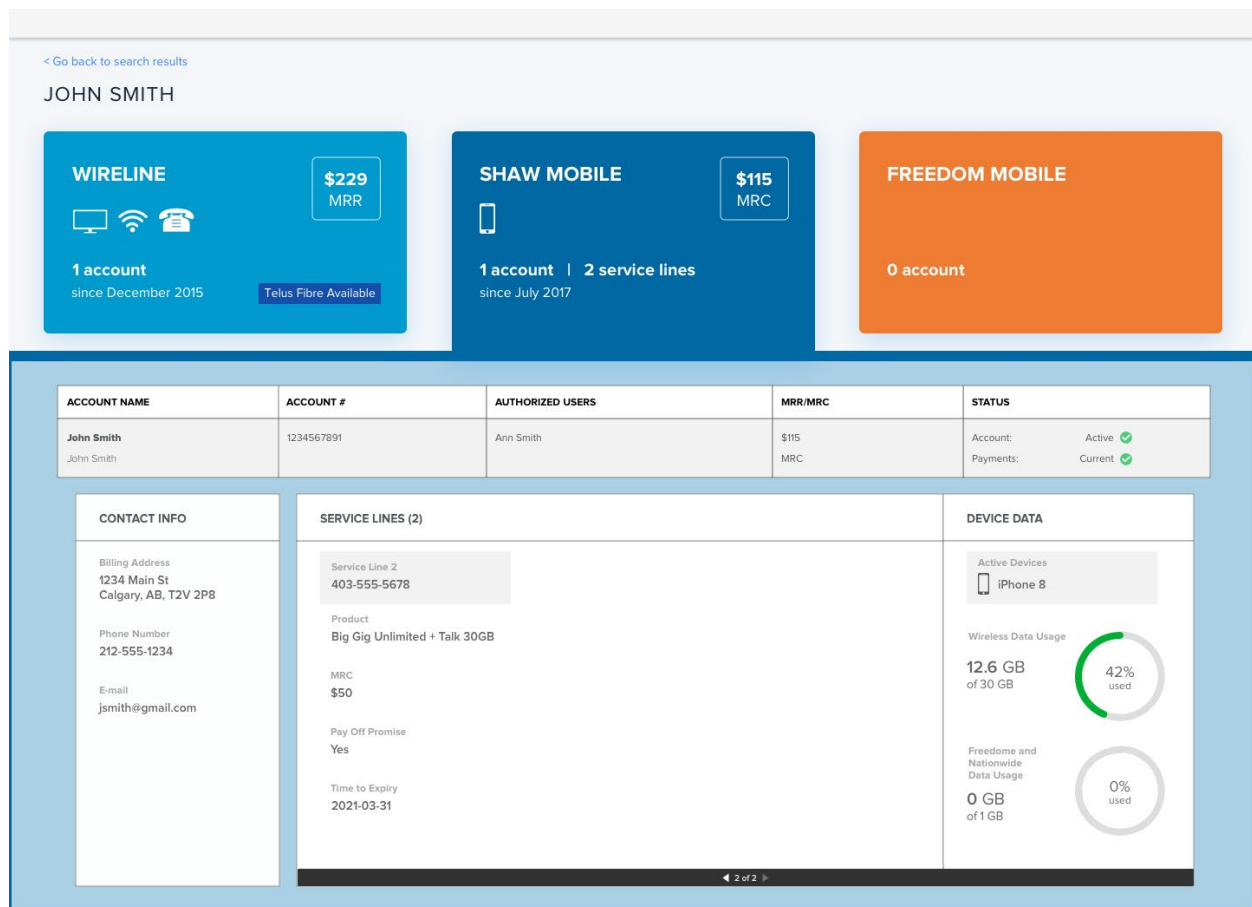

Figure 33 – Device Data Wireframe

8.3. Real-Time Data Loading Process

Our goal has always been to move to more of a real-time data load process for customer account linking and customer search. The challenge is that we are currently dealing with a lot of upstream legacy systems that only support batch exports of data.

There is still some room to optimize the schedules being used for batch loads. Transitioning to event-based schedules will help us load data as soon as it is ready. Snowflake recently announced its Unistore workload which expands the capabilities of Snowflake to support modern transactional data and analytical data in one platform. Keeping data in snowflake could eliminate the Snowflake-to-DynamoDB data load which moves the freshness of data up by 30 minutes.

Real-time data processing will require source systems to support event-based data streams. The UCP platform would subscribe to these event streams and use the data to build additional metrics about a customer.

9. Conclusion

Prior to the introduction of the Unified Customer Platform, our front-line agents would need to access multiple back-office systems across different lines of business. This “swivel chair” experience was time consuming and very inefficient while serving customers that lead to customer frustration and longer call times.

UCP simplifies this for our agents by allowing them to quickly search for a customer by name, account number or phone number. Once the customer is found, UCP displays the accounts and service attributes for all services that the customer subscribes to, eliminating the need to find these accounts across multiple interfaces. UCP provides all the information needed for an agent to understand the current customer engagement with Shaw across different LOBs. In addition, our agents can use the information in the tool to determine if a customer is eligible for any current promotions. UCP serves the intent that we were after: to utilize the data to best serve our customer base and allow our agents to talk intelligently with them.

Over time, we will continue to build on the foundation that we have built and extend the platform by including the ability to link customer accounts in a more formal and verified manner in real time. Our value-based iterative delivery and ability to unlock the true value of enterprise data will help us meet the goals that we have set for ourselves.

1. Abstract

‘The Truth/Devil is in the Details’ is a common saying referring to the mysterious or hidden elements knowable only with infinite parsing of all obtainable information. And truth be told there are many places where valuable information about a network as vast as Comcast’s resides. To obtain, visualize and correlate all these pieces of information requires innovation in hardware and software – in intersecting cycles that virtuously enhance each other.

Comcast serves tens of millions of residential customers and businesses. In our efforts to increase capacity and enhance reliability, Comcast has a host of hardware and software telemetry tools that monitor various factors that affect the performance of our network.

This paper will focus on ways we are taking advantage of our highly digitized network to automate wavelength management, speed up fiber event resolution, and enhance fiber construction. We will detail how real-time fiber management and auto-calibration of new fiber links are essential to maintaining complex networks and delivering exceptionally reliable services. We will also review how we are addressing fiber repairs. We all know that fiber outage events and wavelength management are significant industry challenges because we rely on multiple data sources and integration of the data for accurate records and expedient repair. We also rely on the identification of the location and distance of events to speed the arrival of repair agents. With our solution, learn how utilizing telemetry, multiple data sources, and innovative technology, a fiber event can be detected, assessed, and dispatched to an accurate location.

2. Introduction

Our networks are becoming more fiber-rich every day. We have smaller node sizes as we are driving fiber closer to the customer in both residential and commercial solutions and the amount of fiber connecting our facilities has only increased. In the past when there was a suspected fiber cut, our operations teams would notify the necessary employees or contractors to deploy to troubleshoot the fiber to determine if there was a fiber cut and if so, the associated footage so the fix agents could get to the repair location as quickly as possible. With XMF, (Xfinity Meter Fiber), a solution that automates traditionally manual fiber impairment analysis work, we have saved considerable time because there is no need to dispatch someone to perform the OTDR (Optical Time Domain Reflectometer) measurement of the fiber, assess the distance, then review the prints to identify the location. Instead, this solution provides the necessary details in minutes, allowing fix agents to be deployed more quickly and reducing MTTR (Mean Time To Repair), and improving the customer experience. But it is not just the fiber that is driving the MTTR enhancements, it is the combination of fiber-intelligent network devices, tooling, process sameness, and automation that drives improved network reliability.

3. Digitization of Data

The documentation of fiber has varied throughout the industry and each group, even within organizations, may have different methodologies to track information. The key areas of fiber documentation are (1) the physical design location (plant maps), (2) the fiber amount or size, and (3) the assignments of what is traversing each fiber. When focusing on repair efforts, the digital analysis and resulting determination of the physical location is crucial to minimizing outage repair time and the digital analytics are the catalyst for making this possible. These analytics define the digital transformation of fiber outage analysis. Digital transformation relies on 4 key business competencies, technology, data, process, and organizational change capability [5].

Technology must contribute not complicate the transformation process and be adaptable to the needs of the business [5]. The first aspect of fiber technology is the fiber itself and how it is utilized within the system architecture. The technology architecture is key to reducing latency and driving resiliency. The fiber location documentation must be captured in a centralized and consistent system that becomes the source of the truth repository. In the past, much of this documentation was maintained in multiple formats, sometimes even as a drawing on the wall of fiber engineers. Digital transformation of the fiber requires that the information be accurately captured in a tool that can then be utilized to provide key location information in the event of a fiber outage.

Data integrity standards may vary, and transformation requires understanding unstructured or invalidated data [5]. Many know that data is important, but sometimes data quality is lacking. Understanding the integrity of fiber information data is an important investment in ensuring the expected impact of digital fiber cut detection is realized. Implementing methodologies to define fiber metadata, automate the capturing of such data, and wavelength management is key to accomplishing data proficiency.

Process transformation requires innovative thinking to envision a new way of utilizing data to evolve manual processes into automation [5]. In many areas, fiber triage requires multiple manual reviews and physical confirmation of the stance of the breakage. Horizontal process management breaks down traditional hierarchal triage methodologies and the results are the implementation of a process-driven by digital and technological capabilities. For XMFR, the remote version of the XMF solution, this requires a detailed review of current processes and alignment with the updated processes to support integration.

Organizational change capability is the final key talent that requires courage to change what is historically rooted in current technology, data, and process [5]. Building new technology solutions is key to digital transformation, but without organizational change, adoption and adaptability will not happen within the business. Committing to understanding the human factor is critical to adoption and success.

All four of these elements are key to the integration of XMFR. The technology platform is the engine that delivers the capability. Data integrity is what fuels the engine to provide key accurate information to fix agents. The process is how we guide the organization to achieve consistent positive results. And organizational change is how we bring all these things together for a successful implementation that is recognized for its value to the business and impact on positive customer experience.

4. Operational Logic, XMF-R

Once the organization is aligned on the digital transformation plan, the operational logic reviews the high-level flow of how an outage is managed and identifies key automation opportunities. In many cases today, fiber outage events are not easily discernable from another outage event. The first step in the operational logic is to identify how to utilize the XMFR capability to create a specific alarm type that indicates a fiber outage event which reduces triage times for the operations center. The next step in the logic is to determine how to eliminate the need to dispatch a headend tech to OTDR the fiber to identify the distance to the fiber event. Direct dispatch of this automated information to the fix agents/persons creates speed to resolution and utilizes the technology and data information to confirm the location of the fiber breakage. The fiber logic flow in Figure 1 illustrates the value of reducing the total number of steps required to drive restoration.

Figure 1 - Operational Logic

Within the operational logic, the reduction of steps optimizes performance, but data and payload provided to the fix agents are essential for optimized restoration. The fix agents require clarity of the event, breakage distance, and location accuracy. These three elements are guides to building the technology, data, and process for operational integration. This one event message then includes:

- Fiber Outage Event
 - Clarity for the fix agent this is a fiber event and not another type of system impairment
- Distance Payload (XMFR OTDR)
 - The XMFR performs an OTDR measurement, and that information is integrated into the event messaging
- Fiber Design Reference
 - Latitude and Longitude information that is referenced to design systems to provide a specific location for the fiber outage event

5. Acting on Real-time Data

5.1. Process Changes

Our operations centers react to many diverse types of alarms and alerts. When a fiber cut is suspected, our normal response for many years was to contact the appropriate teams, based on location, and dispatch them to the appropriate location to troubleshoot the fiber, determine if there was a cut or major impairment, providing the footage details once they were obtained. The Operations Centers would then update the ticket with the footage and dispatch the appropriate fix agents to the site to make the repairs.

With the introduction of XMF, we focused first on deploying the technology between facilities, headend to the headend. This had an immediate operational impact in saving us the time we used to spend sending someone to the facility. This is especially valuable in the instance of an unmanned facility, where, if an issue occurred at night, the time to dispatch, troubleshoot the fiber, and obtain footage could easily be more than an hour. With the XMF solution, the alarm is received in seconds and within a minute or two the operations team receives the distances electronically, updates the ticket accordingly, and dispatches the fix agent.

The second focus included deploying the XMF technology at the node level (XMF-R), in the access network, as we upgrade and shift our nodes from analog to digital. As each node upgrade is implemented, the XMF-R solution is also introduced, allowing for the same benefit across all digital nodes.

The third element that enhances the solution is the end-to-end automation of the ticket and the dispatch with no manual intervention from an operation's center technician. When the XMF solution is installed and configured, many critical details are captured. (The information captured is detailed in the Digitization of our Network section of this paper) This information allows for the autodetection of fiber impairments when our tools see variances based on details captured during configuration (which creates a baseline), versus real-time performance (which either matches the baseline or finds an anomaly to escalate). As tools detect the impairments, tickets are auto-created with all the necessary information and auto-dispatch occurs with no manual, technician intervention. As noted, prior, the result is faster detection and dispatch, and a decrease in fiber troubleshooting/triage and ticketing data entry for the operations center technicians.

5.2. Tool Changes

If the XMF solution only allowed for the time savings associated with removing the need to dispatch and manually shoot the fiber, it would still be worth installing and using. However, we did not stop there! Why capture information automatically and not take advantage of removing manual steps?

Our operations teams utilize National Watch Tower (NWT) for alarming and dispatch activities associated with the Access Network for both demand and planned Maintenance Work. Our NWT teams partnered with engineering to understand the XMF solution and devised a plan to allow NWT to ingest the XMF alerts and payloads, developing the necessary routing solutions to automatically send the demand ticket to the correct fix agent for fiber cuts. Once the fiber cut solution was in place, the NWT team began to develop a similar solution for various types of fiber impairments. Both advancements share the necessary payload details to ensure fix agents have all the needed information to enable the speediest repair.

6. The Access Network

We refer to the access network as the portion of the network from the fiber node to the customer premise. As expected from a top tier service provider, we have been very focused on the reliability of our network. Reliability does not simply mean that the network is 'up', and devices are online. It means the network is operating optimally, delivering expected performance and devices are online. To achieve superior network reliability, we are deploying digital nodes with much more telemetry than traditional analog nodes, utilizing our HFC fiber to deliver expected speeds and capacity, and then complimenting that with intelligent tooling to quickly let us know when the network is not operating optimally, and where to go to fix it quickly.

6.1. Coherent Optics in the Access Domain

A practical deployment strategy of fibers is essential at Comcast. The ability to use a portfolio of fibers for some of the emerging low latency markets, while also driving fiber technology deeper into the network, is the essence of our approach in building the industry initiative of 10G. This technology convergence is an essential balance that optimizes the system architecture.

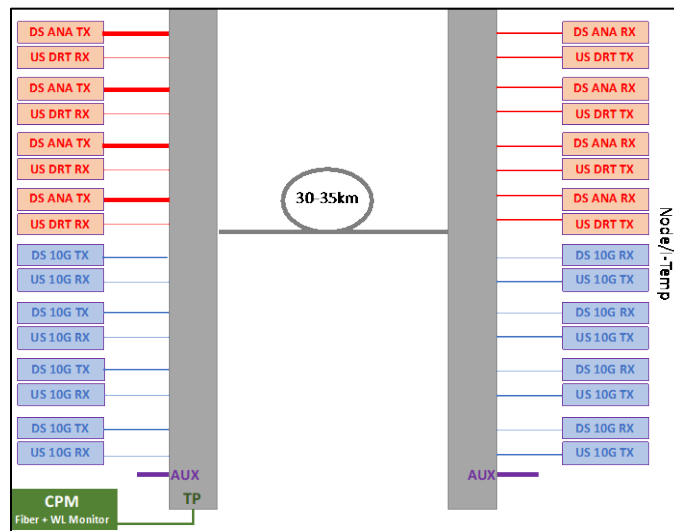

Figure 2 - Access Network Convergence

As the largest broadband company in the US, Comcast serves millions of customers and businesses with a reach that stretches coast to coast. All of this is the result of a large optical network that spans core, metro, and access layers with multiple intersecting points, all intended to increase capacity, reduce latency, and enhance reliability. Operational integration ensures the integrity of the system is maintained with a heightened customer focus.

Photons flood into the Comcast backbone network from the Internet and peer-to-peer traffic through mass-scale routers connected to optical consolidation equipment and reach the various metro centers. At the metro center, the data is reincarnated into photons on a massive IP network and the photons courses thru the highly meshed Converged Regional Area Network infrastructure that terminates in the thousands of our headends. At the various headends, data becomes photons again, traverse access fibers, and light up the many homes, businesses, and fiber nodes eventually completing their journey downstream. A similar process ensures the upstream where photons transmigrate through the access system to the various headends and mesh metro circuits before making their way back through to the internet.

7. Putting it All Together: Role of Orchestration

Deploying an advanced fiber solution and adding intelligence to the network does not immediately deliver the desired benefits. There is a great deal of orchestration across engineering, deployment, tooling/systems development, operations, and, of course, proper people management, required to bring the solution to fruition and maximize the benefit for our employees and our customers. The fiber technology must work together with the operationalization that optimizes event response.

7.1. Deployment and Implementation

Once a new network solution has been developed and tested, it becomes GA (Generally Available) across the network. Engineering teams cannot simply throw it over the fence, expecting adoption by the masses. Engineering partners with the deployment teams to update purchasing plans to acquire the necessary materials and to update our installation plans so the correct materials are ordered, installed, and configured as specified. The solution in this paper includes the fiber purchases as well as the XMF/XMF-R equipment and new policies/procedures for installation and configuration. The operational logic

illustrates how the payload of the OTDR distance and geolocation supports the ability to resolve any post-implementation fiber events quickly and effectively.

7.2. Operational Integration

Once the deployment team has completed their installation and configuration work, they turn it over to operations where validation that the equipment is present within the necessary systems and tools. It is also critical to share these changes and expected benefits with our field teams. We want to make certain everyone is aware of the change and the impact it has on their processes and the customer experience. When deploying the XMF, we communicated the expected reduction in an after-hours dispatch to OTDR fiber, and the fiber benefits regarding reduced latency and increased speed, all of which were well received by the field operations teams

7.3 An Informed Fiber Design

Live fiber information from fiber monitoring tools can improve fiber designs. When teams make design changes to the fiber network, they must have access to real time documentation. Many times, this means a request is made to the Headend or Network Team to validate the fibers or open channels. Utilizing live fiber information, a fiber designer can build a link to a new endpoint knowing what has been provisioned on a mux. This added information improves the speed of design and reduces rework and fiber assignment changes due to the use of outdated fiber system designs.

Use existing fiber information to improve assumptions, resulting in better use of the fiber resource. Fiber designers can utilize real time measured distance and loss to the mux. This new information allows teams to potentially reach further into the network, opposed to using conservative loss or storage assumptions. Fiber teams can also compare system assumptions to better understand the amount of storage or splice loss, from system to system. This new view of the network can ensure that future changes made are based on good information.

7.4 Proper Change Implementation

When implementing process, technological, or organizational changes, it is important to properly lead our people through the change. Detailing what is changing, why it is changing, and understanding the impact on our network and our people is critical to successful implementation and adoption. Recognizing the human factor of change is how organizations optimize evolutionary transformation.

8. Conclusion

Given the general focus on tooling and automation today, it is critical that we analyze all areas of our network to see how we can create better customer experiences and efficient workflows through automation. Given increasingly intelligent alerts and data access, this task becomes increasingly realistic within traditionally manpower intensive areas of the network. This paper discusses the impact of data digitization and the operational logic that is foundational to the technology needed to run advanced fiber networks. The operational logic transforms the manual fiber anomaly analysis procedure from four manual steps to automated processes that reduce troubleshooting time for the business. The process updates drive the development of tool innovation to support automation goals.

The advanced Comcast 400G network described herein, together with the optical monitoring, provisioning, and visualization, we are creating unprecedented robustness and enhancing our customer experience.

At the heart of the Comcast technology evolution is our commitment to our customers and our business goals.

1. Introduction

In North America, cable operators, delivering broadband over their hybrid fiber-coax (HFC) infrastructure, have become leading providers of broadband in the communities that they serve. It's not uncommon for a multi-system operator (MSO) to enjoy 65% market share. And subscriber additions accelerated during the first 18 months of the pandemic.

However, MSOs are now facing growing competition, in multiple forms across their service areas.

These threats mainly originate in three areas. First, fiber competition, both from large telco incumbents such as AT&T, Verizon, and Lumen, and Frontier and small upstart fiber operators. Second, the Mobile Network Operators (MNOs) have been pushing broadband over their mobile platforms very heavily over the past 24 months. (A sub-component also arises from Fixed Wireless Access providers but is a much smaller percentage of wireless broadband). And lastly, a not insignificant industry has materialized that specializes in just servicing multi-dwelling units (MDUs), and that is normally also served via fiber. MDUs can often represent 30-40% of an operator's customers.

Amidst this burgeoning competition, MSOs and their HFC architecture can point to an admirable record of remaining resilient and competitive. In fact, the limitations of the evolving DOCSIS standards have always been discussed, and those limitations have always been shattered.

Up to this point, none of the previous versions of DOCSIS[®] (1.0, 2.0, 3.0, and 3.1) specifications required any major changes to an operator's Outside Plant¹. Implementations have mainly relied on changes to electronics on either end of the 'wire'; either in the headends and hub sites (Inside Plant), or in the home (the cable modem).

Outside Plant changes have been operator-specific and generally driven by overall increases in frequency capability operating within the limits of existing active device (amplifier) housings. These changes have included:

- DS frequency migrations from 550 MHz to 750 MHz, 860 MHz, 1 GHz or even 1.2 GHz by updating node and amplifier modules
- US frequency extension from 42 MHz to 85 MHz or in rare cases to date, 204 MHz, by updating amplifier modules with new frequency diplexers

However, that is about to change.

DOCSIS 4.0², which will be introduced between 2023 and 2025, will require changes to the outside plant. Introducing this new version of DOCSIS, which will activate frequencies all the way up to 1.8GHz, is going to require an overhaul to today's HFC cable plant. This will be a far more invasive and expensive undertaking. Every device in the outside plant will need to be

¹ Perhaps this overlooks the initial 2-way activation of the cable plant in the 1990's, which was a precursor to offering broadband services.

² When discussing DOCSIS 4.0 specifications, this paper will focus on the part that many operators are planning to implement: ESD, or Extended Spectrum DOCSIS, which bumps the cable plant spectral capabilities up to 1.8GHz.

replaced (or in more rare occasions, upgraded). To put this in perspective, using an example of a rather large “fiber node” with a 350 to 400 home serving area, this equates to replacing between 10 and 20 amplifiers, between 10 and 25 splitters, and over 100 coaxial cable taps. The cost to undertake such a retrofit will start to be driven more by the labor involved than the equipment itself.

In this paper, we reference “turbocharged” DOCSIS 3.1 technology as a collection of specific improvements that have been added to DOCSIS 3.1 and DOCSIS 4.0 specifications since the original DOCSIS 3.1 specification was published:

- New deployment architectures (Distributed Access Architecture or DAA)
- Operation with varying impairments at each customer (Profile Management Application or PMA)
- Application latency improvements (Low Latency DOCSIS or LLD)
- Use of enhanced DOCSIS bonding group channel counts in DOCSIS 4.0 cable modems along with higher speed Ethernet interfaces

The “turbocharged” collection of improvements is not a separate specification, but a useful way to categorize an incremental step possible for operators before they deploy networks capable of realizing all parts of the DOCSIS 4.0 specifications. This step is a valuable way to achieve the next step in DOCSIS performance at lower cost than both full DOCSIS 4.0 network deployment and far lower cost than full fiber to the home rollouts.

2. Network Evolution

Broadly speaking, there are a handful of potential technology paths for evolving an HFC network. In between and amongst those options, many smaller choices will need to be made.

The two most significant factors to consider in meeting growing demands on a broadband network are capacity (scale) and speeds. Capacity is the ability to meet the growth in the number of subscribers on the network, as well as the growing consumption needs of each subscriber. Speeds relate to speed tier offerings, and in particular the top speed offered on the network.

To meet the demands outlined above, operators have these options to consider, as they evolve their network:

- Create capacity by segmenting the shared nature of an HFC network into smaller parts. Most often this is facilitated by splitting neighborhoods into smaller service groups, via node segmentations and node splitting.
- Expand the capacity of the network by increasing the breadth of frequencies supported. Choices here include expanding today’s 1GHz plant to 1.2GHz and/or to 1.8GHz.
- Leveraging technology to get more out of the network at hand. This includes running more of the signaling with advanced modulation (orthogonal frequency division multiplexing or OFDM), running higher modulation 2k and 4k QAM, and leveraging systems that can operate on more channels.
- Lastly, changing to a different network altogether; in this case fiber to the premises (FTTP).

3. DOCSIS 3.1 Minimum Capability

DOCSIS 3.1, introduced to field deployment in ~2015 (see [MULPIv3.1] and [PHYv3.1]), has been able to keep pace with advancements needed in capacity and speed to serve both increasing customer usage (widespread uptake in streaming video platforms, proliferation of consumer devices to name a couple) and competition from operators widely deploying FTTP in the same service area.

The current HFC outside plant is faced with several constraints. Today's 1GHz and below plant will eventually create a capacity constraint. And the current low split (~42MHz in North America) configuration, leads to high bandwidth asymmetry, with far more capacity in the downstream than in the upstream. Loosely this is along the lines of a 10:1 ratio.

Upstream speed for subscribers is limited based on frequency split, the condition of the plant (achievable US modulation) and need to support legacy DOCSIS 3.0 and earlier Advanced Time Division Multiple Access (ATDMA) channels and is summarized in Table 1. Operators looking to move to support gigabit upstream (~1 Gbps) speeds are now actively testing, trialing, or deploying High Split networks to move the upstream upper band edge frequency to 204MHz and the downstream lower band edge frequency to 258 MHz.

In the downstream direction, DOCSIS 3.1 cable modems have a minimum bonding group of 32 channels of single carrier QAM (SC-QAM) and two 192 MHz orthogonal frequency division multiplexing (OFDM) channels. With 256QAM modulation for SC-QAM and 4096QAM modulation for DS, the maximum throughput of this bonding group is 32 x ~35 Mbps + 2 x ~1.7 Gbps or 4.5-4.6 Gbps. The availability of spectrum for this total capacity depends on maximum DS frequency limit and the amount of spectrum used to delivery QAM video service, both of which are operator- and location-specific.

Commercially available DOCSIS 3.1 cable modems today are limited to supporting the minimum bonding group noted above and are also limited to maximum Ethernet interfaces using 2.5 Gigabit Ethernet (2.5GE). The combination of these commercially available minimum implementations results in service offerings with the values summarized in Table 1:

Table 1 – DOCSIS 3.1 HFC Outside Plant Minimum Capabilities

Upstream Frequency Upper Band Edge	Upstream Capacity	Maximum Upstream Service Tier	Downstream Bonding Group Capacity	Maximum Downstream Service Tier
Low Split (42MHz)	100-250 Mbps	50-100 Mbps	4.5-4.6 Gbps	3 Gbps
Mid Split (85MHz)	~400-550 Mbps	250 Mbps	4.5-4.6 Gbps	3 Gbps
High Split (204MHz)	~1.3-1.6 Gbps	1 Gbps	4.5-4.6 Gbps	3 Gbps

4. DOCSIS 4.0 Outlook and Considerations

The next version of DOCSIS, 4.0, is due to see equipment released between 2023 and 2025.

The primary objectives in DOCSIS 4.0 as the next version include:

- Support for customer upstream service tiers beyond 1 Gbps
- Support for customer downstream service tiers beyond 2 Gbps

The DOCSIS 4.0 standard (see [MULPIv4.0] and [PHYv4.0]) presents two different implementation options depending on an operator's objectives. The options are:

1) FDX - 1.2 GHz Full Duplex (FDX)

FDX is generally intended for Node+0 HFC with no active amplifiers but industry initiatives are underway to build FDX repeater amplifiers to stretch operation into networks including amplifiers. FDX targets maximum DS frequency with the same 1218 MHz limit as DOCSIS 3.1.

2) FDD/ESD - 1.8 GHz Frequency Division Duplex (FDD)

FDD/ESD is generally intended as an incremental upgrade to a traditional HFC network of actives and passives with an arbitrary number of amplifiers. This second option is commonly referred to as ESD, or Extended Spectrum DOCSIS. Industry demonstrations in 2022 have shown ESD operation to be compatible with traditional amplifier cascades and plant designs. This paper specifically focuses on ESD as an incremental path from traditional DOCSIS 3.1 to DOCSIS 4.0 technology.

Upgrading an HFC cable plant to 1.8GHz will be challenging. The signal attenuation on a cable plant to signals above 1.2GHz are significant. The passive components currently deployed are designed for 1GHz or 1.2GHz and may extend slightly higher, but many of these components will need to be changed out to support operation to the 1.8GHz maximum capability of the DOCSIS 4.0 FDD specification:

- Taps required to direct a portion of the signal energy to/from specific subscribers
- Power inserters for feeding AC into the plant
- Directional couplers and splitters used within the trunk portions of the coaxial

Likely some design changes will be required to other parts of the HFC cable plant. Some areas may require smaller booster amplifiers, estimated to be in the range of 10-20% in early design studies from multiple North American operators. In some cases (less than 5%), older deployed coax cable itself might not support 1.8GHz, requiring new coax to be deployed. These are areas of study that will be necessary for an operator to perform as each company assesses their readiness for DOCSIS 4.0, and their ability to meet the challenges that will arise.

Since the outside plant is changing and frequency is being pushed higher than what DOCSIS has done before in the HFC network, the implementation of DOCSIS 4.0 will require more extensive lab and field testing than previous versions. Many operators are likely to take a "wait and see" approach to DOCSIS 4.0 to see how early field tests and deployments work before making decisions on the future of the HFC plant.

Even when deciding to move forward, with DOCSIS 4.0 deployment, expectations are that operators will progress through multiple incremental phases of DOCSIS 4.0 ultra-high frequency

splits (UHS) as capacity and speed requirements increase. These frequency split options are shown in Figure 1:

Figure 1 - DOCSIS 4.0 Frequency Split Options

Note that the DOCSIS 4.0 standard also includes other splits but these are not included based on operator feedback on probable deployments:

- UHS-300 (300/372MHz) offers only a small improvement above 204 MHz so operators are much more likely to switch to UHS-396 or UHS-492 as the next increment
- UHS-684 (684/834MHz) has no additional downstream bandwidth while requiring more spectrum and providing very high peak upstream rates that are unlikely to be used by service offerings

DOCSIS 4.0 capabilities for these tiers are summarized in Table 2 based on up to 900 Mbps per 96 MHz OFDMA (700 Mbps in low band) and 1.8 Gbps per 192 MHz OFDM channel:

Table 2 – DOCSIS 4.0 Capabilities

Upstream Frequency Upper Band Edge	Upstream Capacity	Maximum Upstream Service Tier	Downstream Bonding Group Capacity	Maximum Downstream Service Tier
High Split (204MHz)	1.6 Gbps	1 Gbps	14.4 Gbps	10 Gbps
UHS-300 (300MHz)	2.6 Gbps	2 Gbps in great plant	13.3 Gbps	10 Gbps
UHS-396 (396MHz)	3.5 Gbps	2 Gbps	12.2 Gbps	10 Gbps
UHS-492 (492MHz)	4.4 Gbps	3 Gbps	11.1 Gbps	8 Gbps
UHS-684 (684MHz)	6.2 Gbps	5 Gbps in great plant	9.0 Gbps	6 Gbps

5. Turbocharging DOCSIS 3.1 Technology

Since the first field deployment of DOCSIS 3.1 networks in ~2015, cable operators and vendors have continued to innovate to improve the performance and operation of DOCSIS-based systems. Bundled together, these enhancements on top of the original DOCSIS 3.1 turbocharge DOCSIS 3.1 technology as a concept of a noticeably improved DOCSIS implementation suited to long term deployment, and as an incremental step towards full DOCSIS 4.0 deployment.

These options available in the DOCSIS 3.1 specifications, if leveraged efficiently, can instantly turbocharge any DOCSIS 3.1 deployment:

- High Split frequency split – full support of the upstream capability specified in DOCSIS 3.1 specifications to enable gigabit upstream service tiers

- Distributed Access Architecture (DAA) – extend all-digital Ethernet fiber deep into the network for reduction in hub space and power needed for an increased number of service group, along with improvements in RF performance
- Profile Management Application (PMA) – optimized subcarrier modulation in downstream and upstream to improve channel capacity for impaired modems or when overall RF plant conditions are non-optimal
- Low Latency DOCSIS (LLD) – reducing overall end-end packet delay through optimized queuing and standardized packet marking, especially for applications such as gaming
- DOCSIS 4.0 cable modems in 1.2 GHz plant – taking advantage of extra OFDM and OFDMA channels likely to come in DOCSIS 4.0 CMs to increase overall bonding group capacity in both DS and US while also supporting service tiers above 2 Gbps in the DS

5.1. Distributed Access Architecture (DAA)

The cable industry has long relied on a centralized architecture in configuring traditional HFC networks. Signals that were broadcast on the cable plant originated in centralized headend and hub site facilities. This practice continued with the introduction of broadband services delivered via the DOCSIS standard. However, the industry is in the middle of a major transition away from this approach, moving electronics from centralized to more distributed locations, with key elements (electronics) being placed in the outside plant fiber nodes. The broad acronym in use to describe this new approach is DAA – Distributed Access Architecture.

A primary initial use case for DAA was to reduce hub space and power by moving the modulation and demodulation of physical layer (PHY) signals (QAM and OFDM) from the hub to the node location. This reduction is necessary to avoid hub expansions as the number of subscribers per service group continues to shrink to provide more capacity and speed to individual subscribers so more DOCSIS and RF equipment is needed. DAA allows the removal of RF equipment including RF combiners, analog/digital optical RF systems, and the extensive wiring needed to connect everything together. Instead, all hub DOCSIS-related equipment is now digital with simplified Ethernet/IP interconnects or removed altogether in the case of Remote-MACPHY architectures.

Along with the reduction in hub space and power, one of the most important advantages of this new approach is that it allows operators to move from “analog optics” to “digital optics” – thus simplifying how signals are transmitted on the fiber portion of an HFC network, and greatly increasing the fidelity of the signals that are transmitted. Field experience from a number of DAA deployments has shown 5 to 7 dB improvement in C/N (carrier to noise ratio), which in essence represents a doubling in RF performance. Such an improvement allows for higher modulation (more bits per hertz), thus increasing overall system capacity.

The advent of DAA also holds promise in addressing some operational problems. Some areas that might be operating on the margin today (ie. Signal quality), could see improved performance from a DAA implementation and reduced trouble calls.

DAA implementations come in two primary configurations specified by CableLabs under the umbrella of Distributed CCAP Architecture (DCA) (see [DCA]). These configurations are

known as Remote-PHY, and Remote-MACPHY. Both have the advantage of moving to digital optics. Both can serve to allow for better RF performance out of the cable plant. Entire technical papers have been devoted to the merits of one over the other, with details being beyond the scope of this analysis. Figure 2 shows a high level view of the DAA architectures.

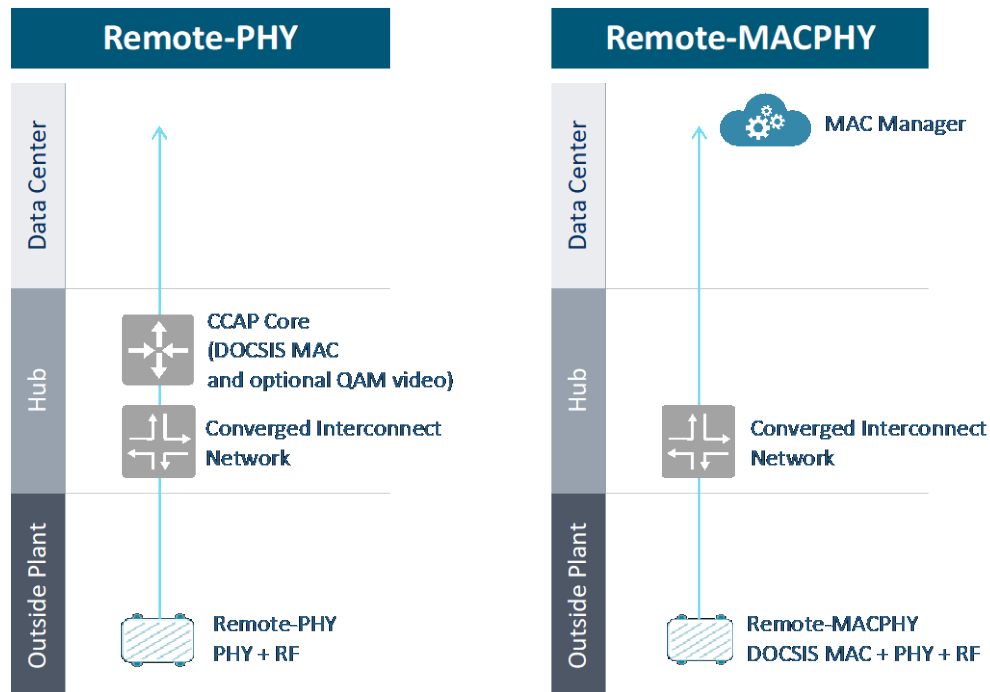

Figure 2 – Distributed Access Architecture Examples

One extremely important consideration, accepted by the industry while developing the specifications, is that DAA architecture will be required to implement DOCSIS 4.0. DAA will be paramount in addressing challenges with supporting spectrum as high as 1.8GHz. As an incremental step towards DOCSIS 4.0, turbocharging DOCSIS 3.1 technology assumes the use of DAA as well.

5.2. Profile Management Application (PMA)

OFDM DS and OFDMA US channels as specified in [MULPIv3.1] and [PHYv3.1] support the use of multiple “profiles” which allow for different data modulations (256QAM, 1024QAM, 4096QAM, etc.) to be configured for each modulated subcarrier. The use of these profiles allow the HFC system performance, in both robustness and overall capacity, to be optimized to the current conditions in the network.

The Profile Management Application (PMA) (see [PMA-TR]) as shown in Figure 3 is an external software solution which uses data on receiver MER and codeword errors from cable modems and CMTS, along with sophisticated algorithms and significant server processing power to optimize the set of available profiles to match current conditions. Without the dynamic changes in available profiles through PMA, modems that are temporarily impaired or operating outside normal design targets would generally use a default modulation of 256QAM.

Figure 3 - PMA Deployment Architecture Example from [Karthik1]

Since the cable plant channel model is quasi-static with slow variations over time due to temperature effects or specific impairment events, PMA solutions update profiles on a periodic interval measured in minutes.

The types of impairments or plant conditions that benefit from PMA include:

- Ingress from wireless communications within the cable band
- Operation in the rolloff region above the current plant frequency. This is particularly interesting as part of turbocharging DOCSIS 3.1 technology since operators can use PMA to extend into a rolloff region (say 1.1 GHz for 1 GHz tap and gain several hundred Mbps of additional capacity without the labor costs of swapping taps in the field for 1.2 GHz.
- Standing waves from impedance mismatches, grounding issues, or other non-ideal operation

Gains achievable, as seen in [Karthik1] are based on a significant set of operator data across several geographies. Capacity gains in excess of 30% improvement over a default 256QAM profile are achievable using PMA techniques.

5.3. Low Latency DOCSIS (LLD)

Many applications such as gaming, interactive videoconferencing, and web browsing do not require significant capacity, but instead require timely responses from remote servers to provide the best user experience. Low Latency DOCSIS technology (LLD), as part of [MULPIv3.1], has been developed by CableLabs, cable operators, and vendors to improve overall application latency, especially for those applications that are not using significant bandwidth.

The primary problem to solve from an end-to-end perspective relates to applications and transport protocols (e.g. TCP) which are capacity seeking. High bandwidth applications like file transfers and streaming IP video run over TCP, using up available network bandwidth until they

experience congestion. Congestion is recognized by way of dropped packets, at which time the application backs off until congestion ceases and then ramps back up until congestion is experienced again, at which time they once again back off. This cycle is repeated, creating a sawtooth pattern of bandwidth usage as shown in Figure 4.

Figure 4 - Bandwidth Usage for Capacity Seeking Applications with TCP

The problem this creates for applications that need low latency is that their packets get queued up during periods of congestion and experience latency and jitter patterns that follow the sawtooth bandwidth usage pattern of the capacity seeking application protocols. The industry has settled on the terms "queue building", to describe capacity seeking applications and transports, and "non-queue building" (NQB), to describe the transport that is needed by low latency applications.

Early methods for dealing with queue building applications included creating larger queues in network devices to absorb bursts without loss of packets. However, these methods were easily defeated by applications which just continued to ramp up bandwidth demands until packet loss was experienced. This made delay and jitter even worse and was referred to unkindly as "buffer bloat".

The solutions included in the overall LLD ecosystem include the following. Many of these solutions are just now progressing to readiness in the broader consumer ecosystem including gaming platforms and major device operating systems:

- A new NQB packet marking that applications can use to indicate that they are non-queue building so that their traffic can be treated differently in the network (e.g. classified into a Low Latency Service Flow), see [NQB1]
- Recommended use of Explicit Congestion Notification (ECN) and ECN Capable Transport (ECT) markings in the Traffic Class field of the IP header by low latency applications and networking equipment (e.g. routers), see [ECN1]
- Support for a new congestion control scheme called Low Latency, Low Loss, Scalable Throughput (L4S) (see [L4S1] and [L4S2]), which leverages Active Queue Management (AQM) techniques and which is intended to be applied in next generation transport

protocols supporting low latency applications. L4S congestion controls are leveraged in low latency applications and in network equipment as follows:

- Low latency applications will mark ECT in their packets
 - Network equipment experiencing congestion involving that ECT traffic will mark ECN Congestion Experienced (CE) in packets before forwarding rather than dropping packets
 - Low latency applications supporting ECT and receiving ECN CE will respond by marking ECN CE in traffic toward the originating application
 - The originating application will respond by reducing its transmission rate
- DOCSIS queuing improvements address queueing delay by allowing applications to avoid waiting behind the delays caused by the current TCP or its variants. At a high level, the low-latency architecture consists of a dual-path approach that treats both queues as a single pool of bandwidth as shown in Figure 5:

Figure 5 - Dual-Queue Approach for LLD from [White1]

- DOCSIS scheduler improvements address media acquisition delays by:
 - Lowering the request-grant delay with a shorter MAP Interval broadcast by the CMTS and associated MAP Processing Time in the cable modem
 - Adding a new scheduler service known as Proactive Grant Service (PGS) to proactively grant to a service flow without incurring the request-grant delay

Simulations published in [White1] show the dramatic improvements in round-trip latency and especially consistency of round-trip latency possible for NQB-Marked Traffic. These results show the 99th percentile of traffic having round-trip latency (DOCSIS part of network) well below 10ms without PGS and below 1ms with PGS, results that are 2-3 orders of magnitude better than standard DOCSIS 3.1.

Figure 6 – Round-Trip Latency with LLD for NQB-Marked Traffic from [White1]

5.4. DOCSIS 4.0 Cable Modems in 1.2 GHz Plant

One key change in the DOCSIS 4.0 specifications is an increase in the minimum number of OFDM DS and OFDMA US channels that can be bonded by the cable modem as shown in Table 3.

Table 3 – DOCSIS Cable Modem Minimum Capabilities

Modem Generation	Upstream OFDMA Channels	Downstream Channels
DOCSIS 3.1	2 x 96 MHz	32 x SC-QAM + 2 x 192 MHz OFDM
DOCSIS 4.0	7 x 96 MHz	32 x SC-QAM + 5 x 192 MHz

In addition, commercial DOCSIS 4.0 cable modems are expected to shift from 2.5GE Ethernet interfaces to 10GE Ethernet interfaces to take advantage of the bonding group capacity to deliver very high single cable modem speeds and enable new service tiers not possible today.

As shown in Figure 7, leveraging this capability without incurring the extra costs of full 1.8 GHz outside plant changes allows an operator to provide a premium service tier of 5 Gbps or higher instead of the 3 Gbps limits resulting from maximum bonding in DOCSIS 3.1.

The UHS-396 with 1.2 GHz plant and UHS-492 with 1.2 GHz plant options in Figure 7 are unlikely to be interesting for deployment unless upstream usage and customer need changes significantly from current projections. The overall DS capacity is limited in 1.2 GHz plant. In addition, amplifiers capable of supporting UHS-396 and UHS-492 diplexers are likely 1.8 GHz capable.

Figure 7 - Capacity by Upstream Split and Plant Maximum DS Frequency with D4.0 CM

6. Operational Considerations

Several operational considerations need careful attention from operators to ensure the largest benefit can be achieved from turbocharging DOCSIS 3.1 technology. These include:

- Spectrum Reclamation – transitioning DS spectrum from QAM video to DOCSIS data use
- Overlapping OFDM Channels – ensuring Mid Split and High Split modems can utilize their full available bandwidth when mixed in the same service group
- Leakage Detection – ensuring regulatory compliance when sensitive aeronautical bands in the 130 MHz range move from being DS signals to US signals as part of High Split transitions

6.1. Spectrum Reclamation – Sunset QAM Video

A key service still provided by most operator networks today is QAM digital video delivery to traditional set-top boxes. The number of channels used is dependent on market and QAM video technology (i.e. broadcast vs. switched digital video (SDV)) but can occupy 30-60 or even 80 channels.

Concerns that arise from keeping QAM video available in the network:

- Insufficient spectrum to transition to High Split

In this case, the transition from low or mid split to high split requires freeing up 150 MHz (108-258 MHz for mid to high split) or 204 MHz (54-258 MHz) of downstream spectrum. If downstream spectrum is relatively full already due to multiple OFDM channels or outside plant DS frequency limits, this spectrum reclamation may not be possible.

- Insufficient DOCSIS spectrum for service tier goals

This case is a concern when pushing service tiers to 2 Gbps and above, especially if using DOCSIS 4.0 cable modems to increase DS bonding group size. QAM video spectrum needs to be reclaimed to achieve maximum capacity.

- Legacy set top box carriers – SCTE 55-1 or SCTE 55-2

Support for operation of the legacy set top box DS carriers above 130 MHz for SCTE 55-1 or 55-2 is a possibility with some set-top boxes but this varies by the specific set top box. Adaptation solutions do exist to deal with these issues: downconverters at the STB from ~250 MHz to 70-130 MHz for seamless operation or use of DOCSIS Set Top Gateway (DSG) to out-of-band (OOB) carrier generators can help.

The primary solution for Spectrum Reclamation is transition to IP video service while sunsetting QAM video except possibly for niche use cases. This transition, already done at many operators, with the full digital QAM video lineup available in IP format to stream as data over DOCSIS channels, also helps operators deliver video service to FTTP customers without the complications associated with RF over the fiber.

6.2. Overlapping OFDMA Channels

The need for Overlapping OFDMA Channels (OOC) comes from DOCSIS 3.1 requirements and common implementations which limit the number of available OFDMA channels in an Upstream Service Group to two.

Deployment of High Split ideally has one of the two OFDMA channels placed at 108 to 204 MHz, and the other OFDMA channel placed immediately below that (e.g., 12 to 108 MHz). The problem is that many operators have fielded Mid-Split DOCSIS 3.1 CMs, which have a diplexer at 85 MHz and which are unable to make use of any OFDMA channel that spans 85 to 108 MHz (or which goes above 85 MHz, to be precise). See Figure 8 for further details on the concern.

Figure 8 – Need for Overlapping OFDMA Channels

As a result, in moving to High-Split operators may be forced to downgrade service levels for subscribers with Mid-Split CMs as these CMs would no longer be able to use any OFDMA. Conversely, the operator would be forced to place one of the OFDMA channels completely below 85 MHz (e.g. 12 to 85 MHz), which leaves spectrum from 85 to 108 MHz vacant.

To make matters worse, most operators are reluctant to deploy time and frequency division multiplexing (TaFDM) which overlaps ATDMA and OFDMA channels and ensures that there are no overlaps in the scheduler. If avoiding using TaFDM, these operators would carve out explicit spectrum for ATDMA channels below 85 MHz and explicit spectrum for the OFDMA channel below 85 MHz, making the OFDMA channel that exists there very small.

DOCSIS 4.0 CMs are also not required to be able to make use of 85 to 108 MHz. This leads to an analogous problem for those CMs when Ultra-High Split is in play (i.e., they cannot make use of an OFDMA channel that spans 85 to 108 MHz).

The solution to this issue is shown in Figure 9 and Figure 10 and now included in [MULPIv3.1]. Each CM (Mid-Split or High-Split) sees the channel that it is capable of transmitting, while the CMTS generates different long and short Upstream Channel Descriptors (UCDs) and MAPs. No schedule conflicts or channel descriptor conflicts exist since Mid-Split just sees a shortened version of the same messages.

Figure 9 – Overlapping OFDMA Channel Arrangement

Figure 10 – Overlapping OFDMA Channel Solution – UCD and MAPs

Implementation of OOC for a plant transitioning from Mid-Split to High-Split can maintain an additional ~200 Mbps of capacity while allowing both Mid-Split and High-Split CMs to be simultaneously deployed.

6.3. Leakage Detection

System leakage monitoring and detection is required to ensure regulatory compliance and avoid interfering with the sensitive aeronautical band in the 108 to 137 MHz range. In traditional Low-Split and Mid-Split deployments, legacy methods for accomplishing this using downstream spectrum and portable field meters detecting specialized CW carriers have been in place for many years and are well-understood.

With High-Split and DOCSIS 4.0 Ultra-High Split frequency plans, the aeronautical band is no longer in the downstream spectrum and instead falls within the upstream spectrum. With these splits, leakage test signals must instead be generated by the CM just above the aeronautical band as shown in Figure 11. The CM uses OFDM Upstream Data Profile (OUDP) test probes, normally assisting with upstream profile validation, to create specific pilot patterns which are detected by the field meters. [Coldren1] provides a summary of the approach.

Figure 11 - Leakage Detection Test Signals from [Coldren1]

Since the standard updates were published in 2021, significant progress has been made towards industry interoperability between operators, field meter vendors, and CMTS/node vendors. Field results has proven the ability to generate the signals in the CM, detect the signals with the field meter, and effectively troubleshoot leakage situations in the outside plant.

7. Upgrade Costs

Absolute costs for upgrading a particular deployed network are location-specific and depend on many factors such as existing installed equipment and cables, operator service offerings, regional regulatory requirements, labor rates, and operational practices.

In assessing turbocharged DOCSIS 3.1 technology as a step in HFC deployment, four upgrade points are considered for relative cost per home passed:

- 1) Turbocharged Baseline: This is an upgrade of the HFC actives (amplifiers and nodes) to high split with 1.2 GHz maximum DS. “Turbocharged Baseline” Assumptions:
 - Passives are assumed to support >1 GHz operation and are not deliberately a part of the upgrade
 - No significant changes to plant design or spacing
 - Amplifiers are upgraded in place to 1.2 GHz – only obsolete or unsuitable amplifiers are replaced
 - Nodes are transitioned from analog and/or digital return nodes to DOCSIS 3.1 DAA nodes
 - Cable modems are DOCSIS 3.1
- 2) Turbocharged Baseline with D4.0 Cable Modem
 - Above and beyond the Baseline scenario, customers are provided with DOCSIS 4.0 cable modems to enable higher DS tiers above 2 Gbps
- 3) Full DOCSIS 4.0 Upgrade
 - All passives are proactively replaced in the network to support 1.8 GHz or greater operation
 - Amplifiers are upgraded in place or swapped for 1.8 GHz

- Booster amplifiers are added in 10-20% of locations
- Some cable replacement (1-3%) is required
- Labor is a very significant portion of the overall cost in this scenario due to the amount of plant touch

4) FTTP Upgrade

- Service group is swapped over to fully fiber to the premise
- Average/median costs across a wide range of geographies and types are used for this analysis

Based on industry and operator feedback for each of these items, we estimate the relative upgrade costs as shown in Table 4:

Table 4 – Relative Upgrade Costs

Upgrade Scenario	Relative Upgrade Cost
Turbocharged Baseline	1.0
Turbocharged Baseline + D4.0 CMs	1.2-1.5
Full D4.0 Upgrade	1.8-2.4
FTTP	10

8. Conclusion

Operators have many tools available to increase capacity and performance of their existing HFC networks to address evolving customer experience targets and competition. DOCSIS 4.0 technology is clearly the long term future of HFC to provide multi-gigabit downstream and upstream capability, but may require significant plant investment to roll out 1.8 GHz capability across the plant to take full advantage of all that is available in the specification.

A more incremental approach with turbocharged DOCSIS 3.1 technology is possible – take advantage of the changes that have been added in the DOCSIS 3.1 specifications with recent industry performance enhancements and include the higher multi-channel capability of DOCSIS 4.0 modems if needed. This turbocharged approach allows an operator to gradually roll out changes to the outside plant while enabling DS tiers to 5 Gbps and significant improvements in latency.

HFC will continue to deliver the service needed by customers for many years – and turbocharging DOCSIS 3.1 technology provides yet another way to get there incrementally.

1. Introduction

HFC/DOCSIS networks are the most widely deployed technology for delivering Internet data services to the consumers. A passive optical network is another option for access technology deployed by operators using EPON, or GPON technology.

One of the performance questions which many in the operator community want to understand is the latency performance of each type of technology and how they compare. We setup a 10GEPON and XGSPON systems in our labs at CableLabs. We ran speed and latency benchmarks on these types of networks in a lab environment and compared the latencies that we get under a variety of conditions. DOCSIS has various options and configurations (D3.0 SC-QAM channels, D3.1 OFDM/OFDMA channels, AQM, LLD etc., while PON has various flavors: 10G-EPON, XGSPON etc. and configurations as well). This paper will give us a better understanding of the efficiencies and the latencies of each of these technology options and the tradeoffs this entails. Based on time constraints during lab testing, this paper is focused primarily on the PON latencies, with some limited testing on DOCSIS systems and a more complete testing and analysis will be part of future work. This paper will give a brief overview of each technology and its evolution and bring out a theoretical comparison of the latency characteristics of each type of technology and mainly reports on the lab testing results for each technology under different operating and load conditions.

2. PON Technologies Background

The continuous growth in bandwidth usage has put demands on the core, metro, and access networks. Gigabit access speeds are now the norm with a large share of US population having an option. Per NCTA, 88% of US Homes have access to gigabit Internet speeds available to them.

Passive optical networks (PON) have been used to serve the end users with high data rate, high split ratio, and high bandwidths. PON provides this to a large number of customers at a low cost. In PON, the Time Division Multiplexing (TDM) method raises the number of end users by using power splitters that split the power of the channel into multiple segments.

P2MP PON based architectures has proven to be the most popular among operators for FTTx deployments because it typically results in lower infrastructure costs. With P2MP, a shared fiber carries traffic to a passive splitting complex close to the end-customers, which can be single stage or cascaded. Consequently, there is no need to deploy a single dedicated fiber all the way to the customer premises from the central office/Headend.

Optical fiber access systems based on PON are currently being deployed on a mass market scale by numerous network operators worldwide. These systems typically exploit Gigabit-class PON systems such as G-PON or EPON as standardized by the ITU-T and IEEE respectively. Both these standards bodies have also defined 10 Gigabit-class PON technologies XGS-PON and 10G-EPON and are widely available today. So, we focus our energy on understanding the latency performance of the XGS-PON and 10G-EPON systems.

The figure below shows the evolution of PON technologies as defined by the IEEE and the ITU-T. both the EPON and GPON standards have been evolving over the last 20 years going from 1 Gbps to now 50 Gbps and beyond.

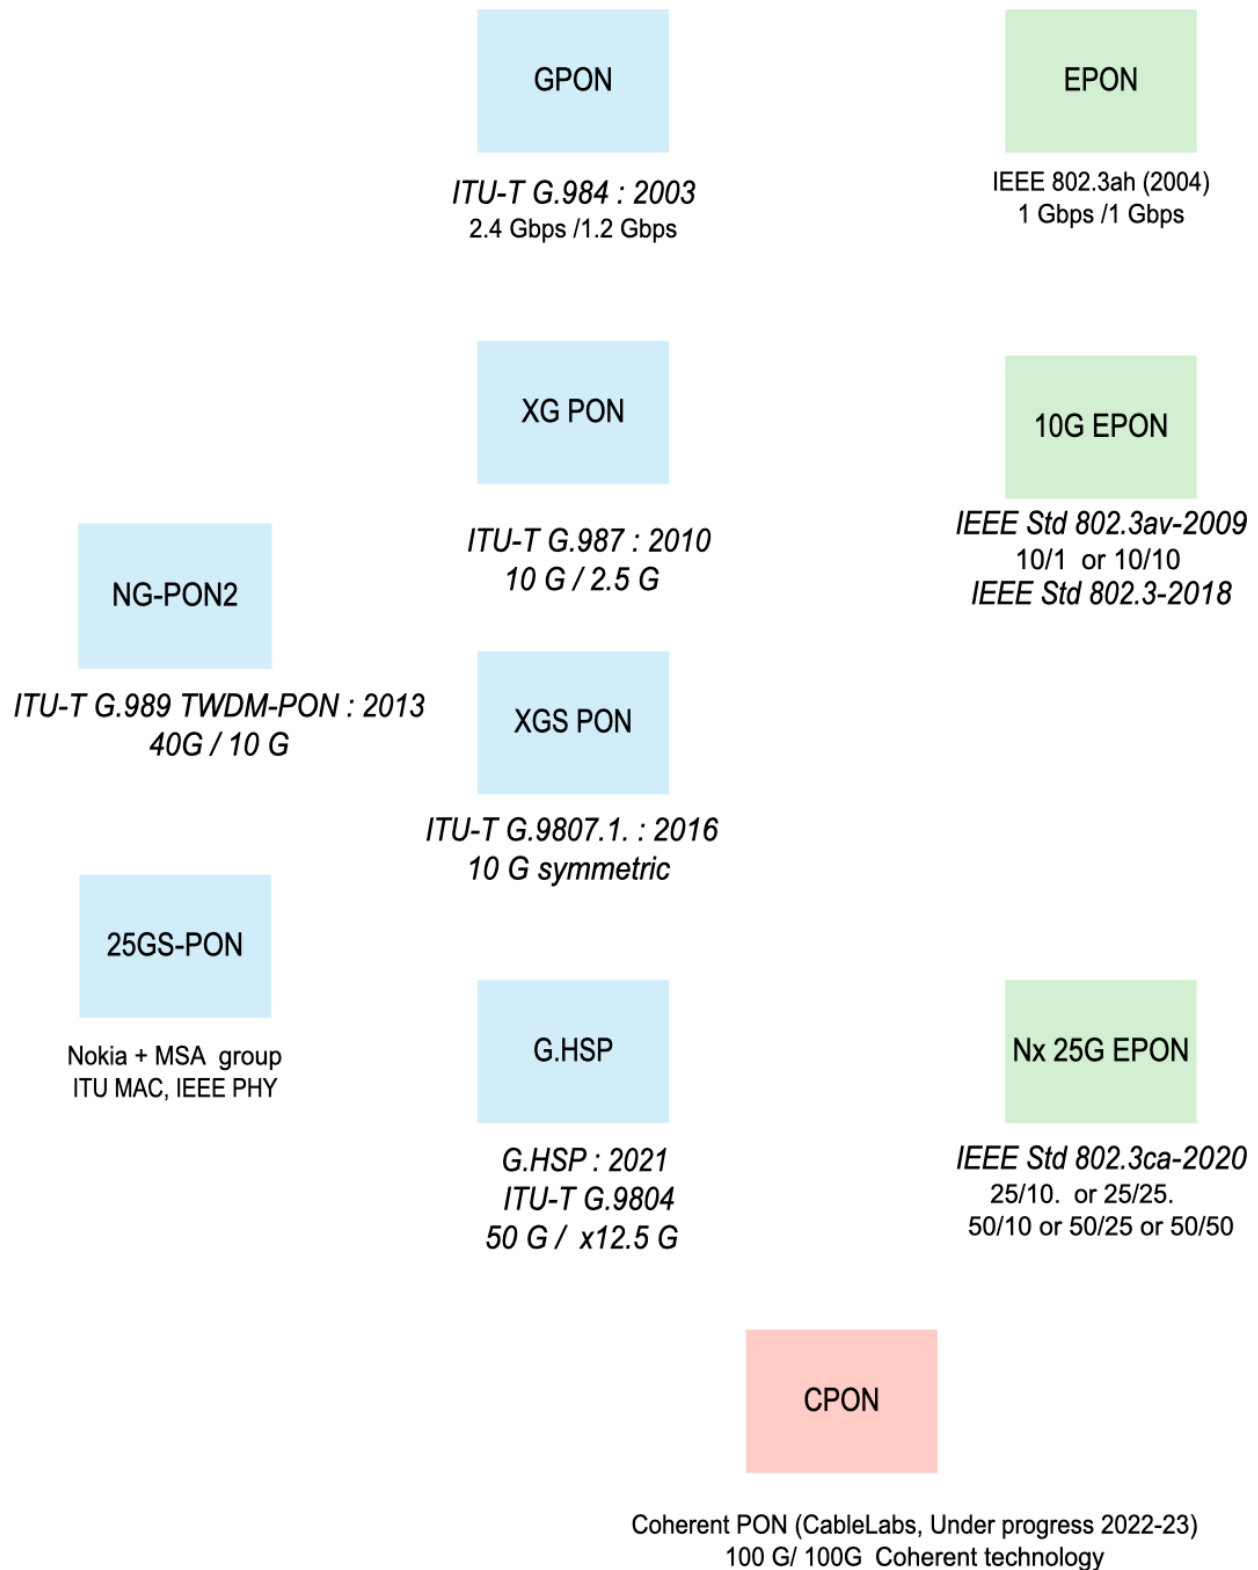

Figure 1 – Evolution of PON Acces technology

Over the last two decades, PON based technology evolved greatly and rapidly, and is one of the most attractive access network solutions for delivering high-speed data and video services. After initial 1 Gbps speeds, PON standards evolved into 10 Gbit/s Ethernet PON and 10-Gigabit-capable PON (XGS-PON). Over the last few decades, the access speed of PON over single wavelength has increased almost 100 times to support the ever-growing bandwidth demand from the emerging services. The 25/50G next-generation Ethernet PON (NG-EPON) specification has been approved by IEEE in 2020, based on 25 Gbps per single wavelength. Most recently, the ITU-T 50G PON standard, based on 50G single-wavelength is close to being a reality as consent has been achieved on multiple part of the series in 2021. Figure 1 above shows a summary of the existing PON standards and the supported downstream/upstream transmission rates.

3. Background of EPON and GPON networks

Optical Access Networks have typically been deployed using point-to-multipoint PON based architectures. In PON networks, Optical networking units (ONUs) communicate with the Optical Line Terminal (OLT) via a passive optical distribution network consisting of a feeder fiber (connecting the OLT and the passive splitter), a passive splitter, and numbers of distribution fibers (connecting each ONU to the passive splitter), as shown in Figure 2.

In the downstream direction (from OLT to an ONU), signals transmitted by the OLT pass through a 1: N passive splitter (or cascade of splitters) and reach each of the ONUs. In the upstream direction (from ONUs to OLT), the signal transmitted by an ONU will only reach the OLT, and not any other ONUs. To avoid data collisions and increase the efficiency of the subscriber access network, ONU's transmissions are arbitrated by the OLT.

This arbitration is achieved by allocating a transmission window (grant) to each ONU. An ONU defers transmission until its grant arrives. When the grant arrives, the ONU transmits frames at wire speed during its assigned time slot. A simplified P2MP topology example is shown in the figure below.

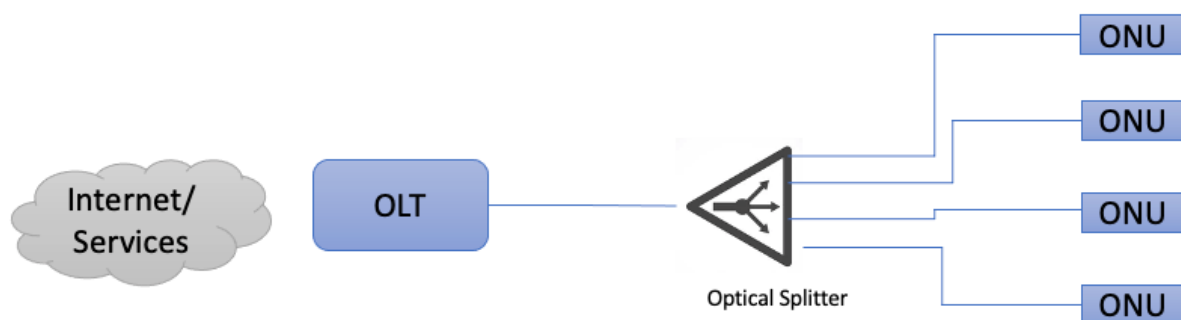

Figure 2 – Simplified EPON Network

The packet delay in a PON network is the time elapsed between a frame's generation at the ONU and its arrival at the OLT. In the most general case, the delay components experienced by a frame include the Delay between frame generation and the transmission of the next REPORT message to the OLT, Propagation of the REPORT message from a given ONU to the OLT, (different for each ONU), processing delay at the OLT between the arrival of the REPORT and the transmission of the GATE message, Propagation of the GATE message to the ONU, delay between the arrival of the GATE message at the ONU and the beginning of the granted transmission window, propagation of the frame to the OLT and the duration of the frame transmission itself.

3.1. EPON Latency background

In EPON, the Multipoint MAC Control Protocol (MPCP) defines the messages and timers, to control access to the P2MP ODN topology in 10G-EPON. Every P2MP ODN topology consists of one Optical Line Terminal (OLT) plus one or more ONUs, as shown in the Figure.

The MPCP and underlying PHY allows an underlying P2MP network to appear as a collection of point-to-point links to the higher protocol layers (at and above the MAC Client). The MPCP achieves this by providing a Logical Link Identification (LLID) to each MAC which is dynamically assigned by the registration process.

The MPCP has the ability to arbitrate the transmitters of a number of ONUs. The OLT controls an ONU's transmission by assigning grants. The transmitting window of an ONU is indicated in gate message where start time and length are specified. An ONU will begin transmission when its local time counter matches start time value indicated in the gate message. An ONU will conclude its transmission with sufficient margin to ensure that the laser is turned off before the grant length interval has elapsed.

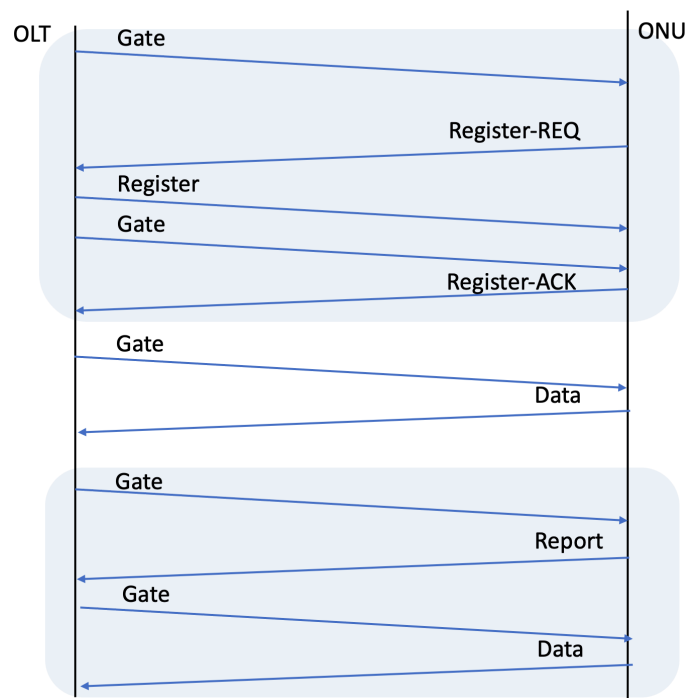

Figure 3 – Simplified Media access in EPON: Gate-Report-data

Multiple outstanding grants may be issued to each ONU. The OLT does not issue more than the maximal outstanding grants as advertised by the ONU during registration. In order to maintain a watchdog timer at the ONU, grants are periodically generated. For this purpose, empty gate messages may be issued periodically.

The purpose of gate message is to grant transmission windows to ONUs for both discovery messages and normal transmission. Up to four grants can be included in a single gate message. The length of the signaled grant, this is a 16-bit unsigned field. The length is counted in 16-bit time increments. The laser-on time, sync time, and laser-off time are included in the grant.

In the [IEEE 802.3] EPON technology, the MPCP protocol relies on strict timing based on distribution of timestamps. The implementations guarantee a constant delay through the MAC and PHY in order to maintain the correctness of the timestamping mechanism. The actual delay is implementation dependent; however, a complying implementation maintains a delay variation of no more than 16-bit times through the MAC stack.

The OLT does not grant less than 1024-time quanta into the future, in order to allow the ONU processing time when it receives a gate message. The ONU shall process all messages in less than this period. The OLT shall not issue more than one message every 1024-time quanta to a single ONU. The unit of time quantum is defined as 16 ns.

A report message has several functionalities. Time stamp in each report message is used for roundtrip time calculation. In the report messages ONUs indicate the upstream bandwidth needs they request per IEEE 802.1Q priority queue. Report messages are also used as keep-alives from ONU to OLT. ONUs issue report messages periodically in order to maintain link health at the OLT. In addition, the OLT can specifically request a report message. Status reports are used to signal bandwidth needs as well as for arming the OLT watchdog timer. Reports shall be generated periodically, even when no request for bandwidth is being made. This keeps a watchdog timer in the OLT from expiring and deregistering the ONU. For proper operation of this mechanism the OLT shall grant the ONU periodically.

EPON implementations typically adopt the traditional Interleaved Polling with Adaptive Cycle Time (IPACT) scheme (with refinements) as the method to allocate bandwidth across multiple ONUs and try to minimize this Gate-Report-data cycle.

3.2. GPON Latency Background

Recommendation ITU-T G.9807.1 describes a 10-Gigabit-capable symmetric passive optical network (XGS-PON) system in an optical access network for residential, business, mobile backhaul and other applications. This system operates over a point-to-multipoint optical access infrastructure at the nominal data rate of 10 Gbit/s both in the downstream and the upstream directions.

A GPON network will be used to carry different types of services, the delay requirements are designed and standardized according to the characteristics of these services.

TDM PON systems use the TDMA mechanism for communicating with multiple ONUs connected to the same OLT PON port. Therefore, Dynamic bandwidth Allocation (DBA) mechanisms and ONU activation mechanisms are needed in the convergence layer, which periodically introduce additional delay to the data transmission in the upstream direction. In real implementations, the data transmission delay of the PON link is considered to fluctuate within about 1.5 ms between service node interface (SNI) and user-network interface (UNI). When the OLT creates a quiet window as part of the ONU activation mechanism, the data transmission delay is significantly increased as a consequence

The XGS-PON OLT support DBA for the efficient sharing of upstream bandwidth among the connected ONUs and the traffic-bearing entities within the individual ONUs based on the dynamic indication of their activity. The dynamic activity indication can be based on the following two methods: (1) status reporting DBA employs the explicit buffer occupancy reports that are solicited by the OLT and submitted by the ONUs in response; (2) traffic monitoring DBA employs OLT's observation of the actual traffic amount in comparison with the allocated upstream transmission opportunities. To guarantee multi-vendor interoperability, the standard specifies the formats of the SR DBA status enquiries and buffer occupancy reports and the associated protocol. An ONU supports DBA status reporting, and transmit upstream reports as instructed by the OLT.

Figure 4 – GPON Upstream Transmission mechanisms

4. Results from Latency Measurements

4.1. Lab experimental Setup

We built a PON plant with a 10GEPON and XGSPON system at CableLabs, as shown in Figure 5. These systems consisted of SFP+ modules of 10GEPON and XGSPON OLTs. These SFP+ OLTs were connected to a 48-port 100Gps switch (Arista 7280R). The fiber cable connection coming out of OLTs were attenuated with a series of optical attenuators and fed into a 5-port optical splitter. An alternate setup was 10 Km of optical fiber to the ONUs. Coming off the splitter we had the two ONUs connected. We had two 10GEPON ONUs and two XGSPON ONUs connected to each of the respective OLTs.

The latency measurement system used here includes a Measurement agent (a STAMP Session sender) and a STAMP session reflector. Additionally, a Controller/Collector was used for visualization of results from the Measurement agent. See [STAMP SCTE21] for further details. These prototype software components are available at [C3 CableLabs] for operators to use.

A hardware traffic generator (ByteBlower with two 10 Gbps optical ports) was used to load the system with traffic. An iPerf server and client were also installed on dedicated servers with 10G NIC cards.

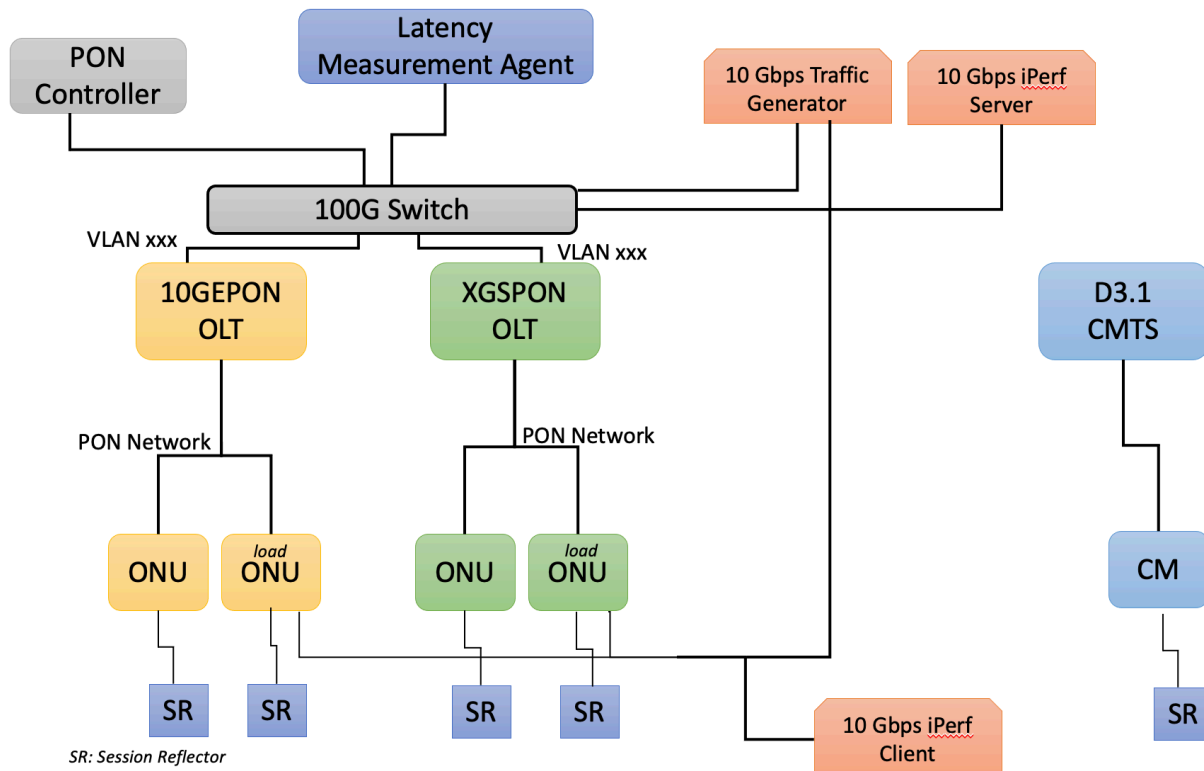

Figure 5 – PON Network Lab Test Setup

The goal of the lab testing was to understand the practical latency on the PON networks by sending different types of load traffic and measuring the latency through the network. Table below shows the default PON configuration on the OLTs

Table 1 – PON Configuration settings

XGSPON		10GE PON	
Discovery Period [ms]:	3000	Discovery Period [ms]:	3000
Encryption:	Bidirectional	Grant Spacing [16ns]:	16
Encryption Key Time [s]:	600	Encryption:	Downstream
Max Frame Size [bytes]:	9600	Encryption Key Time [s]:	900
Downstream FEC:	true	Sync Time [16ns]:	16
Upstream FEC:	true	Laser OFF [16ns]:	32
Guard Time [12.8ns]:	64	Laser ON [16ns]:	32
Preamble Length [12.8ns]:	64	Max Frame Size [bytes]:	9600
Error Det Max Ratio:	20%	FEC:	true
Error Det Min Sample [bursts]:	100	Fiber Reach:	Standard (0..20 km)
Fiber Reach:	Standard (0..20 km)		
Downstream & Upstream SLA Guaranteed: 512 Kbps, rest Best Effort		Downstream and Upstream SLA Guaranteed: 1.28 Mbps, rest is Best Effort	

4.2. Test Scenarios

The main test scenarios and traffic definitions for the tests were as follows.

- Latency Measurement Test Traffic (round trip time - RTT tests)
 - o Raw measurement: 10 pps, 256-byte packets for 2 mins = 20Kbps
 - o Percentile test: 30 pps, 256-byte packets, for 2 mins = 62Kbps
 - o Histogram test : 60 pps, 256-byte packets, for 2 mins = 122Kbps
- UDP Background traffic
 - o Send UDP traffic at different rates as load / background traffic and then measure the round-trip latency of the test traffic
 - o The idea is to send UDP traffic in steps of 1, 3, 5, 7, and up to 9 Gbps (just above the capacity of the two PON networks)
- TCP Background traffic
 - o Send TCP traffic and then measure the round-trip latency of the test traffic
 - o The idea was to have the TCP flows capped at certain rates (1, 3, 5, 7) and also unlimited (capped only by the network capacity ~9 Gbps)

Table 2 – Latency Tests

Scenario name	Load traffic Downstream Data rate	Load traffic Upstream Data Rate
UDP		
S0 Baseline	No load	No load
S1 UDP	1 Gbps UDP	1 Gbps UDP
S3 UDP	3 Gbps UDP	3 Gbps UDP
S5 UDP	5 Gbps UDP	5 Gbps UDP
S7 UDP	7 Gbps UDP	7 Gbps UDP
S9 UDP	9 Gbps UDP	9 Gbps UDP
TCP		
S1 TCP	1 Gbps TCP	1 Gbps TCP
S3 TCP	3 Gbps TCP	3 Gbps TCP
S5 TCP	5 Gbps TCP	5 Gbps TCP
S7 TCP	7 Gbps TCP	7 Gbps TCP
SU TCP	Unlimited TCP	Unlimited TCP

4.3. PON Throughput Test Results

4.3.1. XGSPON Throughput

We ran a baseline throughput test, through the XGSPON system (OLT +ONU), just to understand what the maximum throughput is and what the OLT to ONU one-way latency is. A first port on the traffic generator device is directly connected via the ethernet switch to the OLT and a second port is connected to the ONU as a CPE device. Traffic is being sent in both upstream and downstream directions. The XGSPON system, shows a maximum throughput off 8.564 Gbps in the downstream direction and 8.416 Gbps in the upstream direction. Based on the latency numbers as calculated by the traffic generator device, the average one-way latency is 0.277 milliseconds on the downstream and 0.708 milliseconds in the upstream. The 10GEPON configuration was in the default state as detailed in Table-1.

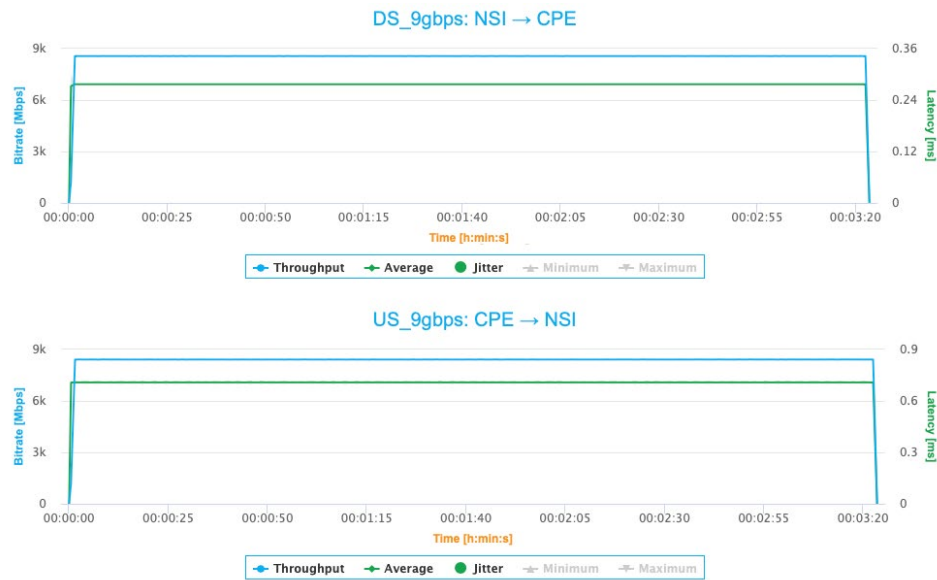

Figure 6 – XGSPON Throughput & one-way Latency(UDP)

Frame Blasting Flows : Throughput

Flow	Source	Destination	TX Frames	Rx Frames	Frame Loss	TX Bytes (+VLAN)	RX Bytes (+VLAN)	Byte Loss	Duration	Average Throughput (Mbps)
DS_9gbps	NSI	CPE	151,822,917	144,442,983	4.86%	227,734,375,500 (+607,291,668)	216,664,474,500	4.86%	3m, 22s 379ms 305µs 757ns	8,564.69
US_9gbps	CPE	NSI	151,823,300	141,561,578	6.76%	227,734,950,000	212,342,367,000 (+566,246,312)	6.76%	3m, 22s 378ms 708µs 613ns	8,416.25

Frame Blasting Flows : Latency

Flow	Source	Destination	Min Latency (ms)	Avg Latency (ms)	Max Latency (ms)	Jitter (ms)
DS_9gbps	NSI	CPE	0.024	0.277	0.281	0.001
US_9gbps	CPE	NSI	0.532	0.708	1.091	0.007

Figure 7 – XGSPON Throughput & one-way Latency in Numbers (UDP)

4.3.1. 10GEPON Throughput

We ran a similar baseline throughput test, through the 10GEPON system (OLT +ONU), again to understand what the maximum throughput and the OLT to ONU one-way latency is. The traffic generator device has the same configuration as the above test. The 10GEPON system, shows a maximum throughput of 8.596 Gbps in the downstream direction and 8.436 Gbps in the upstream direction. Based on the latency numbers as calculated by the traffic generator device, the average one-way latency is 0.636 ms on the downstream and 1.739 ms in the upstream. The XGSPON configuration was in the default configuration as state in Table-1.

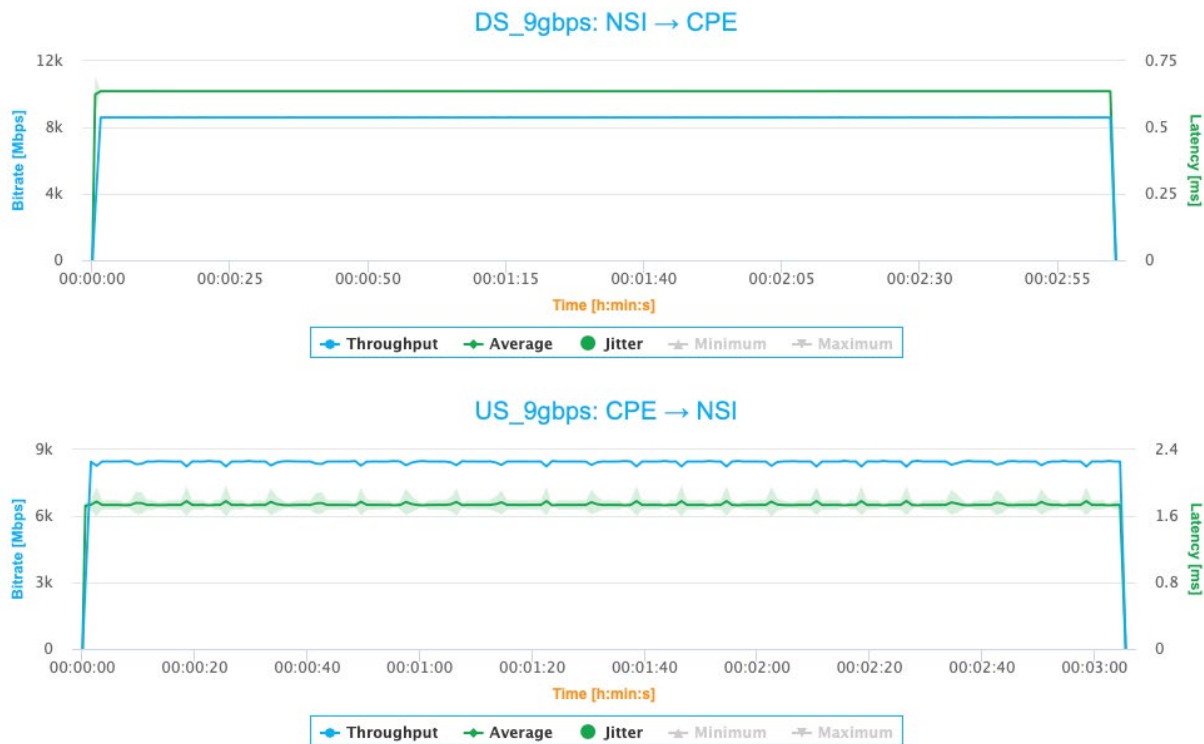

Figure 8 – 10GEPON Throughput & one-way Latency(UDP)

Frame Blasting Flows : Throughput

Flow	Source	Destination	Tx Frames	Rx Frames	Frame Loss	Tx Bytes (+VLAN)	Rx Bytes (+VLAN)	Byte Loss	Duration	Average Throughput (Mbps)
DS_9gbps	NSI	CPE	138,613,303	132,370,647	4.50%	207,919,954,500 (+554,453,212)	198,555,970,500	4.50%	3m, 4s 771ms 334µs 308ns	8,596.83
US_9gbps	CPE	NSI	138,613,615	129,561,132	6.53%	207,920,422,500	194,341,698,000 (+518,244,528)	6.53%	3m, 4s 769ms 526µs 608ns	8,436.89

Frame Blasting Flows : Latency

US_9gbps	CPE	NSI	1.336	1.739	3.604	0.080

Figure 9 – 10GEPON Throughput & one-way Latency in Numbers (UDP)

4.4. Baseline Latency (RTT) Test Results

The next set of tests that we ran is a set of standardized latency measurement tests as defined in section 5.1. Here the basic idea is to have a measurement agent (on the NSI side of the OLT), which sends STAMP (UDP) packets to a session-reflector device (located behind an ONU as the CPE). The session-reflector essentially sends the packet back to the measurement agent who then computes the roundtrip time. The sequence of 1200 packet latency measurements will be used to show a time series of the latency, a histogram of the latency and a latency CCDF as defined in [SCTE21 Latency Measurement]. The figures below also show any packet drops during the test. We also ran a couple of additional tests at the same time, which compute only the histogram of latency and the second one computes only the percentile values though we are not sharing the results from those tests, as for now the raw latency test

has all the information we need. These baseline tests are run without any load on the PON network, i.e., there is no background load traffic

4.4.1. Baseline XGSPON Latency

As shown in the figure below, we see the latency of the XGSPON system to be between 1 to 2.1 ms, with a few outliers going all the way from 2.5 to 3.5 ms.

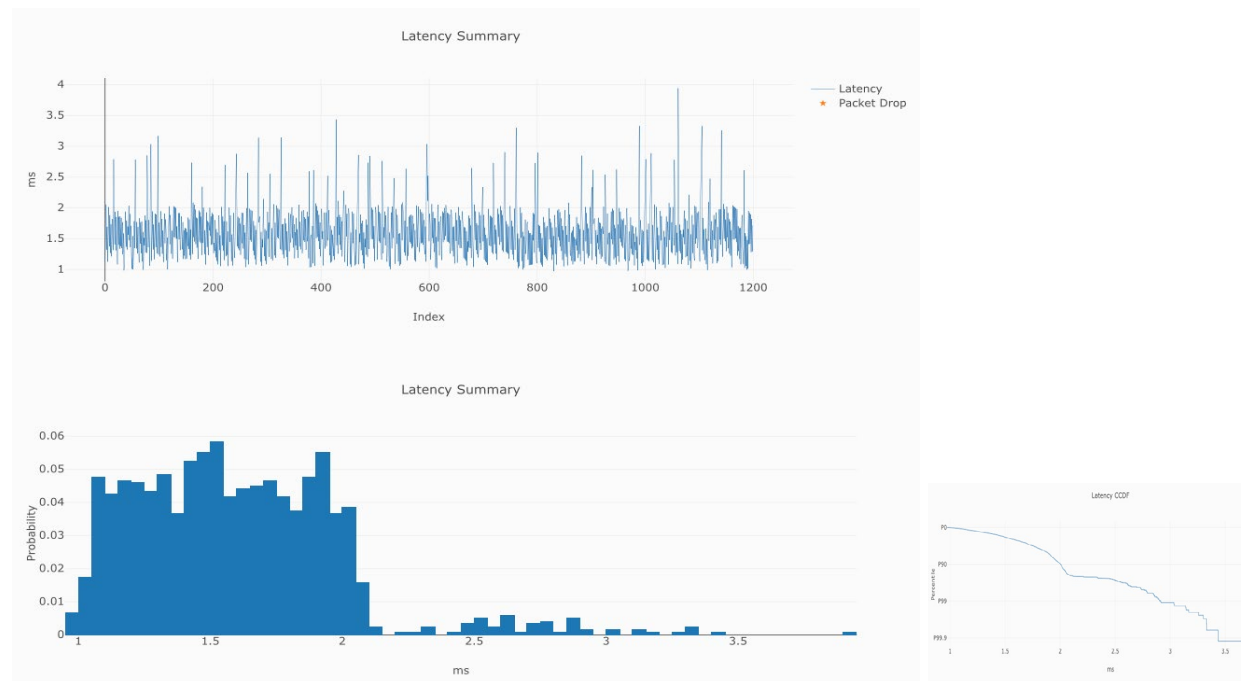

Figure 10 – Baseline XGSPON latency (no load)

4.4.2. Baseline 10GEPON Latency

As seen in the figure below on a 10GEPON system, we see the latency values between 0.8 and 1.9 milliseconds

Figure 11 – Baseline 10GEPON latency (no load)

4.4.3. Baseline DOCSIS Latency

We ran the same baseline latency test on a DOCSIS CMTS (no Low Latency DOCSIS (LLD) configured), to observe a baseline latency between 6.2-9 ms, with outliers in the 9-11 ms range.

Figure 12 – Baseline DOCSIS (with No LLD enabled) and no load

4.4.4. Baseline DOCSIS (with LLD) Latency

We ran the same baseline latency test on a DOCSIS CMTS which is configured with the new Low Latency DOCSIS features (LLD) and observe a baseline latency between **2 and 3 ms**, with some outliers in the 3-4 ms range. This was just out-of-the-box configuration with LLD enabled on both the upstream and downstream. The latency measurement traffic in this test was marked with an IP DSCP Marking of 46 (expedited forwarding). With this we can see that enabling LLD features on a DOCSIS 3.1 CMTS definitely puts the latency in the same level as the EPON and GPON systems

Figure 13 – Baseline DOCSIS with LLD latency and no load

4.5. UDP Load Test Results

Now we have a set of UDP tests where we run different levels of UDP traffic in the background. The load traffic is sent through one ONU, while the latency RTT measurements are being done on both the reflectors that are behind the load ONU, as well as the second ONU which doesn't have any load traffic passing through it.

4.5.1. GPON UDP 1Gbps Test Results

When we run background UDP load traffic of 1 Gbps, we see that for the ONU that is not carrying the load, the latency distribution does not change much and the histogram and the CCDF curves look similar to the baseline case.

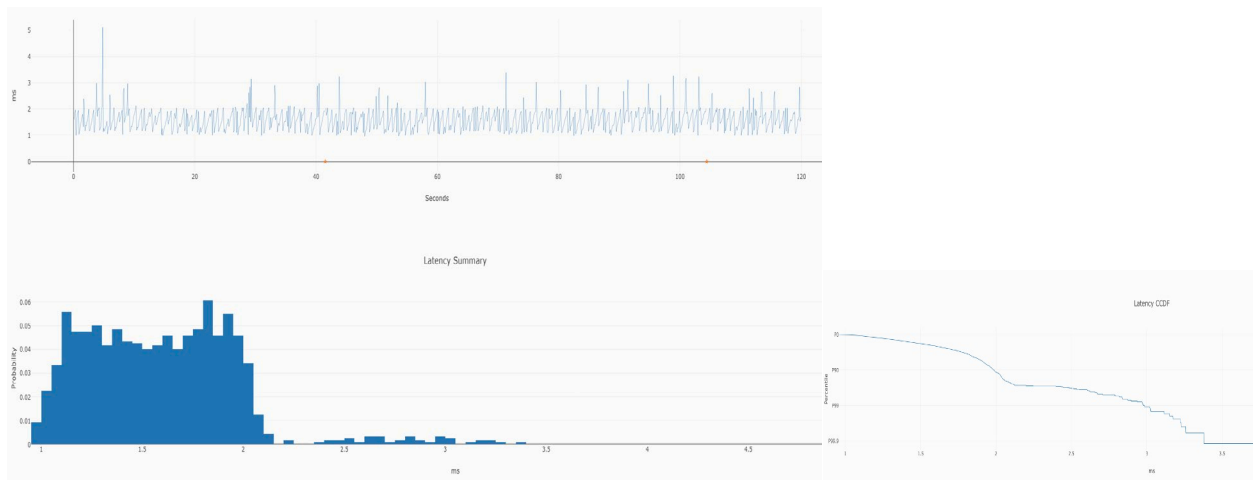

Figure 14 – XGSPON latency – with 1 Gbps UDP background traffic, non-load ONU

When we run background UDP load traffic of 1 Gbps, we see that for the ONU that is carrying the load, the latency distribution does change and the histogram and the CCDF curves actually get better. From the

percentiles test we can tell that the latency for the P50 and P99 numbers actually improved. The 50th percentile latency improved from 1.557 to 1.278 ms and the 99th percentile latency from 2.78 ms to 1.534 ms. With the increased load on the PON network we can see that the polling-request-grant delay cycle is reduced, with a ONU buffer status report being a part of the upstream data frame header itself.

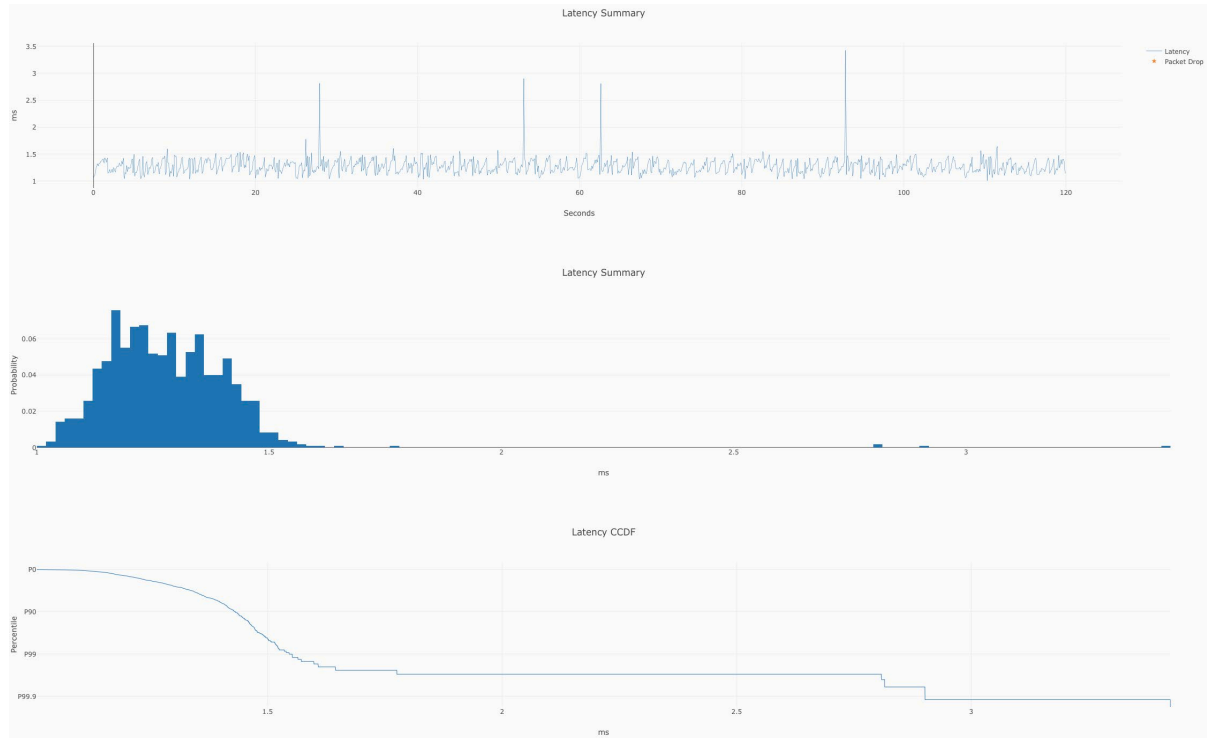

Figure 15 – XGSPON latency – w 1 Gbps background traffic, Load ONU

4.5.2. GPON UDP 9Gbps Test Results

When we run background UDP load traffic of 9 Gbps (above the capacity of the network), we see that for the ONU that is not carrying the load, the latency distribution does not change much and the histogram and the CCDF curves look similar to the baseline case.

Figure 16 – XGSPON latency – with 9 Gbps background traffic on non-load ONU

When we run background UDP load traffic of 9 Gbps, we see that for the ONU that is carrying the load, the latency distribution does change much and the histogram and the CCDF curves get worse as expected. From the percentiles test we can tell that the latency for the 50th percentile latency (P50) increased from 1.557 to 2.423, and the 99th percentile latency changes from 2.78 ms to 3.482 ms. With the fully loaded PON network we can see that there is packet loss and the increased latency of the packets that did make through. This also points to a relatively short buffer on the ONUs and OLTs.

Figure 17 – XGSPON latency – with 9 Gbps background traffic on load ONU

4.5.3. EPON UDP 1Gbps Test Results

When we run background UDP load traffic of 1 Gbps, we see that for the ONU that is carrying the load, the latency distribution shifts to the left (decreases) by 0.4 ms. For the ONU that is not carrying the load the latency remains the same as the baseline case.

Figure 18 – 10GEPON latency – no load.

Figure 19 – 10GEPON latency – w 1 Gbps UDP background traffic- load ONU.

4.5.4. EPON UDP 9Gbps Test Results

When we run background UDP load traffic of 9 Gbps (above the capacity of the network), we see that for the ONU that is not carrying the load, the latency distribution does not change much and the histogram and the CCDF curves look similar to the baseline case. This behavior for this 10GEPON system, is similar to what we saw with the XGSPON system.

Figure 20 – 10GEPON latency – w 9 Gbps background traffic - non-load ONU

When we run background UDP load traffic of 9 Gbps, we see that for the EPON ONU that is carrying the load, the latency distribution does change and the histogram and the CCDF curves get worse as expected. From the percentiles test we can tell that the latency for the 50th percentile latency (P50) increased from 2.132 to 2.423 ms as expected, though the 99th percentile latency improved from 2.769 ms to 2.548 ms. With the fully loaded PON network we can see that there is some packet loss and the increased latency of the packets that did make through. The packet loss on these test flows is much less than what we saw on the XGSPON network, this implies that the EPON implementations have a per-flow queuing mechanism. This also points to a relatively short buffer on the EPON ONUs and OLTs.

Figure 21 – 10GEPON latency – w 9 Gbps background traffic - load ONU

4.5.5. DOCSIS UDP Test Results

For this test we used a high-split CMTS, which has a downstream capacity of 4.8 Gbps downstream and 1.7 Gbps upstream. When we run background UDP load traffic of 4.7 Gbps downstream and 1.65 Gbps (just fully loading the DOCSIS link capacity configured for this setup), we see that for the CM, the latency distribution does change and the histogram and the CCDF curves shift to the right as expected. From the percentiles test we can tell that the latency for the 50th percentile latency (P50) increased from 7.2 to 15.5 ms, and the 99th percentile (P99) latency changes from 11.27 to 20.4ms. This test essentially shows the power of the AQM feature which all operators must ensure is turned on in their network.

As seen in the figure below, we can see that the baseline latency with fully loaded network is at the 7-8 ms mark. When we start the UDP load at about 16 seconds into the test we see that the latency spikes up to 30 milliseconds and then once the AQM algorithm kicks in, the latency stabilizes at about 15 ms.

Figure 22 – D3.1 (with AQM) latency – (4.7 and 1.7 Gbps UDP Load)

In the graph below we have an experiment with Low Latency DOCSIS (LLD) is turned on and the latency measurements are between 2 to 5 milliseconds even when we are sending traffic at 10% above the configured data rate. (In this configuration, service flows are limited to 200 Mbps down/20 Mbps up).

Figure 23 – D3.1 with LLD, UDP test at 10% above service flow limit

The test itself runs traffic at 10% above the 200 Mbps downstream rate limit and 20 Mbps upstream rate limit.

4.6. TCP Load Test Results

The next set of tests includes TCP traffic as load or background traffic either on the ONU under test or on a neighboring ONU on the same PON.

4.6.1. XGSPON TCP Test results

The next three figures show three different TCP Load test scenarios. In the first case we rate limit the TCP flows to be 1 Gbps, in the second we rate limit the TCP flows to 9 Gbps and in the third we run TCP flows using iPerf which are limited only by the network capacity. In all three cases we see that the XGSPON system handles bidirectional TCP flows without a significant change to the latency numbers.

Figure 24 – XGSPON latency – w TCP(1 Gbps, byteblower) - non-load ONU

Figure 25 – XGSPON latency – w TCP(9 Gbps, byteblower) - load ONU

Again, as before when the latency measurement is being done on the ONU which is carrying the load traffic, we see that the latency numbers are actually lower, compared to the ONU which is not carrying any load traffic.

Figure 26 – XGSPON latency – with Iperf TCP on non-load ONU

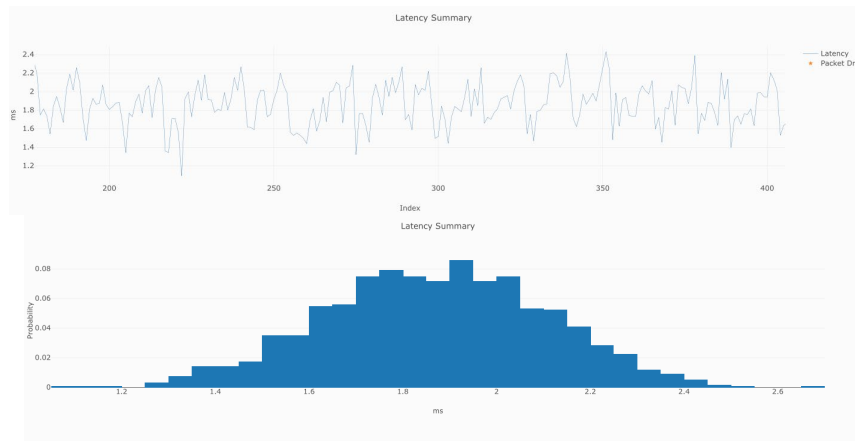

Figure 27 – XGSPON latency – with Iperf TCP on Load ONU

4.6.2. 10GEPON TCP Test results

Similarly, for the 10GEPON system, we see that the system handles bidirectional TCP flows without a significant change to the latency numbers.

Figure 28 – 10GEPON latency – with Iperf TCP on non-load ONU

When the latency measurement is being done on the EPON ONU which is carrying the load traffic we see that the latency numbers get worse, compared to the ONU which is not carrying any load traffic. This behavior is similar to the results we observed for the UDP tests on the EPON network

Figure 29 – 10GEPON latency – with Iperf TCP on load ONU

4.6.3. DOCSIS TCP Test results

We ran a few of the TCP load set of test cases on a DOCSIS CMTS. Now due to various networking issues and corporate VLAN switching issues to connect to the DOCSIS CMTS in a different lab the number of test cases were limited and are left for a future testing effort.

In an older DOCSIS system configuration (without AQM configured or AQM Latency target configured to a high value) we see the latency with a TCP load test increases dramatically compared to the baseline DOCSIS latency seen in the previous sections. This is **no longer an acceptable configuration** and operators should ensure that AQM is enabled on all of their CMTS /CM devices.

Figure 30 – DOCSIS no AQM config– with 1 Gbps TCP

In a D3.1 system correctly configured with AQM, (See figure below), we see the latency with a TCP load test does increase (the histogram shifts to the right by a millisecond and also extends a bit more) to 7-12 ms compared to the baseline DOCSIS latency (6-8 ms) seen in the section: Baseline DOCSIS Latency.

Figure 31 – DOCSIS AQM Enabled Config, no LLD and Iperf TCP load

In a D3.1 system configured with LLD, we see the latency with a TCP load test does increase, the histogram shifts to the right and is a bit more spread (1.9-5ms) compared to the baseline DOCSIS LLD latency (1.8-3 ms) seen in the previous section Baseline DOCSIS (with LLD) Latency.

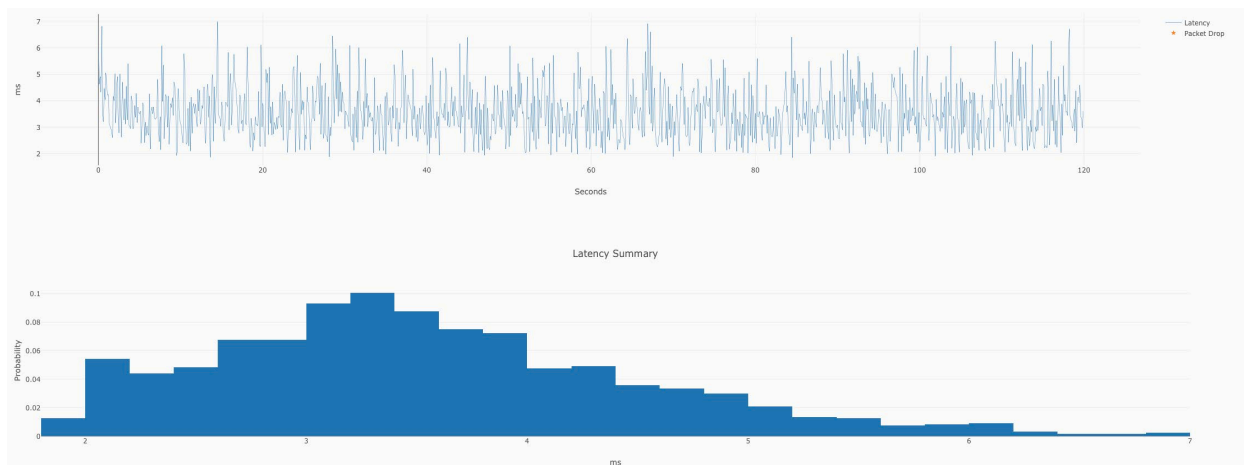

Figure 32 – DOCSIS LLD Enabled, Iperf TCP load

4.7. GPON/ EPON /DOCSIS Test Results summary

Looking at each of these above graphs and CDF's is very enlightening. The below table tries to summarize each of the tests that we ran by documenting three percentile values (0th, 50th, 99th), designated as P0 (minimum), P50 and P99. Please see the next three figures for a visual representation of the three tables. Please note that the DOCSIS testing was done on 3 different CMTS's/CMs, and as such these results from one DOCSIS CMTS cannot be compared with another due to change in the CMTS/CM hardware/Software versions and different plant configurations.

Table 3 – GPON latency Test results , P0,P50,P99

4.8. Multiple LLIDs Test Results (EPON)

The next set of tests that we wanted to do on the 10GEPON system was the use of multiple LLIDs. We created some DPOE (DOCSIS Provisioning of EPON) configuration, which essentially classifies packets based on the incoming VLAN tags and forwards each of those packets on to a different LLID on the PON system. These LLIDs were configured on both the upstream and downstream direction.

The load test we ran was sending five different flows, 2Gbps each, in both the upstream and downstream directions which matched those VLANs. This essentially meant we were pushing the limits of the EPON system by sending 10 Gbps in each direction. Given that the capacity of the PON network was 8.5 Gigabit per second on the downstream and 8.4 Gigabit per second on the upstream we expect to see that the scheduler on the OLT equally shares the bandwidth between the five LLIDs, in both the upstream and downstream direction. In the test results we see that the average throughput on the downstream is about 1.712 Gbps for each of the 5 downstream flows. On the upstream we notice the first LLID almost has no drops with a rate of 1.968 Gbps and the remaining 4 flows share the remaining bandwidth with 1.585 Gbps each.

Flow	Source	Destination	Tx Frames	Rx Frames	Frame Loss	Tx Bytes (+VLAN)	Rx Bytes (+VLAN)	Byte Loss	Duration	Average Throughput (Mbps)

4.9. Challenges and Further testing

This was the first time we were setting up an 10GEPON and XGSPON in our labs. So as expected there was a very steep learning curve in all aspects of the setup configuration and operation of the PON network. Once we got past setting up the physical network using the needed attenuators (10 to 15 dB), the main challenge was related to VLAN configuration. These SFP+ OLTs were connected to a switch which needed careful configuration of VLANs, to make sure we were bridging the traffic to the devices it needed to go. We also needed to build up the lab capabilities with optical to copper 10 Gbps port converters, 10 Gbps NIC cards on servers and clients etc. Learning the provisioning of services on these GPON and EPON systems and getting the right configurations in was another step in the learning process. Also getting packets to flow through the corporate network and reach the DOCSIS CMTS in a different lab had its own set of challenges and limited the testing to some extent.

In terms of future testing, we would like to study in more detail the performance of TCP flows on these PON systems. For an XGSPON system, we would like to enable and test multiple flows (AllocIDs in XGSPON) in each ONU. We would like to do more detailed testing of the DOCSIS system with LLD configured and varying the different configuration parameters. We would also like to measure the performance of TCP flows and the latency, when the measurement agents are located much farther in the network (i.e., adding additional round trip time or delay in the network path). We would also like to enable testing of PON systems with a larger number of ONUs (more than the two that we had currently on each system). We would also like to mix and match different on ONUs with different OLTs to understand the performance. There are many scheduling parameters which can be tweaked on the OLT scheduler, this includes parameters like polling interval, minimum and maximum granting period etc., and we would like to understand the differences in performance by varying each of these parameters.

5. Conclusions

10GEPON and XGSPON networks show remarkably good performance with 8.6/8.5 Gbps symmetrical throughput. Both PON systems show consistent latency performance on an unloaded or loaded PON network. The majority of the latency numbers fall within 1 to 2 milliseconds on a lightly loaded PON network, while we observe latencies up to 2 to 3.5 milliseconds under heavily loaded conditions. (Note that this loaded condition is for the home network i.e. this ONU's load, whereas when the whole serving group is heavily loaded and each ONU is transmitting above the minimum guaranteed rate, the latencies will likely increase.) At least in the configurations we tested it looks like 10GEPON has slightly lower latencies than the XGSPON setup we tested, but given they are all in the 1-3 ms range they both are very similar latency ranges. (The 10GEPON did have more guaranteed bandwidth than the XGSPON setup). We tested the network using UDP load traffic and TCP load traffic and the latency numbers stayed relatively consistent and in the same range. We also compared the latency in a DOCSIS network and see that while without Low Latency DOCSIS(LLD) features, the latency in a DOCSIS network can vary from 6-7 ms (baseline) to ~15 to 30 ms (under load). Enabling LLD brings the latency numbers to be at comparable levels, 2-3 ms (baseline) to 2-6 ms (under load), to that of a PON network. As latencies drop to the sub-5ms levels, the connection to content servers (outside of access network) through the Internet can become bigger contributors to overall end-to-end latency.

All testing was done with limited variations from default out-of-the-box configurations, varying the configuration parameters(for each of EPON, GPON, DOCSIS) may provide more variation in the results, leading to further analysis and understanding.

1. Introduction

The optical networks present today for cable television (CATV) systems look nothing like their predecessors first deployed with the birth of fiber nodes. Over the years, as technology evolved, these networks were augmented and upgraded as customer expectations also grew requiring a more reliable, higher-quality experience. As many smaller CATV companies were operating with various technologies and architectures, mergers and acquisitions continued to take place creating larger multiple system operators (MSOs). Having this variety was not inherently an issue with the residential services the networks were designed to support, which were primarily one-way plants providing linear video. With the advent of two-way plants and high-speed Internet (HSI) access, it was still not an issue to have separate optical networks. Other than backbone, services either originated or terminated on devices in a local headend. There was not a requirement for an optical service to continue beyond this termination. Even as commercial services were originally productized to support cell backhaul (CBH), and soon after retail metro Ethernet (ME) customers, the same access fiber infrastructure used to support hybrid fiber/coax (HFC) architectures fit the bill. Once the fiber circuit reached a headend, if it needed to continue to another location it became an Ethernet service and leveraged the routed Internet Protocol (IP) network. The introduction of two new commercial offerings, wavelength and high bandwidth Ethernet services, has made using the existing architecture a challenge.

This paper demonstrates how the metro optical network, optical transport network (OTN) tails over the access fiber, small optical shelves at customer sites, and dedicated commercial shelves at hub sites can be combined to support multiple types of commercial business. This enables new features like remote management, performance monitoring (PM) data, alarming, and a full end-to-end circuit view including the customer site. In addition to these operational benefits there are other efficiencies seen by using the same hardware and software as the rest of the core network.

2. Network evolution

To understand what the new architecture means it is important to look in a little more detail as to where the metro and access networks started, how the current state was reached, and where they are seen going.

2.1. Many small CATV providers

Some of the earliest deployments of fiber in CATV were to support one-way, video-only nodes, typically using low-count fiber cables feeding large pockets of customers from a headend, and areas that were beyond the reach of long coaxial trunk runs. These were single-threaded and there were some, but not many, hub sites. At this time it was not uncommon to have several small CATV operators with shared borders. Figure 1 represents this with three independent providers and a limited amount of fiber, hubs, and fiber nodes.

Figure 1- Three independent CATV providers

2.2. Acquisitions and HFC

With the upgrades to two-way plant and HFC architectures many new nodes were added as operators began creating hub sites with diverse routes and transport. These were mainly passive, point to point systems with amplifiers (AMP) and multiplexers (MUX) but no reconfigurable optical add / drop multiplexers (ROADM). Mergers and acquisitions continued over the years resulting in larger cable companies. This is shown in Figure 2. The three previously independent CATV networks illustrated in Figure 1 have grown and merged and are now owned by a single operator.

Figure 2- Two neighboring networks continue to grow

2.3. Networks merge, advanced services, cell backhaul and ROADMS

With advanced service deployments like HSI and video on demand (VOD) in full swing, the idea of placing routers in the hubs with redundant feeds to regional aggregate routers and video content servers became common. Systems continued to merge and some of the headends became hub sites. Each previously separate network was connected with fiber and active transport. ROADMs become more prevalent. This is also when the first commercial services over fiber were introduced, consisting primarily of CBH connecting cell towers to carrier's mobile switch centers (MSC). This made sense as the access fiber placed during HFC builds passed close to many towers. The routed infrastructure was getting more robust and resilient. At this point, there were many transport vendors and technology types. While the geographic borders between networks are blurring, transport networks that do not interop stop in the same hub keeping the optical networks still mostly segregated.

Figure 3- Single network with CBH, redundant hubs, some ROADMs and various transport vendors

2.4. All ROADMs, Flex Technology and one vendor

Over time, bandwidth needs became much greater for residential and commercial needs. Many systems within a region became part of the same network. The same technology type and vendor of transport are being deployed and meshed in the metro optical network. The access still stops at the metro hub.

From here forward all networks are being deployed with flex technology with an initial focus on supporting 400 gigabits per second (Gbps) wavelengths.¹ This paves the path for the IP infrastructure to use 400 gigabit Ethernet (GbE) native interfaces. Flex technology is also known as a colorless

¹ To better understand sections in the remainder of this paper there are important definitions when referring to wavelengths that are dependent on context. Wavelengths can be defined by the center frequency that aligns with an International Telecommunication Union (ITU) standard channel. The width of the wavelength can also be referenced in gigahertz (GHz). And lastly while referring to a network facing wavelength the transmission rate can be reflected in Gbps.

system. Instead of a traditional fixed wavelength grid add and drop structure with either 50 GHz or 100 GHz channels, flex technology allows 6.25 GHz slices of spectrum to be combined into any width wavelength. Doing this allows more efficient use of spectrum and future proofs the network against new technology that may require wider wavelengths than the fixed grid systems can support. At the same time, Comcast has decided to add two additional optical design requirements: Layer 0 (L0) control plane capable which allows protection and restoration of optical paths through wavelength switching and L band. These both make the network more robust by adding resiliency and capacity.

Figure 4 - Meshed Metro Optical Networks with ROADMs and Flex Technology

3. Products

Equally important to understanding the underlying fiber and transport infrastructure is knowing the requirements and challenges of the two products that drove the creation of the unified architecture.

3.1. Wavelength Services

Wavelength services is a product that delivers a single or diverse point-to-point, optical (Layer 1) 10 Gbps or 100 Gbps circuit over the Comcast dense wavelength division multiplexing (DWDM) network. There is no Layer 2 (L2) switching, Layer 3 (L3) routing, or any IP customer premise equipment (CPE) provided by Comcast.

Simply stated, wavelength services are point-to-point, transparent pipes over long distances with extremely low latency. The customer can connect their own IP devices between sites and as far as they are concerned, it is like a fiber jumper, is transparent, and lower latency than Ethernet services.

It is different than dark fiber in that PMs are available to observe for degradation or other issues. It can also go much farther because it uses optical transport.

3.2. High Bandwidth Ethernet Services

This product differs from wavelength services in that there is a Comcast owned and managed CPE on the end of the circuit and can be either point-to-point between customer sites or Internet access, referred to as Ethernet dedicated Internet (EDI). To achieve this at 10 GbE and lower rates, the CPE are connected over the access network to Comcast routers using coarse wavelength division multiplexing (CWDM) or DWDM optics, and leverage the IP infrastructure to transit to other customer sites or the Internet. With customers now requesting much larger bandwidth (up to 100 GbE) this cannot always be supported without extensive augments to the IP network and platform upgrades to support 100 GbE interfaces. This can lead to long deployment times and be cost prohibitive.

To solve this issue the access and metro optical networks can be used together with the same unified optical architecture as wavelength services to backhaul the high bandwidth Ethernet services to locations that the IP infrastructure can support.

4. The Building Blocks

The unified optical architecture started as a solution for wavelength services. This product needed to be launched in several markets that had different transport vendors and technology types. All tools for order processing, design, service delivery, and service assurance were centralized and needed standards applicable across the board to successfully provide the experience customers expect. It would not be possible to handhold each service and use development cycles on several iterations of the same product.

As seen above in the network evolution, the metro optical network is starting to be well-defined and positioned to carry any line of business (LOB) to any location. While the access is also maturing to support distributed access architecture (DAA) technology, it does remain segregated from the metro. This is not necessarily a bad thing provided the two networks can work together when needed.

With the metro being able to carry any LOB agnostically there needed to be a way to provide demarcations for engineering, service delivery, and service assurance. This was done by subtening independent devices dedicated to commercial services under the metro shelves. These needed to have the same role and functions regardless of the vendor. Thus, the network terminating equipment (NTE) and wave integration shelf (WIS) were born.

4.1. Network Terminating Equipment

The NTE is a small optical transport shelf that today can support 10 GbE and 100 GbE services over up to 400 Gbps wavelengths. It resides at a single customer site or data center to serve multiple customers and assumes the role similar to a CPE or edge gateway (EG) would for Ethernet-only services. A challenge when developing wavelength services was deciding how to hand off to the customer. Being an all-optical product, a point of demarcation was required to be the handoff. When only a demarcation was needed, a fiber patch panel could be used. A fiber patch panel directly connecting a customer to the network was not an option because there also needed to be a way for the wavelength and transmit power to be controlled.

A major roadblock for using high bandwidth Ethernet services was that anything over 10 GbE of committed information rate (CIR) would require the use of a 100 GbE interface. The use of 100 GbE

optics in IP platforms is not new. This has been widely adopted by the industry for years. 100 GbE has become the new 10 GbE. However, these are all 1310 nm, long reach (LR) optics. The only way a CPE could be connected to the IP core with these optics would be through a dedicated pair of fiber with no MUXs assuming the customer was within ~10 km of the Comcast router. At the time of creating this architecture, coherent DWDM optics at 100 Gbps or greater for the routers and CPE were in their infancy and were not within the project timeline. Even as this paper is being written these optics and their host platforms are still being developed and are not ready for production at scale.

The solution for this is to use optical transport cards that support DWDM optics at 100 Gbps (or greater). This allows taking a 1310 nm, LR signal from the router and CPE, and converting it to a DWDM wavelength for use over the access MUXs as shown in Figure 5.

To deploy this LR to DWDM conversion a place was needed to house the transport cards. The NTE fit this role perfectly at the customer site.

An additional benefit to placing the NTE is now the device can be remotely managed and enrolled in the transport network management system (NMS). This allows alarms to be monitored, PM data is available, loopbacks can be placed remotely for troubleshooting, provides an end-to-end circuit view and other features useful for supporting the service.

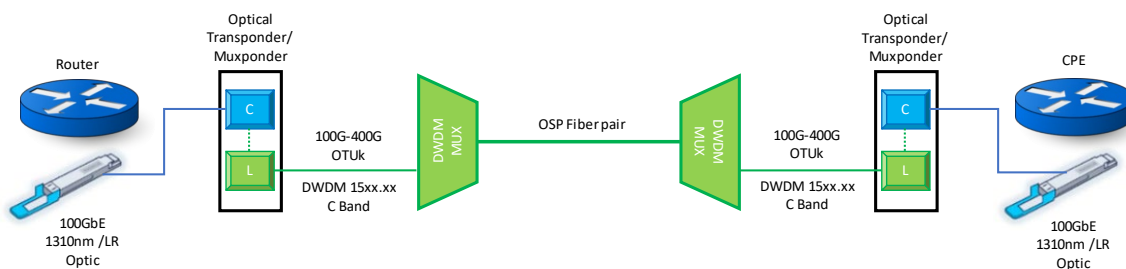

Figure 5 - LR to DWDM conversion

4.1.1. NTE Remote Management

With many proposed solutions come new challenges. To enroll the NTE in the transport NMS and be able to reach it remotely it needs a management IP address. In most cases the IP for transport devices is provided by directly connecting to a co-located switch. With the NTE being in a customer site there is no switch present. The closest switch is typically in the hub at which the fiber from the customer site terminates. The solution is to use the general communications channel (GCC). The GCC is bytes embedded in the overhead of transport links and can be used for small amounts of information. There is GCC0, which is two bytes within the optical transport unit (OTU) overhead, and GCC1, which is two bytes in the optical data unit (ODU) overhead. GCC0 was selected because the OTU is on the line (or network facing) interface. GCC1 is associated with ODU which is tied to the client payload. While both are transparent to the customer it was decided to keep the management on the network facing interface partially due to more hardware supporting GCC0.

One caveat when considering hardware in this architecture is that not all interfaces support GCC0 or GCC1. Due diligence was required to select the right transport cards and shelf for the NTE role to ensure it supported this feature.

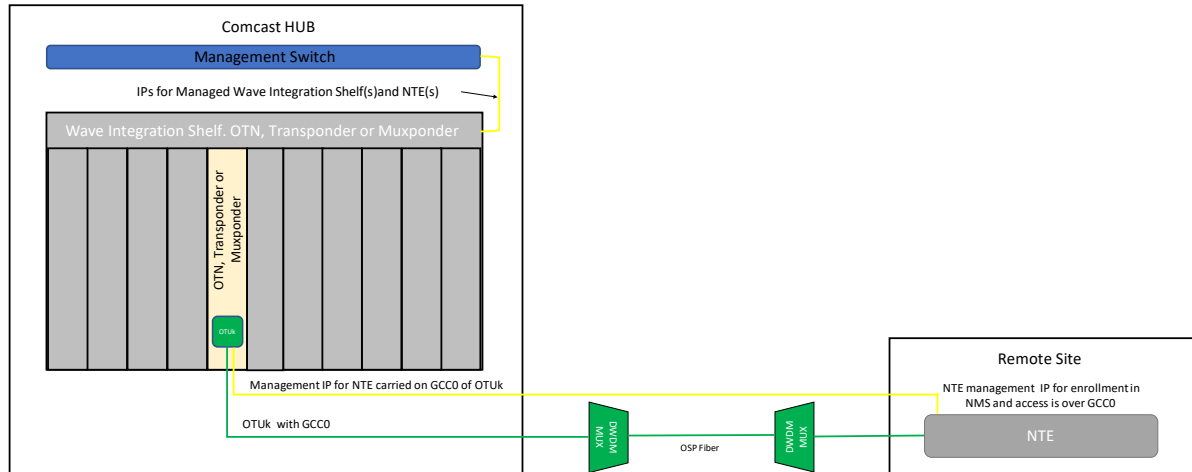

Figure 6 - Management IP for NTE being distributed using GCC0

4.2. Wave Integration Shelf

In addition to needing a device in customer sites another role was needed in the hubs and headends. It serves a similar point of demarcation function as the NTE. It also functions as an optical aggregation point. Other than more effectively using wavelengths through aggregation this also solves another issue. As optical networks are upgraded to flex technology they are optimized for coherent channels. In doing this the dispersion compensation modules (DCM) are removed. Without dispersion compensation 10 Gbps non-coherent channels will not work on most spans. By making the WIS an aggregation point for 10 G channels they can be combined onto 100 Gbps to 400 Gbps coherent wavelengths for transit across the flex optical network. There was a decision to be made here regarding the type of aggregation technology to use.

Traditional muxponders could be used to combine the nx10 Gbps circuits to a single coherent trunk. As seen in Figure 7, all traffic must have the same A and Z ends. Analysis showed it would not be common for multiple 10 Gbps circuits to be going to same end point except in the case of dense data centers.

A better solution was to use OTN switches. This allows traffic to be assigned to a slot on the trunk that can be picked out at a location along the path between A and Z without impacting the pass-through services. This is particularly effective when you expect a common A end with different Z ends along a path as is often seen with single customer sites that need to reach a common data center.

Figure 7 - Muxponder. All circuits share A and Z termination

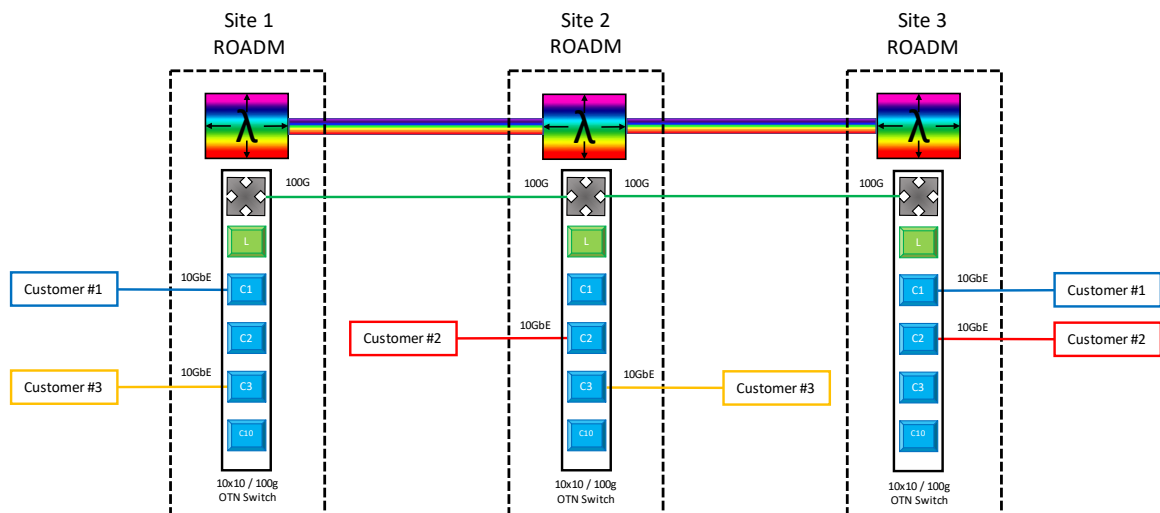

Figure 8 - OTN aggregation allowing different A and Z termination

4.2.1. Capacity Planning

Much of the focus on creating the unified optical architecture has been on engineering and operations but another important piece is planning, specifically capacity planning. Commercial services have sales forecasts, but they are very fluid. Residential networks have well-known, proven compound annual growth rates (CAGR) and can be planned with good accuracy. Since the metro optical network supports all LOBs to effectively manage slot capacity, each demand, or group of demands, benefits from having its own client shelf to support the cards needed. The WIS fits this role perfectly. It provides a shelf that will only support commercial services. Here is an example to illustrate the benefit.

Assume a shelf in a headend that supports both residential and commercial had five open slots, and the CAGR for residential traffic dictated that over a year one slot per quarter would be consumed.

That leaves one slot to support a commercial sale. Initially, that is not a significant issue. With commercial being so fluid though, sales can come in at any time. If more than one was to come in before the planned residential circuits were turned up, the commercial asks would consume the slots planned for residential. Everything could be oversized to make sure there is enough slot capacity but with space and power being a premium it does not make sense to do this “just in case.”

The WIS solves this issue by giving the commercial cards a place to reside other than the well-known static needs of the residential network.

This benefit proved itself with the capacity explosion during COVID-19. With no risk of a commercial demand unexpectedly consuming a slot in the residential shelf, engineers were able to execute augments to keep up with bandwidth needs on the residential network without delay while at the same time being able to provide high bandwidth commercial services to business customers to support remote employees needing to reach their infrastructure.

5. Leaveraging Access and Metro together: OTN Tails

Now that the hardware and roles have been defined to solve those challenges, we can address the separation of the access and metro networks and how they can be merged when needed to create a single end-to-end circuit.

As seen in the above fiber evolution maps, the metro transport has become more meshed and better able to support an any-to-any traffic pattern. The access has also gone through evolutions but what has stayed the same is the fact that it stops at the hub site. It has been found that most customers can connect to the access and be brought back to a hub site. But the remaining question is how can they be connected to each other if their fiber terminates at different hubs? Or in the case of EDI, how do they get to the router that provides internet Access? This is where the access and metro can work together by using OTN tails.

OTN is taking an Ethernet (or other protocol) payload and encapsulating it in a wrapper to be carried across an optical transport network. It is completely transparent, and a standard governed by ITU G 7.09.

An OTN tail is transmitting that wrapped payload over dark fiber or a channel on a MUX over fiber.

Using this tail and transponders (or muxponders) in the NTE and WIS facing each other can extend the metro core over the access without using ROADMs or even AMPs.

This tail is then transmitted over the core by a second card in the WIS with an OTU client-to-client connection to the card facing the NTE. This back-to-back configuration allows a DWDM OTN signal to face the NTE and the add / drop structure of the metro. Client-to-client connections have been made in the past as Ethernet where a similar design was used for regens. In this case the decision was made to keep them OTN so that the circuit remains transparent from end-to-end. There is no conversion to Ethernet and back to OTN. One advantage of this is that the trail trace identifier (TTI) trail trace remains intact from end-to-end even if the circuit crosses to another network or even to another vendor. You can transmit a trace on the A end and read it on the Z end. This is particularly useful for troubleshooting and topology verification.

The signal flow described above is applicable to 100 GbE services using a 100 Gbps to 400 Gbps trunk.

10 Gbps services differ slightly at the WIS. They still use an OTN tail over access from the NTE to the WIS but instead of back-to-back cards the 10 Gbps is aggregated on the OTN switch card.

Using the back-to-back cards or OTN switch card has also solved another issue with using MUXs in the access. By having the ability to tune to any wavelength facing the NTE or the metro it is not required to maintain the same wavelength end to end from NTE to the metro, across the metro, and to the other NTE. An effective way to illustrate this is to imagine many MUXs being deployed in the access with ITU channels (Ch) 20-59. The metro uses the same channels and, in some cases, adds another set of 50 GHz spaced channels the access does not use. If Ch 20 is used on the A end without this recoloring (that is, changing wavelength) in the WIS you would need to have Ch 20 open on your metro and the other end of the circuit over the access. Once you use Ch 20 for one circuit in the access or metro you cannot use it again. Back-to-back cards allow any channel that can reach the hub site where the WIS is located to be recolored to any open channel across the metro.

Figure 9- Recolor with back-to-back cards in WIS

5.1. Access MUXs to support 400 Gbps

With the metro being a flex system, it can combine slices of spectrum in 6.25 GHz increments to create the width needed per channel. Legacy fixed grid transport used two sets of 44 channel 50 GHz MUXs. This provided up to 88 channels but with a maximum per channel width of 50 GHz. This would support up to 200 G channels that are typically ~37.5 GHz wide.

The Access followed the same fixed grid pattern with one important distinction. The MUXs used were 100 GHz spaced. Why is this important? The last major technology advance that has been heavily adopted is the use of 400 G line rates. Depending on vendor and specific technology type, the width of this is ~75 GHz. With the access having up to 100 GHz of width available per channel, 400 G wavelengths can be deployed on a system that was first created and optimized to run 10 G. This is a fantastic use of the available spectrum; however, it does appear to be the end of the road. The next technology being adopted by the industry, including Comcast, is 800 Gbps wavelengths. As can be seen in Figure 10, an 800 Gbps wavelength occupies ~112 GHz of spectrum and will not fit in the 100 GHz MUXs used in the access.

Figure 10- Spectrum consumption by 200 Gbps, 400 Gbps and 800 Gbps Wavelengths

There is one particularly important caveat when using 100 Gbps and greater wavelengths over the access. Today's coherent optics by nature require both the transmit and receive frequency (wavelength) to be the same. This requires the use of a two-fiber MUX. A single-fiber MUX uses different frequencies for the transmit and receive.

Being that single fiber MUXs are the standard deployment at Comcast for all new DAA builds this puts the unified optical architecture at odds with DAA. However, work is being done in the industry to create bidirectional coherent optics to use for this application that would operate on a single fiber MUX.

Comcast Fellow and industry leader in this effort Venk Mutalik says, "Many businesses are within a short distance of optical fiber nodes, and with the expansion of DAA, we are going to have more of them out in the field. So, a really great way to use fiber assets already available is to converge business services on the same fiber as the residential services. This is done rather easily with 10 Gbps services, but with the ability to do the same with 100 Gbps and even 400 Gbps coherent services on the same fiber, access convergence is a game changer for the industry!"

6. Complete end to end architecture

With the building blocks established and the access and metro working together, a complete end-to-end architecture can be established. In Figure 11, each colored line represents a different commercial service type and rate.

All services, regardless of type, originate or terminate on an NTE at the customer site, use an OTN tail over access and are added into the metro optical network via WIS.

In Figure 11 the following types of services are shown.

- Blue – 100 GbE EDI
- Red – 10 Gbps wavelength service, customer site to data center
- Green – 100 Gbps wavelength service, customer site to customer site
- Orange – 100 GbE EDI

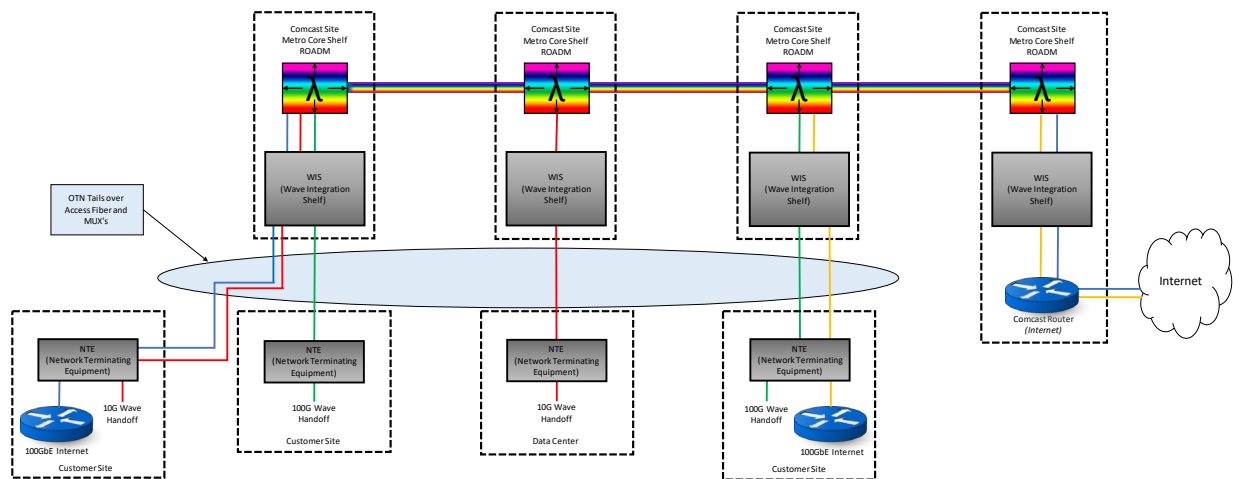

Figure 11 - Unified Optical Architecture

7. Benefits

All the work is now done. Building blocks have been assembled, technology challenges have been overcome, and a unified optical architecture to support multiple lines of commercial services has been created. The benefits are simple and clear. By developing this vendor-agnostic, unified optical architecture, commercial circuits can be deployed and supported the same way every time regardless of the type of service or traffic pattern, while increasing efficiency and maintaining or improving customer satisfaction.

The overarching theme is sameness. As explained by Shane Portfolio, Comcast Senior Vice President of Network Services, and leader of the Comcast One Network Initiative, “The value of sameness should not be underestimated. It allows for speed to market, greater scale, increased customer felt reliability, costs reductions, and enables next generation technology like machine learning, automation, and artificial intelligence to come to life because it is a homogeneous system that can be built to leverage these technologies in ways doing things differently simply cannot. It’s a game changer.”

7.1. Engineering and Service Delivery

By using the same architecture regardless of vendor, engineers can streamline processes and become deeper subject matter experts. The designs will always include the basic building blocks of the NTE, WIS, access and metro core. They will always follow the same device and port naming standards.

7.2. Procurement and Deployment Engineering

Using the same equipment as the metro networks benefits procurement by reducing the number of unique items in the ordering systems. A basic tenant of economics, volume buying power, also applies here.

Deployment engineering benefits from the ability to shuffle hardware to the highest priority project. Using the same hardware for multiple demands makes this possible. This again was a valuable option to meet demand and bandwidth shifts during COVID-19.

7.3. Operations and Service assurance

Possibly the biggest benefactors are the operations and service assurance teams. They are tasked with keeping the circuits and network healthy and code up to date. The ability to see PM data like optical levels and errors on an interface as well as place loopbacks at the customer site remotely is invaluable. By using the access to create OTN tails and merging them into the metro, the power of the NMS can be used to see a circuit from end to end including a simple green is good, red is bad, graphical representation. Alarms are also collected from all the optical devices and centrally managed in the NMS. This can dramatically cut the time to resolve an issue. Using the same hardware as the metro for NTEs and WIS also streamlines code certifications, deployment, and development efforts by reducing the variety of equipment deployed.

One of the greatest accomplishments this architecture has made possible is the development of software that merges customer account information, provisioning details, and correlates L2 and L3 ports to their connected transport clients. This also shows a hop-by-hop trace of the circuit from the NTE over the access and metro. Work was even done to stitch together circuits on multiple networks provided by different vendors. This creates a true end-to-end view with all the information an engineer needs to understand the circuit in one place. Comcast and a partner company co-developed this software.

8. Conclusion

All the work that was done to create a unified optical architecture may seem obvious. Why wouldn't the same equipment and standards already be used everywhere? The reality is that with the speed at which networks have merged and evolved they have been in a perpetual brownfield state with a variety of architectures. If everything were a greenfield build with no existing network to support, this would certainly be a lighter lift. In addition, optical technology has gone from 10 Gbps to 1.2 terabit per second (Tbps) wavelengths over the last decade. Simply keeping up has required the full attention of all teams. To put everything together has taken several years and a dedicated effort beyond keeping the lights on. In the end, though, by creating this unified optical architecture the goals to continue to deliver or improve the experience customers are accustomed to, offer new technology, and increase efficiency have been achieved. By not only solving the challenges present today but looking ahead to the future while creating this architecture, the networks are well-positioned to deliver the next generation of 400 Gbps wavelengths and 400 GbE to the customers with no changes.

Abbreviations

AMP	amplifier
CAGR	compound annual growth rate
CATV	cable television
CBH	cell backhaul
Ch	channel
CIR	committed information rate
CPE	customer premise equipment
CWDM	coarse wavelength division multiplexing

1. Abstract

The goal of tooling automation in operations centers is to speed the identification of issues and translate them into the swiftest fix agent response. Efficient management of outage events relies on multiple layers of detection tools that provide critical information for operations centers to coordinate event management and resolution. Numerous operation centers rely on Lines of Questioning (LOQs) to walk agents through key troubleshooting points to create consistent outcomes for identifying the root cause of system events.

The opportunity to reduce triage time comes from integrating key event knowledge points and automating LOQs to streamline assessment and dispatch tactics. Outage Pre-Verify (OPV) is a tooling automation strategy that creates technology solutions to automate current operation center processes. Process automation requires in-depth linkage of available system status data, understanding outcomes expected from LOQs, tooling development strategy, process optimization, and the capability to transition people through system changes. OPV takes the technology outage telemetry and enhances operational center processes by reducing triage time, improving event response time, and optimizing fix agent resources.

This paper and presentation will review strategies for identifying automation opportunities in outage triage. It will discuss how to optimize effectively transitioning people and business processes to integrate new tooling automation. Authors Kathy Fox, VP of Product Management, Excellence in Operations Centers (XOC), and Joann Shumard, a VP of Engineering Operations at Comcast, are leaders in Shane Portfolio's organization focusing on operational technology integration. They will detail the tooling transformation process and the impact on the user community. Emphasis will be given to effectively integrating automation change while simplifying the user experience and transforming operational processes.

2. Introduction

For several years now, teams at Comcast have focused on finding best practices and implementing them across all three Comcast divisions. As part of this best practice identification, process sameness opportunities have been discovered and implemented in the design, engineering, construction, and operations. While finding and implementing a best practice across three different divisions often takes a good bit of analysis, debate, and planning, once process sameness is in place, we then look to identify opportunities for simplification and automation. In this paper, we will review the automation of Comcast's OPV work where we focused on implementing process sameness related to both digital and analog node outages, measured the results, and then worked closely with these teams to identify specific improvements we could implement. We will review how we worked through data analysis, use case development, tooling requirements development, and finally tooling development, testing, and implementation to deliver automation that resulted in time savings for operations center technicians and truck roll reduction for our plant maintenance technicians both of which ultimately lead to a better customer experience.

3. Process Alignment

One area we previously gained alignment on across our three division operations centers was OPV. After much analysis and discussion, the teams had agreed upon a single process which included the same LOQs (Lines of Questioning) and timing for node outages to "soak", a term we use to indicate the period during which node components self-clear any alarms. It is important to note that nodes go into soak when a certain percentage of modems served by that node goes through a registration state change (to offline). The cost savings that resulted across our divisions with this process were noteworthy with a significant reduction in No Trouble Found (NTF) or Power Outage-related incidents as well as overtime savings.

However, the additional troubleshooting did create many more tasks (which means more time!) for our access network staff in the operations center. On a few occasions, the LOQs added enough triage time that the operations technicians were not able to keep up with all the triage activities, especially when node outages increased during inclement weather events, resulting in increased plant maintenance truck rolls.

The team began to investigate what efficiencies or automation we might deliver to the business to lighten the load for our operation center teams. There is a great deal of information that can be obtained from our network and the project team began to investigate what information might be available to help us more quickly determine if there was a power outage in the area. Any information that would tell us that nodes were in soak because a lot of customers had lost power would save our operations technicians a good bit of triage time either checking power providers' outage notification tools or calling the appropriate power company.

4. Technical Development

Aligned processes pave the way for automation. When processes and procedures are different across groups, the tooling is maintained in a customized and typically inefficient way. Once there is full cooperation in the way work is completed, the LOQs can be evaluated for automation opportunities. For OPV, building automation is focused on accuracy in identifying dispatchable outage events while reducing triage events for the operations centers. When considering the major steps of event detection—triage (LOQs), and Dispatch of a fix agent—automation provides the opportunity to bypass the manual triage and move the event to an auto dispatch state.

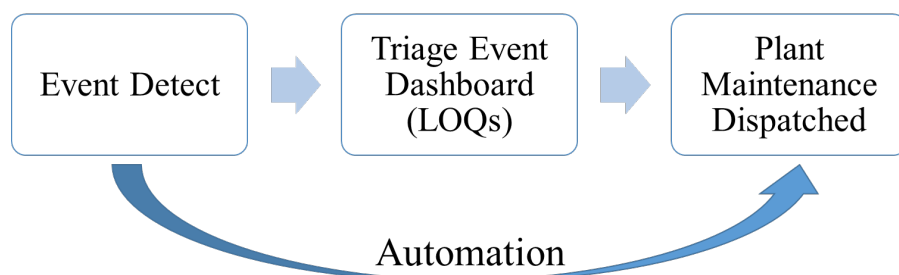

Figure 1: Manual to Automated Transformation

4.1. Design Methodology

In agile development methodology, the needs of the users drive the development requirements [1]. Sprints are used to develop iterations and progress towards initial implementation. For OPV automation, the requirements were captured from the initial manual implementation of standardized LOQs. This required a full review of which aspects of the LOQ could be translated into automated machine language.

Another aspect of agile development is to ensure there is clarity in task prioritization [1]. This is important to reduce the potential of rework and lost development. For OPV, this required full

alignment will all key users to collaborate to maintain the standard from manual to automation. This ultimately translated into the initial user story used for the technology development.

During development, continuous user feedback was required to make final adjustments or address issues [1]. This required consistent connections with the teams currently managing outage events using the manual implementation of OPV. It also provided an opportunity to ensure the process was collaboratively reviewed for improvement opportunities.

Figure 2: Agile Methodology [1]

4.2. Design Details

The logic of recreating the LOQs and drive automation capability was built to align with reduced field truck roll requirements while also reducing transactions for the operation centers completing the manual review. The summary of the key logic points of the LOQs and automation creation are:

- Upstream (US) Bandwidth Utilization.
 - Identification of a significant drop in US traffic;
- Upstream In Bps.;
 - Identification of a significant drop in US traffic.
- Power Supply Telemetry;
 - Identification of power current changes;
- Node Device Offline %;
 - The entire node was determined as a whole node outage determined by % of devices offline;
- Interactive Voice Response (IVR) Call Threshold; and
- Storm Mode Status.

These logic points are based on leading outage-based plant characteristics and time-boxed to provide assessment considerations for the algorithm. The target was to ensure that the logic was constructed so that it could be configured and adjusted as a part of continuous agile improvement. When considering the build of this type of automation, these characteristics and thresholds may fluctuate based on system

architecture variations. The storm status is a specific consideration that considers how the algorithm adjusts as a system transitions from plant outages created by typical event types (degradation, plant damage, etc.). to the more rapid pace of storm creation where dispatching may be held until it is safe for fix agent technicians to engage.

4.3. Challenges

Through the agile process, consistent feedback from the users was key to preparing for the adoption of the technology. One challenge was ensuring consistency in the thresholds across the organization. There was considerable discussion about the variety of plant characteristics and local considerations that had to be integrated into the final algorithm. Overall, this challenge was met through the partnership commitment to consistency and the agility of adjustments throughout the build process.

The integration of power outage information is a continuing challenge that the team continues to evaluate. When the power supply telemetry identifies the absolute loss of commercial power, it combines into the logic cleanly. The issue is that power grid boundaries do not consistently line up with node boundaries which makes the automation more challenging. The logic requires telemetry of every system power supply to be reporting consistently but due to maintenance issues, a number of units may not be fully reporting. This ambiguity in the power status supporting the node can cause the event to transition from an automated event to a manual review triage requirement.

Obtaining a unified buy-in of the working logic of the resource teams required a commitment to integrating continuous feedback while utilizing data modeling to confirm impact assessment. The logic build required that consistency is maintained through collaboration and strategic focus on a common goal. With multiple division teams, opinions on the solution path varied at times but having a change strategy supported the success of the implementation.

4.4. Delivery

This logic sits in a user interface tool that is used to process the logic and translate it into actionable alerts and jobs. When the automation logic triggers a pre-verified outage event through automation, the logic flows to an automated dispatch of a plant maintenance technician to resolve. This ultimately reduces triage time by operations team members. Events that do not meet the logic parameters or are unclear become a dashboard task for triage and validation. The introduction of automation creates an immediate reduction as well as creates a platform for continuous process improvement.

5. Trusting The Technology

Research tells us that people will inherently trust technology to be accurate, but it relies on the simplicity of the data and how well they know the technology [2]. Research shows that people are more suspicious of accuracy when they tend to confirm information validity using their expertise and skills. This algorithm complexity also drives the teams who have historically reviewed the work directly to want to see incremental validation before trusting the value.

The trust-skepticism balance can be overcome through targeted training and providing cross-reference data that illustrates confirmation of event accuracy [2]. Balance can be achieved by implementing system verification and reporting to work in parallel with the new technology algorithm. The skepticism is created from the psychological bias that some may have against trusting the technology to replace the work they are completing. The vetting of information through the agile process development is a key component of the feedback loop.

Since Outage Pre-Verify (OPV) was an embedded manual process being conducted by industry experts, building trust in the information was key to preparing to adopt the new technology. This was accomplished through the trial process where events were confirmed valid when tagged for automated dispatching. Another key aspect was the creation of reports that illustrated that the volumes were not significantly changing while also measuring the value to the business.

Understanding the impact of the change is a key component of preparing the teams to trust the innovative technology. This logic analysis is designed to reduce LOQ manual tasks. The trust in the automation requires the team to build confidence in the accuracy of what is dispatched without manual validation.

6. Change Impact

With any technological change, we must care for the tools, the processes, the documentation, and most importantly, the people. Organizational change management has become part of our standard project practice and has been well-received by the teams we serve. Our teams have been utilizing the Prosci ADKAR Model (Awareness, Desire, Knowledge, Ability, Reinforcement) for a few years now with impressive results. This powerful model is based on the understanding that organizational change can only happen when individuals change. The ADKAR Model focuses on individual change—guiding individuals through a particular change and addressing any roadblocks or barrier points along the way [3]. We have found that investing time upfront to understand the impact on our people and to develop plans that care for those impacts, enables an improved implementation experience and is time well spent.

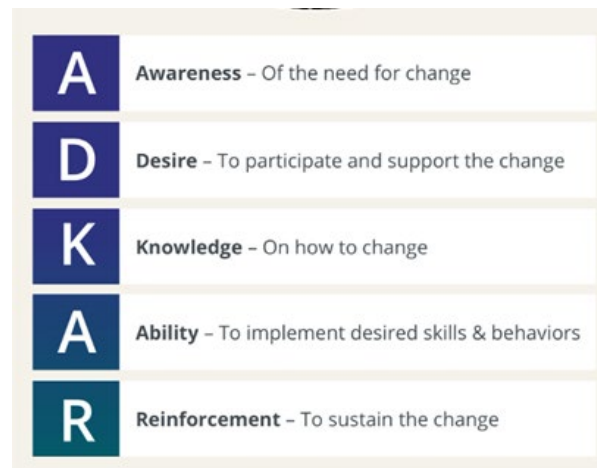

Figure 3: The Prosci ADKAR Model [3]

6.1. Planning the Change

During the initial project planning stages, we perform a change impact assessment. This involves project team members, change agents, and representatives from each of the expected impact areas. During the assessment, we look at each impacted role, discuss the expected impact in detail and determine if the change impact is high (a ‘5’) or low (a ‘0’ or ‘1’) or somewhere in between. That information is then used in the development of the organizational change management plan.

For OPV, our operations center teams had been investigating node outages for several years, so they knew the time needed to determine if a node is in soak because of a commercial power outage. Our three division operations centers have somewhat different staffing models. Although the three divisions had agreed upon a single set of LOQs for OPV, one of our divisions had difficulty executing all the questions

for the node soak triage because of staffing. As a result, they omitted some of the questions in the LOQ, expecting that future development would introduce time savings and negate the need for these questions. One of our other divisions had added the full set of LOQs but had not increased staffing for this effort so the team was feeling the impact on their workload. There was a desire on the part of the divisions to reduce the workload for the operations teams while maintaining the benefit of reduced plant maintenance truck rolls. The solution developed by the technical team was expected to reduce triage time by three minutes which is a significant impact given the thousands of triages performed by the operations centers each week. For the one division that had the abbreviated list of LOQs, the automation aligned them with the other two divisions.

For this technological change, the team quickly understood the resulting work benefit and considerable time savings, but there was also the potential that this advancement could introduce feelings of job insecurity or there could be a lack of trust in the solution being implemented. Insecurity or lack of trust in the solution could lead to resistance by the individuals impacted by this change. We wanted to proactively address the concerns and make certain the operations teams had Awareness of the change and a Desire to adopt it and the Knowledge to trust the solution (the “A” Awareness, “D” Desire, and “K” Knowledge in ADKAR).

6.2. Implementing the Change

When we can introduce an operational change as a trial, allowing the end-users to execute testing, it is a significant benefit. The first benefit is those end-users know the different scenarios they encounter every day, and they usually assign their most skilled users to conduct testing, validate the solution, or find issues that need to be addressed. The second benefit is the testers are part of the solution, they take ownership and often become champions of the change being implemented, helping other team members to adopt and accept the change once we move to full operationalization, supporting the “A” for Ability in the ADKAR Model.

Implementation plans will vary based on the Change Assessment results. For high-impact changes, we are certain to include formalized training, extensive communications, both written and verbal, and often, testimonials from testers or early adopters. We have created a detailed list of tactics that should be used based on the degree of impact. For the automation related to OPV, we considered it a medium-level impact and focused our communication on the efficiencies being provided to the teams while also sharing the new areas of focus for the teams. We were removing busy work to free them up to focus on more complex activities.

6.3. Challenges

Innovative technology implementations typically produce challenges. With OPV, we were fortunate to have the operations teams take part in the trial/testing phase which helped identify several technical improvement opportunities before implementation. We also found a number of process variances related to multi-node outages but were also able to address those, allowing for the solution development to be built one way.

7. Value & Results

The development process first determined what the initial goal was to create business value for the organization. The expected results were used to identify what level of reduction could be accomplished to reduce manual tasks. The reduction is calculated based on the total number of Hybrid Fiber Coax (HFC) outage events created then calculating the number of outages that were captured in the OPV engine

and sent directly to the fix agent technicians. The total time per task for the manual process is calculated for this series of events. To calculate an estimate of cost savings, an industry estimated rate of \$40 per hour is used for illustration. The launch of the new algorithm was implemented in mid-January 2022. The year-to-date average of reduced manual triage handling is 24% which is now the basis to increase automation in future iterations.

The figure below shows how significant the time savings are. The top line shows OPV performance for the three months before implementation of the OPV Automation. The bottom line shows the improvement for the most recent three months' performance with automation. The number of outages to be triaged is significantly less and the average completion minutes has dropped by more than the expected three minutes. Proper change planning ensured that the teams were part of both the journey and the solution, knowing what other tasks they would be working on once this automation was delivered. This type of reporting is shared with the teams to reinforce the benefits and highlight their contributions; the "R" in ADKAR is for reinforcement.

Table 1: Average savings, in minutes, for triage activities with automation

	#Triage	Avg Completion Min	Avg Min on Dash	Max Min on Dash
OPV Prior To Automation	220,917	9.8	18.6	797
OPV With Automation	167,958	5.1	12.2	594
Reduction/Improvement	52,959	4.7	6.4	203

Susan Bean, Sr. Director, XOC & Excellence in Plant Maintenance (XPM) summed up the OPV benefit this way. "Last year, the division XOCs set out on a journey to showcase processes and collectively solve for areas of opportunity. One area of focus was finding efficiencies for node outage triage with the goal of quicker restoration times for our customers. The collaboration of the operations and development teams was critical to finding a common approach. We were able to identify a successful solution, removed non-complex tasks for our operations teams, and redirected their efforts to more complex work."

When calculating the value of the business implementation there are two considerations. The first is the overall task reduction which can be multiplied by the average manual task time to get working time saved for the quarter view. The secondary improvement is generated in the reduction of task triage time through the streamlining of the LOQs and reducing handle time. This led to an opportunity to save approximately 250k minutes in the quarter that could then be used to support additional events.

Table 2: Quarterly Time Savings Potential

	# Jobs Triage	Average Completion Minutes	Total Time Minutes
OPV Prior To Automation	220,917	9.8	2,164,987
OPV With Automation	167,958	5.1	856,586
Time Saved	52,959	4.7	248,907

8. Conclusion

This evolution of automation followed a path from the historical manual triaging process of plant-related events but was transformed into a path of optimizing performance through automation. Aligning processes is foundational to tool development. When processes vary, the implementation of the tool is inconsistent and inefficient thus restricting the ability to automate. The focus of this initiative was to

capitalize on the efficiencies gained through the consistent process and LOQs and utilize technology to reduce transactions and time to complete tasks.

Having an agile and inclusive development plant paves the way for the adoption of these new changes. Through collaboration, the continuous feedback loop in the development lifecycle aided in change acceptance and building trust in these new ways of completing work tasks. This first phase of automation has reduced total transactions by 24% while improving LOQ time efficiency by 48%. These strong results illustrate the reinvestment opportunity of these resources completing manual work by providing them the opportunity to focus more on complex tasks.

As the network continues to become more intelligent, there will be more information available, allowing our tools to self-diagnose and self-service for repair. This will free up our people resources to focus on more complex issues that need investigation as well as occasional problem escalations for resolution. To be successful, we must utilize agile development methodologies and exercise proper organizational change management practices to advance the network, systems, tools, and people collectively.

1. Introduction

As high split deployments begin to ramp up, demand for broadband services keeps driving the need for higher network capacities. Operators are required to do plant hardware reconfigurations and upgrades across their Hybrid-Fiber Coaxial (HFC) networks. Plant hardware reconfigurations and upgrades are expensive. This is why implementation of techniques and strategies that minimize physical changes in the HFC networks is crucial to allow cable operators to optimize their HFC networks for the long-term, and to remain competitive.

DOCSIS 3.1 introduced features that not only allow operators to increase network capacity through their HFC networks, but also to optimize downstream and upstream transmissions in a more granular manner to obtain better performance. One of those features is Orthogonal Frequency-Division Multiplexing (OFDM), which is associated with higher modulation orders (up to 4096-QAM) and can be deployed over existing HFC plants to significantly increase network capacities, while deferring the need for immediate RF spectrum expansions. However, higher modulation orders do require higher Modulation Error Ratio (MER) and distortion performance, and not every HFC network will support the highest orders ubiquitously. Flat OFDM profiles only support one order of modulation across the entire OFDM channel and can be deployed initially to take advantage of higher MER conditions in specific areas, but do not necessarily result in optimal transport capacity. This is especially the case when plant impairments in specific areas of the HFC spectrum force the use of lower modulation orders across every single OFDM sub-carrier. Optimizing bandwidth utilization and transport capacity requires a dynamic mechanism to track MER performance for every OFDM sub-carrier, identify HFC plant impairments, and assign the most efficient modulation orders to one or more OFDM sub-carriers for a given set of plant conditions.

The Profile Management Application (PMA) is a cost-effective, software-based implementation to address the demand for more network capacity through data collection, analysis, and efficient selection of OFDM profiles. The selected profiles for each OFDM channel can assign different modulation orders to groups of subcarriers within the channel, known as segments, based on plant conditions. PMA not only will prove to be a valuable tool in evolving the network, but also will help MSOs improve network efficiency by maximizing modulation rates to and from each modem in the network, enabling higher user throughput overall.

This paper will present the results of the practical application of PMA in an HFC plant. The primary focus will be on OFDM operation in HFC plant roll-off areas as a practical mechanism to gain additional network capacity by increasing the modulation order and bit loading capacity of individual subcarriers for those CMs reporting higher RxMER values. The paper will discuss first the observed roll-off characteristics between 1.0 GHz and 1.2 GHz for a representative HFC plant segment configured with a mix of 1.2 GHz amplifiers and 1.0 GHz passives, and the worsening conditions impacting this portion of the HFC spectrum as the number of cascaded 1.0 GHz passives increases. It will discuss next the maximum expected MER and modulation orders at various tap locations throughout the cascade, and how an initial optimization of OFDM parameters for operation in roll-off areas using only flat modulation profiles can deliver limited capacity gains prior to a PMA deployment. Finally, the paper outlines how a full PMA approach is used to correctly identify physical channel conditions as seen by individual customer modems, and how this data is used to dynamically select the most appropriate OFDM profiles for optimal roll-off operation of modems connected throughout the cascade. Expected overall capacity gains when applying a PMA approach that enables efficient operation of OFDM carriers in roll-off areas will be discussed.

2. HFC Lab Network Description

Testing was performed in a typical node-based HFC network segment designed with a remote fiber optical node feeding a cascade of RF amplifiers, taps, and express, distribution, and drop cables. Total cable footage was 4,800 feet of RG-11 cable.

As seen in Figure 1, the express cables, illustrated in green, connect the optical node to the first (amp 1) and second (amp 2) 1.2 GHz system amplifiers. These express actives are Mini-Bridger (MB) type radio frequency (RF) amplifiers, designed to overcome cable attenuation and passive losses over sections of the network where there are few splitters and directional taps. The distribution portion of the HFC network, represented in blue, includes a combination of two line extenders (amp 3 and amp 5) and one MB amplifier (amp 4) to boost the RF levels to provide adequate signal level to multiple taps. In between the distribution amplifiers there are 1.0 GHz passives including: directional couplers (DC), power inserters (PI) and taps.

The drop portion of the network consisted of a 100-foot span of RG-6 cable from the tap port to the input of a two-way splitter, and 50 feet of RG-6 cable from the output of the two-way splitter to the Cable Modem (CM) input.

For the worst case scenario at the farthest end of line, there are a total of 20 1.0 GHz passives between the optical node and the CMs connected to the last tap.

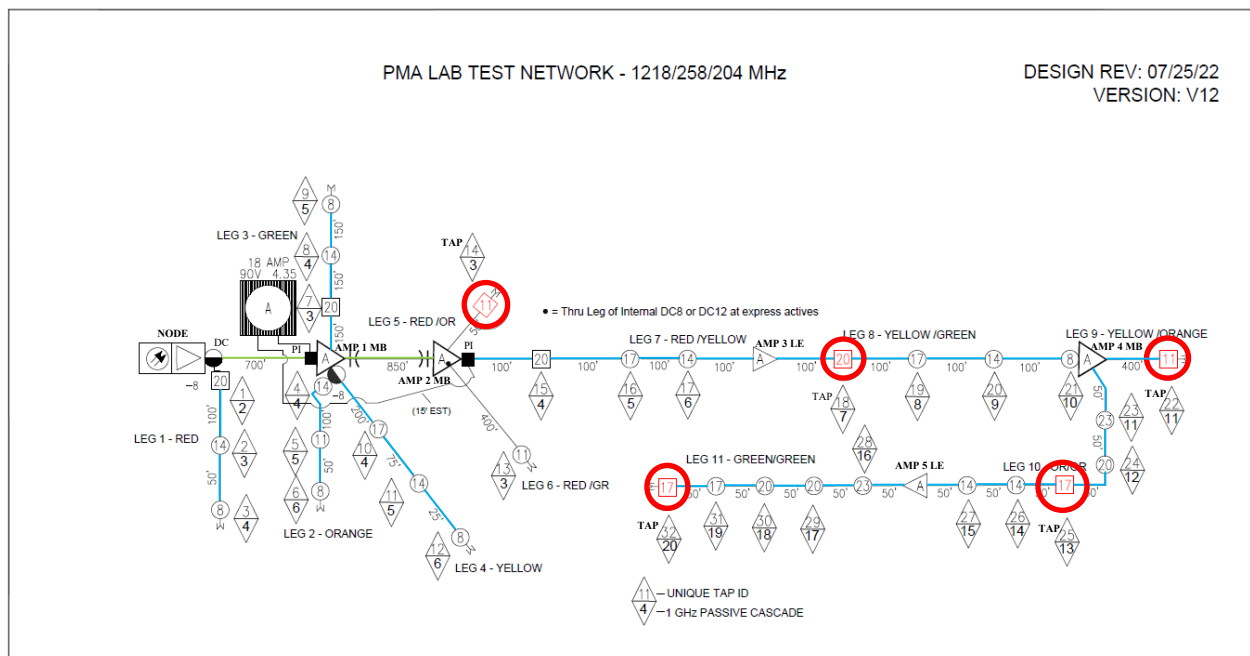

Figure 1. Typical HFC plant using 1.2 GHz actives and 1.0 GHz passives

The series of tests described below were performed using a high split Cable Modem Termination System (CMTS) that supports two downstream OFDM channels and two upstream OFDMA channels. Five sets of four different D3.1 CMs were connected to tap ports at five different tap locations, circled in red, across the network (Tap ID 14, 18, 22, 25 and 32). The 1.2 GHz actives in the test-bed were aligned to meet the designed RF output levels and tilt up to 1.2 GHz, but only loaded with a partial 1.0 GHz channel

line-up. This ensured that after completing the alignment, the addition of a 192 MHz OFDM channel in the 1.0 to 1.2 GHz range, required for the first round of testing, would not affect amplifier performance.

3. Deploying OFDM in the Roll-Off Region

The advantages of OFDM operation over traditional Single Carrier Quadrature Amplitude Modulation (SC-QAM) channels have been widely documented. OFDM has allowed cable operators to increase downstream efficiency and to transmit data more robustly. OFDM transmits data over a combination of orthogonal narrowband sub-carriers. Each sub-carrier can have a different modulation order (bit loading) within the OFDM channel as determined by the different segments configured within a modulation profile. The number of segments that can be configured within a profile will vary by CMTS vendor.

The ability to configure multiple profiles allows the OFDM channel to operate higher modulation orders in parts of the spectrum with minimal impairments. Conversely, OFDM sub-carriers can operate with lower modulation orders or profiles that are more robust in the presence of impairments such as frequency roll-off in the 1.0 to 1.2 GHz range, which is introduced by the accumulated non-flat signature of cascaded 1.0 GHz passives.

The frequency response curve of 1.0 GHz passives beyond their defined passband has different peaks and valleys. The non-flat frequency response of a single 1.0 GHz passive in the 1.0 – 1.2 GHz range can be considered fixed, but it does vary in severity by manufacturer. The combination of poor return loss and higher insertion loss creates a non-flat roll-off signature that increases in severity as the number of 1.0 GHz passives increases. The cumulative effects of higher insertion loss and poor return loss in the 1.0 to 1.2 GHz range after four passives in cascade, using passives from two different vendors, are illustrated below in Figure 2 and Figure 3.

Figure 2. Cumulative Insertion Loss after four 1.0 GHz passives - two different vendors

Figure 3. Cumulative Return Loss after four 1.0 GHz passives - two different vendors

As shown in Figure 4 the non-flat frequency response signature creates a roll-off that worsens as the number of 1.0 GHz passives increases. Eventually, the distortion of the OFDM carrier is such that CM operation may not be possible. RxMER data from individual CMs was no longer accessible after 11 passives, CMs stopped receiving data on the lowest modulation profile due to the amount of uncorrectable codeword errors. Ultimately CMs were unable to bond to the OFDM channel. As a result, the sequence of plots of the 192 MHz-wide OFDM channel across the five selected tap locations was obtained using a spectrum analyzer.

Figure 4. Roll-Off in the 1.0 – 1.2 GHz region at each of five selected tap locations across the network

Consequently, it is important to understand the overall impact of the roll-off on CM operation, and to select optimal OFDM parameters prior to enabling PMA in order to minimize issues such as those listed below and described in [PMA-D3.1-CL]:

- Profile flapping, which is defined as the process of a CM switching from a higher modulation profile to a lower modulation profile and back. It can be a result of the RxMER for the OFDM channel being marginal, falling slightly below the configured threshold for the CM to decode a certain modulation order. Therefore the CM starts to experience uncorrectable codeword errors on the assigned profile. The CM reacts by sending a CM-STATUS profile failure message to the CMTS, the CMTS response is to send data on a lower profile to the CM. If the RxMER increases over the configured threshold, then the CM will send a recovery CM-STATUS message to the CMTS, informing the CMTS that it can use a higher-modulation profile.
- Impaired channel operation due to loss of lock on the OFDM channel caused by high uncorrectable codeword errors on the assigned modulation profile. When loss of lock is

detected, the CM sends a loss-of-lock event message to the CMTS. The CMTS can either reprogram the OFDM channel or the profile.

- Partial channel mode occurs when, despite detecting lock loss, the OFDM channel is still partially functional for data reception, but uncorrectable codeword errors are high either in the PLC, NCP or profile A, and the CM tries to maintain use of the OFDM channel. When a CM enters partial channel mode the CMTS can either switch the CM to another profile on the OFDM channel or stop sending data on the reported profile.

HFC networks have different cascade depths that vary from node to node, as does the number of passives and type of passives that have been deployed throughout the years. Consequently the cumulative frequency response across different HFC plants will also vary. This is why it is important for MSOs to implement tools that help characterize and adjust to their network's performance. This ensures that subscriber quality of experience (QoE) is not impacted due to high volume packet loss and loss-of-lock events while operating an OFDM channel in the roll-off region. In addition, it is important to implement profiles with different modulation orders that account for the frequency response of the HFC plant to avoid significant network capacity reduction and/or intermittent connectivity issues caused by profile flapping. Further it will benefit MSOs to leverage extra network capacity by assigning a set of profiles based on the RxMER levels reported by different groups of CMs across different areas of the HFC spectrum.

Additional variables cable operators should consider when deploying and operating DOCSIS 3.1 (OFDM) channels in an HFC network with roll-off, due to the non-flat frequency response of 1.0 GHz passives in the 1.0 to 1.2 GHz range, are the configuration settings of the OFDM channel. A clear understanding of DOCSIS 3.1 configuration parameters is crucial to leverage stable CM operation of OFDM channels in the roll-off region. Parameters such as location of the OFDM channel, location of the PLC and NCP subcarriers within the channel and CM-STATUS messaging frequency can all affect the overall efficiency of the OFDM channel [PMA-D3.1-CL]. This impact will be discussed in more detail in the following sections.

3.1. Baseline testing: characterizing roll-off and MER impact using flat profiles

A first round of baseline measurements was taken using a DOCSIS 3.1 field meter. A 192-MHz OFDM channel was configured using default OFDM settings as shown in Table 1. No attempt was made to optimize these setting as the primary objective was to identify the impact on RxMER due to the non-flat frequency response above 1.0 GHz when mixing 1.0 GHz passives and 1.2 GHz actives across the HFC network.

The first round of testing was performed using the default OFDM settings as shown in Table 1. These parameters were re-configured as shown later in Table 3 to optimize CM operation in the roll-off region pre-PMA implementation. The latter approach is discussed in more detail in section 4.

Table 1. Initial OFDM settings

OFDM SETTINGS	PARAMETER
OFDM Channel	996-1188 MHz
PLC location	1004 MHz
Primary capable	No
Pilot-scale-factor	48
NCP Profile	16-QAM Flat
Max-event-hold-off	20 minutes

As mentioned in [OFDM RxMER], RxMER plots per sub-carrier are a valuable tool to characterize impairments such as roll-off. CMs will report via SNMP MIBS different RxMER values based on tap location and RF spectrum conditions across the network. Therefore an imperative first step in our process was to measure and record RxMER values using a typical DOCSIS 3.1 field meter. Not only did these measurements, collected manually, help quantify and map the impact of plant roll-off across a full 192-MHz channel spectrum and at various points in the cascade, but they could also be used to validate the accuracy of CM reported RxMER values.

For the initial measurements, the test bed was configured as follows:

1. Channel loading: 4 SC-QAMs below 1.0 GHz and a 192 MHz OFDM starting at 1.0 GHz;
2. OFDM settings were as described in Table 1;
3. Four flat profiles were configured, each supporting a single modulation order for all subcarriers across the entire OFDM channel.

RxMER values at different tap locations through the HFC network were recorded to identify RF signal degradation from 1.0 to 1.2 GHz due to the non-flat frequency response of the 1.0 GHz passives. As expected, the overall result is increasingly degraded CM performance (RxMER) as the number of cascaded actives and passives increases. In practical terms, this means that while CMs closer to the node can support 4096-QAM modulation across all sub-carriers within the OFDM block, CMs that are progressively farther away can only support 4096-QAM order of modulation over an increasingly reduced set of sub-carriers within the same block.

Recorded RxMER values at increasingly deeper locations within the cascade can be grouped by frequency blocks of varying widths across the entire 192 MHz OFDM channel. Each colored block then represents the maximum reported RxMER value within that frequency block that can be maintained by the CMs at a given tap location. The colored frequency blocks for the last tap in the cascade would illustrate the maximum RxMER values that could be maintained by the farthest end-of-line CMs connected to that last tap.

As seen in Figure 5, the RxMER values reported by four different CMs across a 192 MHz channel at the third 1.0 GHz passive (Tap ID 14) in cascade is within tenths of a dB and it is enough to support 4096-QAM operation across the full OFDM channel.

Figure 5. Reported CM RxMER levels across a 192 MHz OFDM after three 1.0 GHz passives

As seen in Figure 6, when the amount of 1.0 GHz passives in cascade is at seven, the roll-off region starts to affect a minor portion of the upper frequency edge of the 192 MHz OFDM channel. It was observed that CMs started to experience a few correctable codeword errors due to the lower RxMER values in the last 48 MHz of the OFDM channel, but the RxMER degradation of the affected sub-carriers did not have a meaningful impact on overall performance. RxMER was enough to support the highest modulation profile (4096-QAM).

Figure 6. Reported CM RxMER levels across a 192 MHz OFDM after seven 1.0 GHz passives

Referring to Figure 7, as the 192 MHz OFDM carrier travels even deeper into the cascade and the number of 1.0 GHz passives increased to 11 (Tap ID 22), the first 48 MHz block within the OFDM channel remains capable of supporting a MER of 40 dB for all sub-carriers within that block. As the roll-off starts to affect a higher percentage of sub-carriers in the OFDM channel RxMER progressively drops to 38 dB for the next 76 MHz block, to 36 dB for the next 20 MHz block, to 30 dB and to 26 dB for the next two 10 MHz blocks respectively. Ultimately RxMER for the sub-carriers of the last 28 MHz portion of the 192 MHz OFDM channel sank to 18 dB. At this 11th tap, CMs were not able to bond to the OFDM channel and stopped receiving data on the lowest modulation profile due to the amount of uncorrectable codeword errors.

Figure 7. Reported CM RxMER levels across a 192 MHz OFDM after 11 1.0 GHz passives

At 13, 1.0 GHz passives (Tap ID 25) as visually illustrated in Figure 8, the first 48 MHz block within the OFDM channel remain capable of supporting an MER of 40 dB for all sub-carriers within that block, which should enable modulation orders of up to 4096-QAM . The second 26 MHz block was not significantly affected by the roll-off and can support an MER of 38 dB. However, as a higher number of sub-carriers are affected by the roll-off the MER values started to progressively drop to 32 dB and 30 dB for the third and fourth 40 MHz blocks. Eventually the fifth 10 MHz block can only support an MER of 20 dB and the last 28 MHz block of the OFDM channel can only support an MER of 13 dB across the entire network. As a result, none of the CMs were able to bond to the OFDM channel.

Figure 8. Reported CM RxMER levels across a 192 MHz OFDM after 13 1.0 GHz passives

At 20, 1.0 GHz passives in cascade at the EOL tap (Tap ID 32), Figure 9 shows only the first 24 MHz block still able to support a MER of 39 dB, but the severity of the roll-off significantly reduced the usable bandwidth of the OFDM channel. As a result the MER values decreased at a higher rate, reducing to 37 dB for the next 24 MHz then to 33 dB and 27 dB for the next 6 and 10 MHz blocks respectively. After MER values sank rapidly to 17 dB for the next 10 MHz block. Ultimately the MER for the last 118 MHz started to drop below 10 dB.

Figure 9. RxMER values across a 192 MHz OFDM after 20 1.0 GHz passives

This distribution of MER values across frequency blocks within a 192 MHz OFDM channel across different tap locations begins to uncover the value of a PMA approach. Without PMA, only flat modulation profiles are possible across the RF spectrum. Referencing Figure 5 through Figure 9, a flat modulation profile based on 4096-QAM operation that leverages the MER value distribution of Figure 5 can only be used by those few CMs closer to the node (Tap labeled 14). Likewise at seven passives in cascade (Tap labeled 18), 4096-QAM could be supported even though some sub-carriers started to be affected by the roll-off as shown on Figure 6. However CMs at the farthest end of line and reporting a distribution of MER values similar to that shown in Figure 9 reported a maximum RxMER that is considerably below the threshold for 4096-QAM. These CMs failed to operate with a flat 4096-QAM profile even though the subcarriers in the first 48 MHz block within the OFDM channel would support it.

3.2. Understanding CM operation in the roll-off

There are different ways for a CMTS to check the CM performance on a downstream OFDM channel. In the case of this paper, the CMTS sends an OFDM Downstream Profile Test Request (OPT-REQ). The OPT-REQ is used to test the CM ability to receive the specified OFDM profile and query the CM RxMER statistics. The CMTS uses the data from the OFDM Downstream Profile Test Response (OPT-RSP) to decide which OFDM profile is better for the CM at the time of collection. After this, the CM can still fail any available OFDM profile for other reasons such as the ones mentioned on [MULPIv3.1].

3.2.1. Results for CM performance when the OFDM channel width is varied

The objective of this test was to determine the tap location and RxMER threshold at which CM would start downgrading OFDM profiles. In addition, a throughput test was performed at the selected tap locations to quantify the additional throughput obtained above 1.0 GHz when using OFDM channels of varying width. All CMs were monitored as the roll-off severity increased across the test plant.

1. Channel loading: 4 SC-QAMs below 1.0 GHz and a 48 MHz wide OFDM starting at 1.0 GHz;
2. The same four flat profiles from the previous section were configured across the entire OFDM channel;
3. Tap location, profile, and the value of RxMER were recorded;
4. Throughput measurements were taken;
5. The OFDM bandwidth was increased in 6 MHz steps from 48 MHz to 192 MHz, and steps 3 & 4 were repeated.

As the OFDM bandwidth increased, CMs at tap locations further from the node were not able to achieve stable operation on the reported profile when the reported RxMER was between the threshold values showed in Table 2.

Table 2. Configured Flat MER Profile Thresholds

MODULATION RATE (QAM)	FLAT MER [dB] PROFILE THRESHOLDS
64	20.5
128	23.5
256	31
512	29.5
1024	33
2048	36
4096	38

For instance, when the RxMER was slightly below or above a configured RxMER threshold value (Table 2), as the upper end of the OFDM channel increased to about 1145 MHz, at 11 1.0 GHz passives in cascade (tap 22), all four CMs locked to the OFDM channel but CMs started to experience uncorrectable codeword errors. When CMs experienced enough codeword errors, the CMs sent a CM-STATUS message to the CMTS to communicate a profile failure on profile 2048-QAM due to the amount of uncorrectable codeword errors in the profile. The CM was reporting an RxMER slightly below 36 dB, which is the configured threshold for profile 2048-QAM. It was observed that CMs took a long time to drop to the next profile. After analyzing the CM's debug log it was found that the CM-STATUS message was not sent in a timely manner. The CMTS default setting for the max-event-hold-off was set to twenty minutes. See Table 1. This parameter was lowered to five minutes to allow the CMs with a marginal RxMER to switch to a lower profile faster.

Similarly, for the four CMs located farther from the node 13 passives into the cascade (tap 25), as the OFDM bandwidth increased beyond 1110 MHz some CMs reported RxMER below the 1024-QAM threshold. Other CMs were able to operate on 1024-QAM with some correctable errors, but when the upper end of the OFDM channel was increased up to 1150 MHz CMs were not able to bond to the OFDM channel due to the amount of uncorrectable codeword errors reported on the 1024-QAM profile. When the OFDM bandwidth was increased in 6 MHz steps between 1110 to 1150 MHz, CMs began to experience profile flapping between profiles 2048-QAM and 1024-QAM.

At 20, 1.0 GHz passives in cascade (tap 32) the cumulative effect of the 1.0 GHz passives worsened, and with a 48 MHz-wide OFDM channel some CMs started to experience uncorrectable codeword errors. These CMs notified the CMTS of a profile failure on 4096-QAM due to the RxMER being below the 38 dB MER configured threshold. This behavior was not as expected because we predicted that CMs connected at 20 1.0 GHz passives in cascade would work with a 48 MHz OFDM channel on the highest modulation profile as shown in Figure 9. In addition, when the OFDM channel width was increased beyond 66 MHz, all CMs went into partial channel mode or partial service mode due to high FEC errors in the used profile (1024-QAM) but continued trying to use the OFDM channel. These CMs sent a CM-STATUS message to inform the CMTS of a loss-of-lock event. Some CMs were able to fall back to the

lowest modulation profile 256-QAM, but due to the amount of uncorrectable errors were not able to lock to the OFDM channel.

During this test, the main observation was that only CMs closer to the node (less or equal than seven passives deep, tap 18) were able to operate using a full 192 MHz OFDM channel, and did not experience uncorrectable codeword errors because the severity of the roll-off was not affecting as many sub-carriers in the OFDM channel. As shown in Figure 10, all four CMs connected to the third and the seventh 1.0 GHz passive (tap 14 and tap 18 in Figure 1) reported a similar RxMER of approximately 40 dB. The CMTS sent traffic on the highest modulation profile and the overall throughput was not impacted. Due to the CM operational issues just described, CM RxMER data was not measured at 11, 13 and 20 passives in cascade.

Figure 10. D3.1 Avg. RxMER values per CM at three & seven 1.0 GHz passives for a 192 MHz OFDM channel

4. Optimizing OFDM Performance for Roll-off Operation

It can be seen from section 3 that it is crucial to revise certain OFDM configuration parameters before PMA implementation in the roll-off region to ensure stable operation. The OFDM settings mentioned previously in Table 1 were optimized in Table 3. Optimized settings can help minimize Partial Channel Mode, impaired OFDM channel, and profile flapping events similar to those reported in this paper. Optimization will also help ensure that a CM is assigned the most appropriate modulation profile for specific plant conditions such as severe roll-off.

Table 3. Optimized OFDM Settings

OFDM Setting	Optimized Parameter
OFDM Channel	996-1188 MHz
PLC Location	1004 MHz
Pilot-scale-factor	120
NCP Profile	16-QAM from 996 to 1100 MHz and 0 QAM from 1100 MHz to 1188 MHz.
Max-event-hold-off	5 minutes

After analyzing the flat OFDM profile configuration and CM behavior it was determined that NCP-profile should be dynamically adjusted based on the roll-off characteristics of the plant. Also the pilot scale factor was set to the highest value (120). As described in [PMA-D3.1-CL] the CMTS defines modulated sub-carriers with a particular modulation pattern as pilots in the downstream. All the CMs in the system know this to allow interoperability. The pilot scale factor increases the amount of continuous pilots that occur at fixed frequencies in every symbol, as shown in the following formula:

$$\text{Number of Continuous Pilots} = \min \left[\max \left(8, \text{ceil} \left(M * \left(\frac{F_{\max} - F_{\min}}{192^6} \right) \right) \right), 120 \right]$$

The value of M is the pilot scale factor in the equation and can be adjusted at the CMTS between ($120 \geq M \geq 48$). The pilot factor was adjusted from $M = 48$, which results on a total of 56 pilots (48 + 8 PLC pilots) for a 192 MHz channel to $M = 120$, which equals to 128 pilots (120 + 8 PLC pilots) for 192 MHz to improve OFDM downstream channel estimation.

4.1. Pre-PMA implementation baseline

The objective of this test was to establish a new baseline after adjusting OFDM settings to ensure the maximum amount of CMs were able to use the OFDM channel in the roll-off region across the entire HFC network pre-PMA implementation:

1. Channel loading: 4 SC-QAMs below 1.0 GHz and a 192 MHz OFDM at 1.0 GHz;
2. The following 4 profiles were configured across a 192 MHz OFDM channel:
 - a. Profile 0: 256-QAM from 996 MHz to 1050 MHz and 0 bit loading from 1050 MHz to 1188 MHz
 - b. Profile 1: 256-QAM flat
 - c. Profile 2: 1024-QAM flat
 - d. Profile 3: 4096-QAM flat
3. OFDM was configured as described in Table 3;
4. RxMER at different tap locations throughout the HFC network was recorded to identify RF signal degradation from 1.0 to 1.2 GHz due to the non-flat frequency response of the 1.0 GHz passives.

As seen in Figure 11, after adjusting OFDM settings to the values in Table 3, CMs were able to operate in the roll-off region with a 192 MHz OFDM beyond tap 18 (seven 1.0 GHz passives in cascade). Consequently, all CMs located at 11 (tap 22) and 13 (tap 25) passives in cascade were able to bond to the OFDM channel after initialization based on the configured CMTS MER thresholds in Table 2. At the end of line (EOL) tap 32 only CM 3 was able to bond to the OFDM channel. CM 1, CM 2 and CM 4 were not able to bond to the OFDM.

Figure 11 quantifies the positive impact the changes made in the OFDM settings had in CM operation throughout the network. Most CMs were able to successfully bond to a 192 MHz channel after the changes, and only two CMs did not report RxMER at the EOL tap. The root cause for the failure to bond for these two CMs is still under investigation.

Figure 11.D3.1 Avg. RxMER values per CM at 3,7,11,13 & 20 passives for 192 MHz OFDM channel

At three (tap 14) 1.0 GHz passives in cascade, the average (mean of all supported sub-carriers) RxMER value of CM 1, represented in blue in Figure 11, was obtained from the expanded RxMER plot per sub-carrier shown in Figure 12. Correspondingly, the RxMER of CM 3 located at 20 (tap 32) 1.0 GHz passives, represented in green in Figure 11, was calculated from the RxMER plot per sub-carrier illustrated in Figure 13.

Figure 12. RxMER per sub-carrier for CM 1 located at three 1.0 GHz passives

Figure 13. RxMER per sub-carrier for CM 3 located at 20 1.0 GHz passives

At three (tap 14) and seven (tap 18) 1.0 GHz passives in cascade all CMs reported an average RxMER close to 40 dB allowing the CMs to use all profiles and operate with the highest profile and the highest modulation order (4096-QAM) as shown in Figure 14 and Figure 15.

Figure 14. Reported RxMER per four CM vendors and used profiles after three 1.0 GHz passives

Figure 15. Reported RxMER per four CM vendors and used profiles after seven 1.0 GHz passives

After configuring 0 bit loading on the NCP-profile in the severe roll-off region, the ability of CMs to bond to the OFDM channel was greatly improved. For the Pre-PMA baseline, as seen in Figure 16 all CMs located at 11 (tap 22) 1.0 GHz passives were able to bond to the OFDM. An interesting observation during this test was that different D3.1 CMs reported slightly different RxMER values. CM 3 and CM 4 stopped receiving data on the highest profile three due to uncorrectable codeword errors. The CMTS responded to the CM-STATUS message by downgrading the profile to a lower profile in this case profile 2.

Figure 16. Reported RxMER per four CM vendors and used profiles at 11 1.0 GHz passives

Even though the cumulative effect of the non-flat frequency response of the 1.0 GHz passives was worse at 13 1.0 GHz passives, all CMs still bonded to the OFDM channel. However, higher differences in the

reported RxMER values from all four CMs were observed. CM 1 and CM 3 were able to receive data on profile one, but CM 2 and CM 4 were able to only use profile zero due to the amount of uncorrectable errors on profile 1. See Figure 17. The differences in reported RxMER values among CM manufacturers have not yet been explained at the time of this writing. Further testing needs to be performed to research possible causes.

Figure 17. Reported RxMER per four CM vendors and used profiles at 13 1.0 GHz passives

As the non-flat frequency response of the 1.0 GHz passives accumulated the severity of the roll-off worsened. As a result CM 1, CM 2 and CM 4 located at tap 32, after 20 1.0 GHz passives, were not able to use any of the configured profiles. See Figure 18. However CM 3 was able to receive data on profile 0, a major observation is that it appears that certain D3.1 CM manufacturers do not report RxMER values if the channel is in Partial Service/Channel Mode. This can potentially be of concern for a PMA implementation since profile generation is based on CM RxMER reported data.

Figure 18. Reported RxMER per four CM vendors and used profile at 20 1.0 GHz passives

In summary, as shown in Figure 19, some CM manufacturers were able to achieve a maximum throughput of approximately 1.569 Gbps after up to 11 passives in cascade, while other CMs were able to achieve a maximum throughput of 1.343 Gbps at 11 passives. With optimized OFDM settings more CMs were able to operate with higher flat modulation profiles at the same tap location in the network compared to typical OFDM settings. At the cascade EOL, at 20 1.0 GHz passives in cascade only one CM was able to operate on profile 0 while the other CM were impaired on the OFDM channel.

Figure 19. Typical Throughput of OFDM at 1.0 GHz for Full Coverage of All Taps

5. PMA vs No-PMA

PMA alone does not allow operation in the roll-off region, particularly for CMs further away from the node that are severely affected by the cascading effect of the non-flat response of the 1.0 GHz passives. We must use a combination of optimized OFDM settings to get as many CMs online as possible before PMA is implemented.

CM performance testing has proven that CMs can operate modulation orders with MER thresholds below the specified D3.1 MER thresholds [MULPIv3.1]. Hence the thresholds used in the PMA engine to generate the variable modulation profiles were lowered and were less conservative compared to the MER thresholds used during the baseline testing described in section 3.2. As a result, more CMs were able to operate in higher order modulations at the selected tap locations. The lowered MER thresholds are listed in Table 4.

Table 4. PMA engine MER profile thresholds

MODULATION RATE (QAM)	PMA MER [dB] THRESHOLDS
64	19
128	22
256	25
512	28
1024	31
2048	34
4096	37

Figure 20 illustrates the four modulation profiles used during the Pre-PMA baseline testing performed in section 4.1. Profile 0 is deliberately non-flat because, as seen in Figure 9, the severity of the roll-off is such that 256-QAM can only be supported up to 1050 MHz. Since profile 0 must be usable by all CMs, zero-bit loading was configured for the rest of the subcarriers in the OFDM channel.

Figure 20. Pre-PMA Baseline 4 profiles

Figure 21 shows the four variable modulation profiles generated using the modified CableLabs PMA tool based on the reported RxMER data from 18 out of 20 CMs connected to the five tap locations mentioned previously in Figure 1. The MER thresholds used to generate the four variable modulation profiles in Figure 21 are listed in Table 4. These profiles were converted to CMTS commands and applied to the CMTS.

Figure 21. CableLabs PMA tool – Four variable modulation profiles

PMA allowed us to create custom-made profiles consisting of segments of different modulation orders based on plant conditions over the frequency range of the OFDM channel. In the case of impairments such as roll-off, the profiles are adjusted to follow the non-flat frequency response of the 1.0 GHz devices. As a result most CMs were able to bond to a 192 MHz OFDM channel.

Figure 22 contrasts the difference in overall throughput by applying four flat modulation profiles (Figure 20) vs. the four variable modulation profiles obtained from the PMA tool (Figure 21). By using the four variable modulation profiles generated by the modified CableLabs PMA engine, some CMs were able to operate at higher speeds across the network than when using flat profiles. For instance, as shown in Figure 22, at 11 passives there was a 4% increase in average throughput across four CMs. At 20 1.0 GHz passives, there was a 35% increase in average throughput.

Figure 22. Baseline vs PMA overall throughput

There is a close correlation between the mean RxMER reported by the five four-CM groups at five tap locations across the HFC network and the results previously presented in sections 3 and 4. As the cumulative effect of the non-flat frequency of the 1.0 GHz passives worsens, an increasing number of sub-carriers in the OFDM channel are affected and mean RxMER decreases creating five distinct clusters that correspond to the five selected tap locations in the HFC network as shown in Figure 23. The RxMER data reported by the four CMs located at tap 14 (three 1.0 GHz passives), circled in yellow, resembles the mean RxMER values of Figure 14. Similarly, the average RxMER values

circled in lilac, correspond to the average RxMER values reported by the four CMs located at tap 32 (20 1.0 GHz passives in cascade) and illustrated in Figure 18.

Figure 23. Median vs Standard Deviation for CM across the HFC plant

PMA is a valuable tool that generates customize profiles with different modulations (segments) based on impairments CMs experience across different HFC networks. PMA not only helps MSOs increase the reliability of their networks, but it can leverage the operation of an OFDM channel in HFC networks with severe roll-off. PMA implementation provides extra network capacity that can be used to alleviate traffic during peak hours. Further testing will be performed to continuously implement the benefits that PMA can provide.

6. Conclusions

- When operating in the roll-off region, there will be significant differences between the average reported RxMER values across the HFC network at different tap locations. As the number of 1.0 GHz passives increased, the severity of the roll-off increased, and usable modulation orders decrease due to the lower RxMER values. This was expected since the non-flat frequency response of the taps worsened as the number of passives in cascade increases.
- The amount of uncorrectable codeword errors on the OFDM channel operating in the roll-off region increased as the severity of the roll-off affected a higher number of sub-carriers across the network. As a result, CMs farther from the node started experiencing loss of lock to the OFDM channel. This was alleviated by changing OFDM configuration parameters such as NCP-profile and pilot-scale-factor, allowing more modems to be online at the EOL tap. It also helped some modems to use higher modulation profiles across the network. This also reinforces the need for optimization of OFDM parameters prior to PMA deployments.
- When using flat profiles, the non-flat frequency response of legacy 1.0 GHz passives in the 1.0 to 1.2 GHz range creates challenges as a result of profile flapping and partial service for D3.1 CM operating in the roll-off. Uncorrectable codeword errors were recorded for the OFDM channel as the severity of the roll-off increased across the network.
- The severity of the frequency response (peaks and dips) will vary by tap manufacturer, and will worsen as the number of passives in a cascade increases. As a result, successful reception of an OFDM channel will be limited to a maximum cascade depth depending on deployed passive

manufacturer. Since cascade depth varies from node to node, as does the number of passives and the nature of the induced roll-off, attempting to create custom OFDM modulation profiles manually can be time consuming and yield unpredictable results. A PMA approach will greatly simplify operation in the roll-off regions.

- PMA provides operators the ability to implement proactive and adaptive network operations in a network with inevitable impairments such as roll-off. The benefits include reduced trouble calls, a higher throughput, and the ability to scale and deploy incrementally. However, should an operator decide to operate OFDM in roll-off regions, the OFDM carrier should be configured/optimized first to ensure the highest possible performance prior to PMA implementation. Once optimal performance is achieved pre-PMA, higher and stable capacity gains can be obtained through the implementation of a fully automated PMA solution.
- When using PMA, CMs were ranked by RxMER quality, they naturally fell into clusters or groups that closely aligned with the tap locations selected and the severity of the experienced impairment, as shown in Figure 23. This natural clustering helps ensure that the set of profiles created by the PMA tool are optimized and targeted to the specific degree of impairment severity as seen by the CMs across the HFC network.
- Cable modems experienced the effect of the roll-off differently across the network. The impact of the roll-off region on cable modem operations was observed as a degradation of the RxMER values of the sub-carriers operating in the roll-off region. But by configuring the profiles generated by the PMA engine, the CMTS assigns customized profiles based on the type of collected RxMER per groups of cable modems, thus minimizing transmission errors on the network and maximizing the overall network capacity with up to a 35% gain at EOL tap compared to a non-PMA solution.
- The maximum throughput of approximately 1.569 Gbps over the OFDM and SC-QAM channel combination used for this testing was not achieved consistently, unless the CM is in close proximity to the node and within a limited number of passives in cascade (depends on the profile signature of the passive) and the CM manufacturer.
- Higher network capacity gains may be possible if the number of modulation profiles increases beyond four. Additional testing is planned to explore the overall network capacity gains in the near future with six and eight dynamic modulation profiles.

1. Introduction

Operators of Hybrid Fiber Coaxial (HFC) have a long history of delivering continuous advancements in speed, capacity and performance. With the rise of DOCSIS 4.0 and 10G, operators are poised to take the next huge leap in delivering faster speeds, greater capacity, advanced security, and improved reliability. Anytime we update the HFC plant, we must conduct a thorough analysis of the drafted plant to decide whether the existing maps are accurate and if so, where and how plant upgrades should be made. This document will refer to this analysis as “pre-vet.” While HFC plant maps are a reliable source for beginning a pre-vet, changes to the area (new streets, buildings, plant repair, etc.) may not always make it into the plant map in time for the analysis. Layering additional data onto the plant maps can further enrich the data and increase the level of accuracy for the designer to make an informed decision on where capacity upgrades and plant extensions should take place.

The pre-vet process begins by capturing the node boundary of the existing plant map that has been documented. **Figure 1** shows a very simplified example of an HFC plant map. Information such as street addresses, parcel size, and where the node and other HFC equipment is located is represented on the map. While this helps show where the equipment is and the type of equipment used, it does not address capacity concerns on its own.

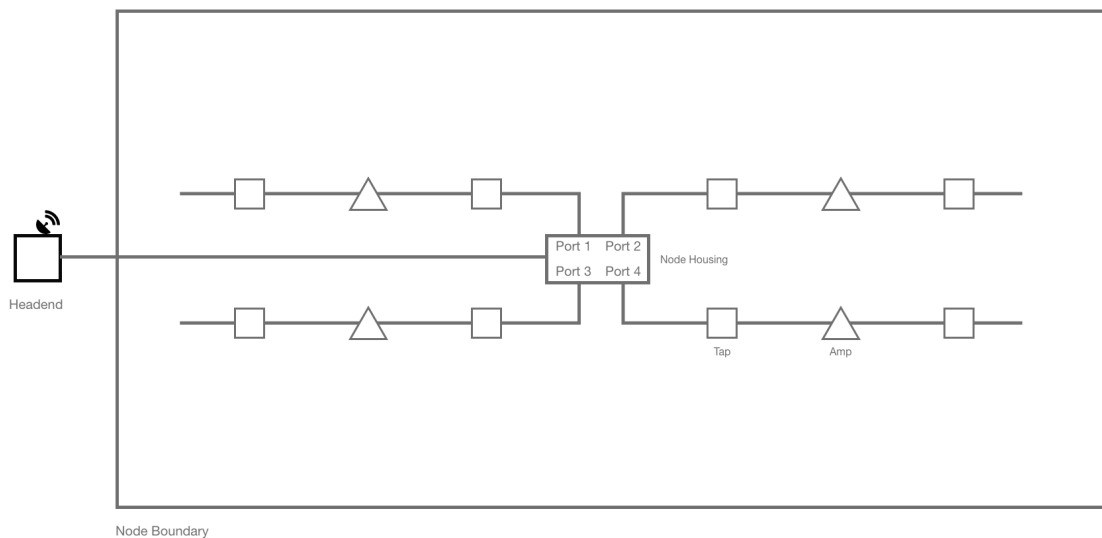

Figure 1 - Simplified Plant Map

Next, as shown in **Figure 2**, serviceable addresses and device counts connected to the CMTS are added to the plant map. The combination of the two data points indicates to the designer where the strain is on the network. By aggregating this information at the amplifier (amp) level, the designer can pinpoint where on the bus leg to place a new node to alleviate the strain on the old node. In addition, this level of data can identify gaps in the plant maps. For example, each leg should serve around 50-500 homes. If the aggregated data shows more than that it is a clear indication that either the plant map requires adjustment, or the serviceable addresses associated with the plant requires investigation regarding accuracy.

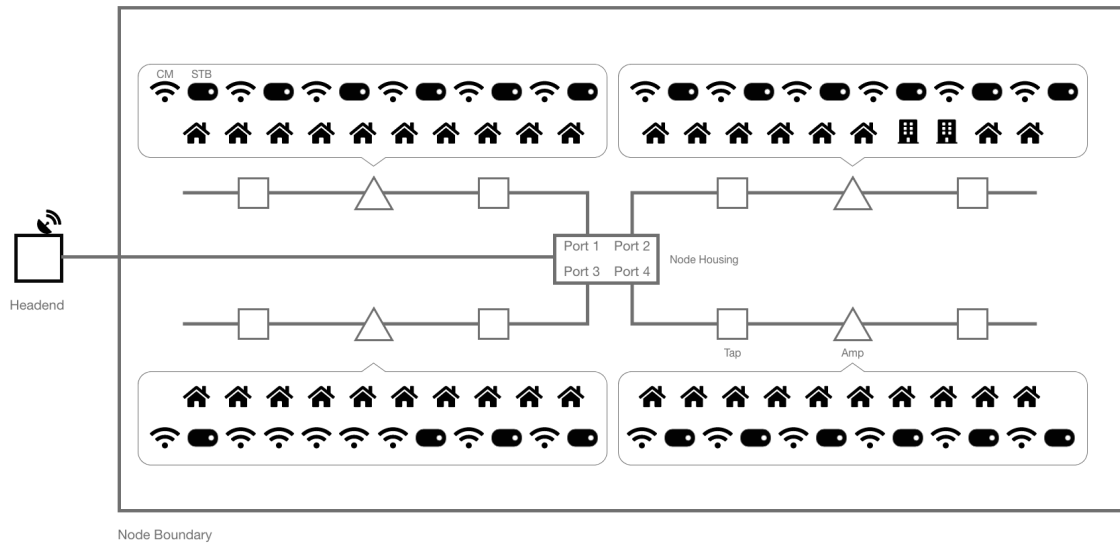

Figure 2 - Adding Serviceable Addresses and Device Counts

Historically, creating a pre-vet has been a manual, labor-intensive process, taking around 2-8 hours to create the package for a single node housing. As the need increases for upgrading the HFC plant, it will be pertinent to make this process more efficient by automating the aggregation of the serviceable addresses and device counts and visualizing the data on the plant map. This paper will discuss the data collection, analysis, and automation of creating a pre-vet package.

Note that the network maps and data shown in this paper do not include any names or personal data about subscribers.

2. Pre-Vet Data Collection and Analysis

2.0. System Overview

Subscriber service location (address) and device network communication location correlated against the drafted RF network map provides clues about the accuracy of the maps. Clusters of service locations that cannot be connected to the drafted network indicate opportunities for improving the drafted map. The example network shown below (which is NOT actual data) shows a cluster of service locations that cannot connect to the drafted network. An orange circle highlights these service locations. Notice that some service locations below the circled addresses reside outside the node boundary, but within acceptable distance to the drafted network.

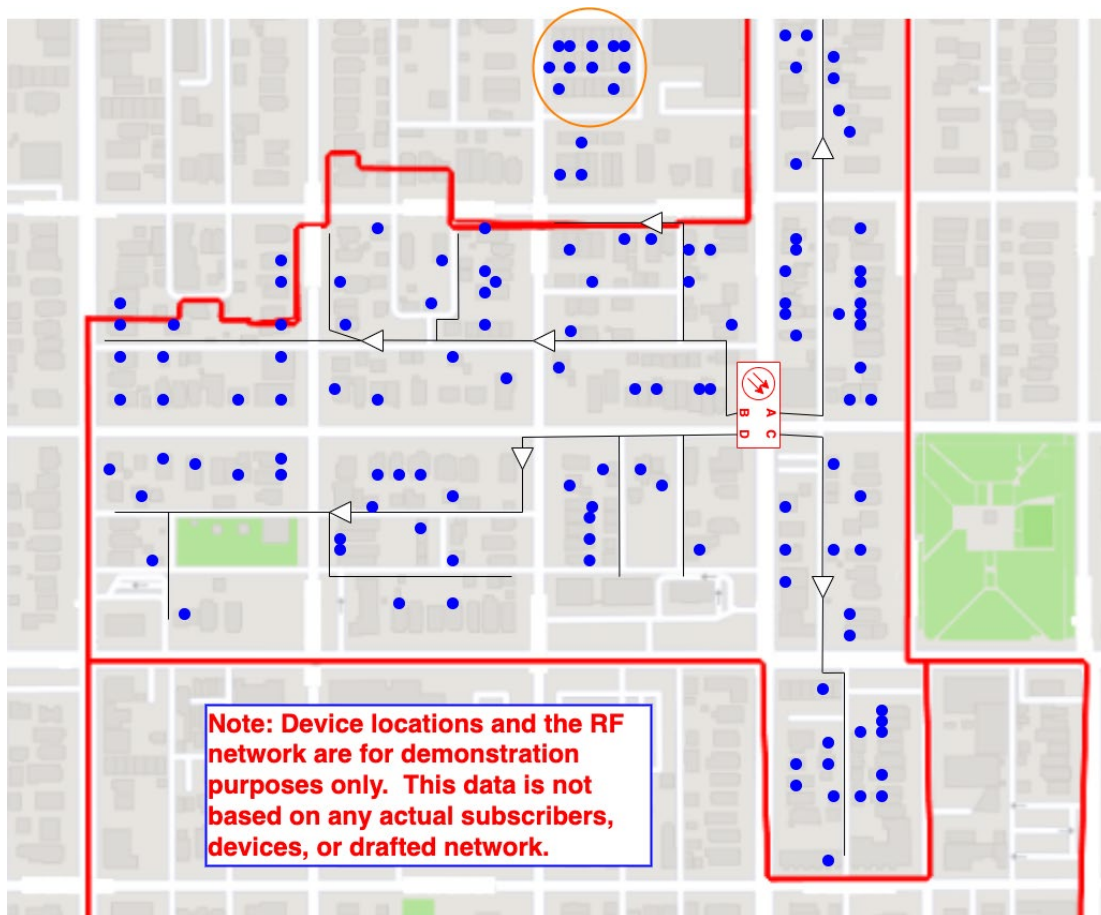

Figure 3 - Using Device Locations to Identify Map Improvement Opportunities

Once the drafted RF network map has been validated, the pre-vet process calculates homes passed and actual device counts at key locations throughout the RF network map to aid the designers in node segmentation or node split analysis.

To perform an automated pre-vet analysis of a node housing, data must be collected, correlated, and analyzed from several sources including:

- Design and drafting platform;
- USPS address database;
- Subscriber account database; and
- Device telemetry.

The figure below shows an example system for performing the pre-vet operation.

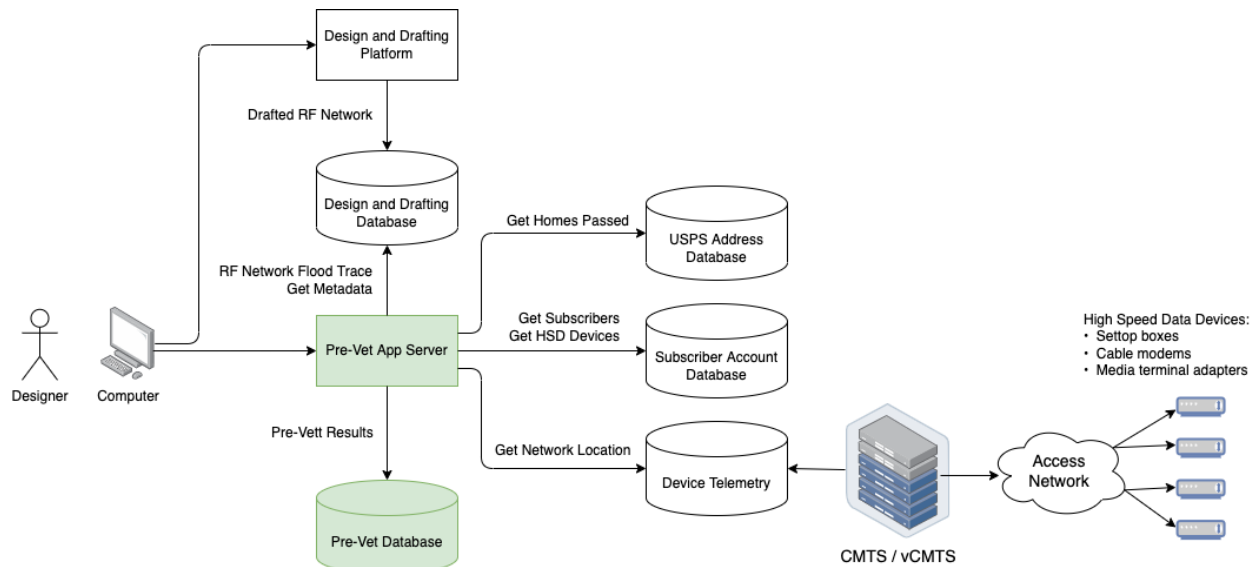

Figure 4 - Pre-Vet System Diagram

The design and drafting platform maintains the physical details of the support structure, cables, and equipment for the access network. This platform maintains connectivity information between elements, provides maps of the access network, and performs power and loss calculations. The drafted data may link the access network equipment to service address locations, but this linking is inconsistent and may be outdated.

The USPS address database contains the official USPS addresses and their geolocations (latitude and longitude). This database minimally must contain addresses for premises passed by the MSO access network.

The account database stores the subscriber account information, including service address and list of devices provisioned to the account. Each subscriber account links to a service address.

Device telemetry identifies the presence of communication with high-speed data (HSD) capable devices, such as cable modems (CM), set-top boxes (STB), and media terminal adapters (MTA). Telemetry data provides the set of ports on the cable modem termination system (CMTS) or remote PHY device (RPD) where messages from the HSD devices are received. The set of subscribers that communicate upstream to a specific CMTS or RPD port are described in this paper as a "node segment."

The steps to collect and correlate this data include:

- Build a graph representation of the RF network for a specific node housing.
- Retrieve the service location addresses based on the node boundary.
- Determine node segments if not already known.
- Retrieve service location addresses associated with node segments.
- Associate service locations to RF taps.
- Count homes passed and devices at amplifiers and splitters.
- Identify service address or network gaps.

Details for these steps appear in the following sections.

2.1. RF Network Graph

To analyze the RF network for a given node housing, one needs to understand the relationship between the equipment and cables downstream of the node housing. The RF network shall be represented as a graph data structure, which is a series of vertices and edges. A graph provides efficient mechanisms for determining connectivity between elements and also provides searching capabilities. Some example uses for the RF network graph include counting devices serviced by each amplifier and determining max amplifier cascade by bus leg.

Vertices in the graph represent the cables and equipment (node housing, RF cables, taps, amplifiers, splitters, etc.) while edges represent connectivity between the vertices. Notice that the edges do NOT represent cables. Edges are connectivity. A vertex associated with an RF cable will have two edges, representing other RF equipment or cables connected at each end of the cable in question. The vertex for a node housing will contain 4 edges, one per bus leg (RF output port). For the RF network analysis, the fiber network connecting to the node housing does not need to be represented in the graph. The RF network graph will have a root node that is the node housing.

Building the RF network graph is dependent on the design and drafting platform used by the MSO. In general terms, performing an RF flood trace on each bus leg of a node housing will specify a list of elements and connected ports. An example of port connectivity is shown below.

Table 1 - Example Port to Port Connectivity from RF Flood Trace

Source			Destination		
Type	ID	Port	Type	ID	Port
CoaxCable	DMTARCMC1853065972850	N/A	Splitter	DMTARPMC18536598	Input
Splitter	DMTARPMC18536598	Output-1	CoaxCable	DMTARCMC1853065991823	N/A
Splitter	DMTARPMC18536598	Output-2	CoaxCable	DMTARCMC1853065964851	N/A
CoaxCable	DMTARCMC1853065991823	N/A	Tap	DMTARTMC18536621	Input

Notice that port level connectivity means that most RF equipment or cables will have multiple entries in the RF flood trace details – one for each input and output port. The method to build the graph must account for this duplication so that only a single vertex is created for each RF element. Ports identified in the RF flood trace shall be annotated in the edges of the graph.

The graph building algorithm will also create a hash map that maintains the equipment ID to vertex relationship. This will be called the equipment map. The equipment map provides a method to quickly find the vertex of any RF element without requiring a graph search.

The algorithm to create the RF network graph and equipment map is specified below:

- Create vertex for the node housing and add the vertex as the root of the graph.
- Load the node housing metadata from the design and drafting system.
- Add node housing metadata to vertex.
- Add the ID and vertex of the node housing to the equipment map.
- For each RF output port on node housing:
 - Perform RF flood trace on RF output port; and
 - For each connection pair in RF flood trace:
 - Search equipment map using the equipment source ID and destination ID from the connection pair to find the equipment vertices.

- For each vertex not found:
 - Create vertex for the equipment and add to graph;
 - Load equipment metadata from the design and drafting system;
 - Add equipment metadata to vertex; and
 - Add the equipment ID and vertex to the equipment map.
- Create an edge between equipment vertices.
- Add the port IDs and port types of the equipment to the edge.

Port types can include coax ports, power ports, and drops. Tracking the port type is important since the pre-vet analysis will not analyze power and thus power ports can be ignored. Although shown in the figure below, the power port edges can be pruned from the graph.

An example RF network graph is shown below for node housing “NJHB00750”. Each of the four bus legs can be seen connected to the root node of the graph, which is the node housing.

Figure 5 - Example RF Network Graph

To better visualize the correlation of the RF network graph with the drafted plant data, the figure below focuses on bus leg A from the figure above. The below figure shows a side-by-side comparison of the RF network graph and the drafted network. Each RF cable or RF equipment element is represented by a

vertex in the graph. Notice that the power supply is missing from the graph. This may be a drafting issue indicating that the power cable running to the power supply is not actually connected.

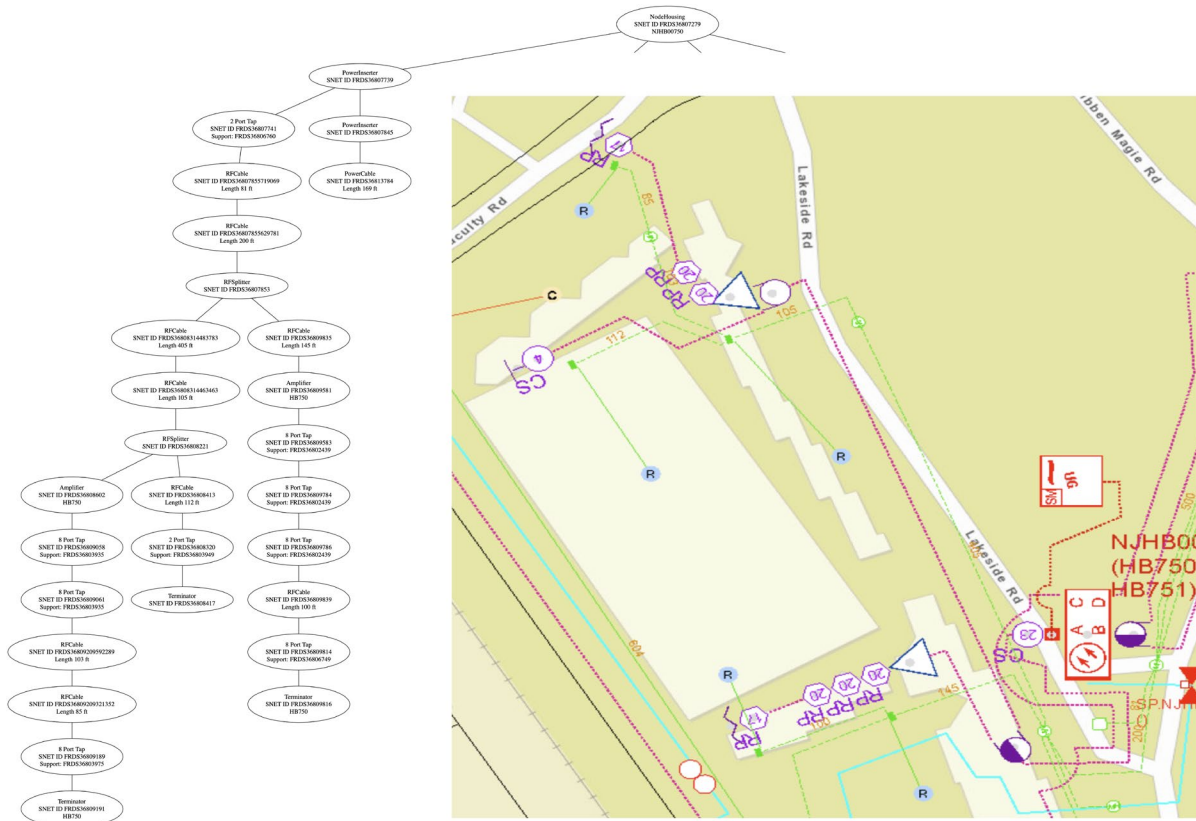

Figure 6 - Correlating RF Network Graph with Drafted Network

2.2. Linking Addresses to the Graph

An important method to evaluate the accuracy of the drafted RF network is to examine the subscriber locations and the high-speed data (HSD) capable devices on the network. HSD devices communicate with the cable modem termination system (CMTS). The upstream communication for a set of subscribers – the “node segment” – is typically on a specific CMTS port for a physical CMTS or remote PHY device (RPD) port in the case of a virtual CMTS (vCMTS). A node segment may be comprised of one or more bus legs from the node housing. The figure below shows an analog 2x2 node housing, with two upstream node segments.

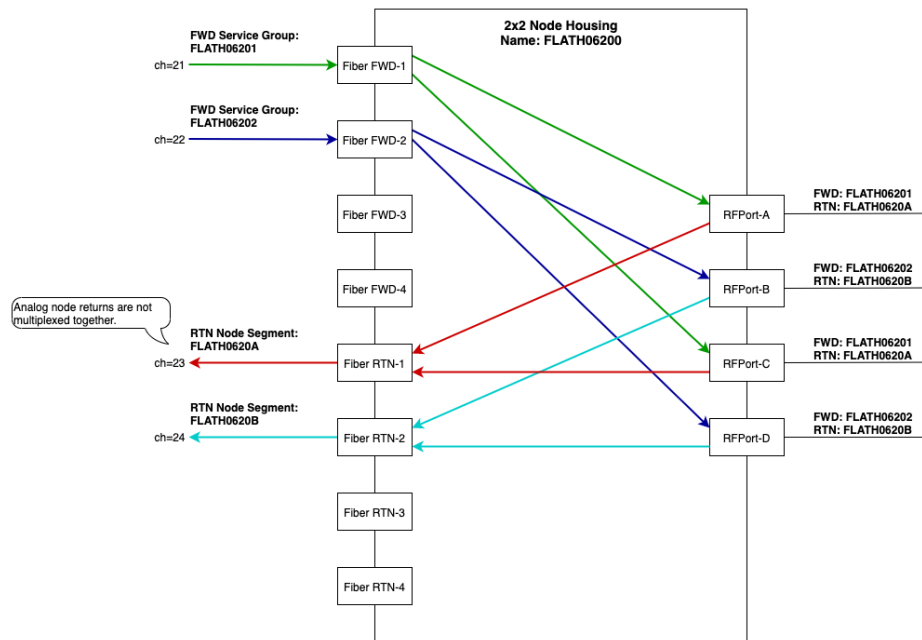

Figure 7 - Node Segments to Bus Leg Association

The node segment for an HSD device can be determined when the device communicates with the CMTS or RPD. Through the provisioning process, HSD devices are linked to subscriber accounts. These accounts have service address locations. Under ideal conditions, the drafted network includes drops that link the RF taps to drafted address locations. These drafted address locations exactly match the service locations assigned to subscribers and their associated provisioned devices. Thus, a direct link can be made from the drafted RF tap to the subscriber HSD devices and the associated node segments. Unfortunately, there are several factors that could prevent that direct association:

- Constructed network has changed since the design was drafted (e.g. plant extension or capacity upgrade).
- No drop was drafted to link the RF tap to the address location.
- Address has changed since the network was originally drafted (e.g. street renamed).
- Originally drafted address was not the official USPS address, but a place holder for new construction (e.g. drafted network has lot numbers instead of USPS addresses).

The pre-vet analysis will perform several steps to overcome these conditions. These steps include querying address locations based on the node boundary, querying addresses associated with node segments of devices, and linking address locations to RF taps by proximity.

2.2.1. Addresses Inside Node Boundary

Designers draft boundaries to indicate the coverage area for each node housing. Most address locations serviced by the RF network of a node housing reside within the drafted boundary. Therefore, querying the drafted boundary provides most of the service addresses needed for the network analysis. Note that depending on the address database that the MSO queries, the address locations may be homes passed (e.g.

USPS address database) by the RF network or subscribers' service addresses (e.g. subscriber account database).

Designers may draft distinct types of node boundaries including node housing, node segment, and bus leg boundaries. One or more bus leg boundaries should comprise the node segment boundary. Node segment boundaries comprise the node housing boundary. Only one type of node boundary needs to be queried to retrieve the service addresses associated with the node housing. Querying the service address locations within the node's drafted boundaries and associating those addresses with active devices will allow discovery of the node segments associated with the node housing. The figure below shows address locations of homes passed (not subscribers) for a set of node housing boundaries.

Figure 8 - Address Locations within Node Boundaries

An example Oracle query to retrieve the service address locations of homes passed within a node boundary is shown below:

```
SELECT A.ID, A.STREET_NUM, A.STREETNAME, A.UNIT_TYPE, A.UNIT_VALUE, A.CITY,
       A.STATE, A.POSTALCODE, A.LATITUDE, A.LONGITUDE
FROM ADDRESSES A
WHERE
SDO_RELATE (
  A.LOCATION,
  SDO_GEOMETRY(
    2003,
    4326, -- WGS84 coordinate system
    NULL,

```

where <LIST OF COORDINATES> are the node boundary polygon coordinates. Coordinates are specified as longitude and latitude pairs.

Example:

```
SDO_ORDINATE_ARRAY(
  -87.28482973277373, 37.25299509730186,
  -87.27747974176278, 37.25299509730186,
  -87.27747974176278, 37.24625992935859,
  -87.28482973277373, 37.24625992935859,
  -87.28482973277373, 37.25299509730186 )
```

Note that some addresses in this query may not actually be serviced by the node housing in question. Drafted node boundaries are not precise and RF networks from different node housings may overlap such that it is extremely difficult to draft boundaries that are completely distinct. Additional processing of the data, discussed below, will isolate and remove address locations associated with other node housings.

Fields returned in the query include a unique ID assigned to the address, street number, street name, unit type and value (for multi dwelling units), city, state, postal code, latitude, and longitude. The latitude and longitude are based on the geocoder for the address database, not the drafted location.

Table 2 - Example Service Address Information¹

ID	Number	Street	Unit Type	Unit Value	City	State	Zip	Latitude	Longitude
2198101	101	Main St.	Apt.	A	Philadelphia	PA	19103	39.9547	75.1685
36198354	222	First Ave.			Philadelphia	PA	19103	39.9621	75.0981

2.2.2. Addresses for RF Taps Outside Node Boundary

The design and drafting platform will have the latitude and longitude of the RF taps (and the location of the support structure where the RF tap connects). Query all RF taps within the node boundary used to query the service addresses. In an ideal case, all RF taps from the RF network graph are in the query results. However, it is possible that some RF taps in the graph are outside the drafted node boundary. It is also possible that some RF taps from the RF network of other node housings are in the query results. Save these “extra” RF taps for use in the proximity-based address to RF tap correlation step below.

On the graph, RF taps that are significantly outside the node boundary will require an additional address query to capture the associated service addresses. Drops that connect the RF tap to an address location are typically limited to about 300 feet. To account for white space in the drafting process, if the location of the support structure where the RF taps are attached is more than 500 feet outside the drafted node boundary, then an additional address query needs to be executed to capture the locations.

For each RF tap outside the node boundary, query all addresses within a 500-foot circle of the support structure on which the RF tap is connected. Add these addresses to the addresses from the node boundary query.

2.2.3. Addresses Associated with Node Segments

To identify missing plant extensions from the drafted map, it is not sufficient only to examine the addresses in the drafted node boundary or addresses associated with drafted RF taps since the data

¹We collect, store, and use all data in accordance with our privacy disclosures to users and applicable laws.

returned can only be associated with the drafted access network. The address search needs to expand to include any address that has devices in the node segments associated with this node housing.

Using the assumption that the drafted network is at least partially accurate, one can use the service addresses queried from the map to obtain the set of node segments associated with the node housing. Some of the queried addresses passed by the drafted network will be actual subscribers. These subscriber accounts link to provisioned devices, whose telemetry includes the node segment on which the device reports.

Join the addresses retrieved above with the subscriber account database to identify subscriber accounts among these addresses. Find the device IDs of the provisioned HSD devices for the accounts and use that to retrieve the node segment from telemetry data. These queries are MSO specific. Below is an example table with the joined account to device to node segment data. Note that the data below is not actual customer data and was created only for demonstration purposes.

Table 3 - Example Node Segments for HSD Devices²

Account ID	Device ID	Device Type	Node Segment
335056384	A3:98:31:C9:ED:71	CM	FLD0010A
242012225	22:3E:C1:B5:CC:8E	CM	FLD0010C
263370322	B7:C0:39:D2:AC:4F	STB	FLD0010D
619042765	FA:45:22:13:D2:1C	CM	FLD0010A
390653365	6F:4A:70:D6:E8:44	MTA	FLD0010B
133703447	E5:7B:B2:84:0A:FC	CM	FLD0009D
423544086	9A:16:8C:CB:0E:B5	STB	FLD0010C
195661518	37:7E:08:47:DC:F4	STB	FLD0010B
444325235	0E:03:81:4C:60:D5	CM	FLD0010B
386919575	AA:6C:D7:AE:61:FA	MTA	FLD0010D
339519483	FD:00:9A:C0:04:9E	CM	FLD0010A
110301259	9F:F7:FD:E6:0B:5C	STB	FLD0010A

In an ideal case, the result should be between 1 and 4 node segments. There cannot be more than 4 node segments since the node housing has a maximum of 4 bus legs. Note that some of the address locations may be associated with other node segments and may have been retrieved since node boundaries of other node housings are adjacent or overlap. If more than 4 node segments are found, use the 4 instances that occur most frequently. In the example table above, the node segments FLD0010A, FLD0010B, FLD0010C, and FLD0010D appear most frequently.

It is still possible to identify more node segments than are associated to the node housing. For example, the node housing may actually contain only 2 node segments, but 4 node segments were identified due to node boundary overlap with adjacent nodes. These extra node segments will be removed when individual bus leg to node segment association is calculated below.

²We collect, store, and use all data in accordance with our privacy disclosures to users and applicable laws.

Given the set of node segments, query the device telemetry data for the full set of HSD devices that communicate on these node segments. Then use the device provisioning data to determine the service addresses for these accounts.

Add these addresses to the previously collected addresses.

2.2.4. Linking Addresses to RF Network

Addresses must be associated to RF Taps in the Graph to find map inconsistencies, calculate homes passed and device counts, and find the node segment per bus leg. In an ideal case, the service addresses from the USPS database or subscriber account database can be connected to the addresses specified in the design and drafting platform, which are then linked to the RF taps by drops on the drafted RF network. However, in many cases, drop details are missing or the address specified in the drafted network does not match USPS addresses or subscriber account addresses. Another method must be used to link addresses to the RF taps in the RF network.

The algorithm outlined below uses proximity of the address geolocation to the support structure on which the RF tap is attached. Support structure locations are typically more accurate than the RF equipment locations, which may be offset for white space management purposes. The figure below shows a drafted set of support structures and RF equipment relative to the parcels of service addresses.

Figure 9 - Drafted Supports and RF Taps Relative to Service Addresses

Each address location shall be linked to the closest support structure location that has capacity for the address if the distance does not exceed 500 feet. Note that long drop lengths are typically limited to 300 feet. However, allowances must be made for the geocoder assigned location of the address not matching the actual drop location of the building or the drafted position of support structures not being exact.

The figure below shows proximity-based assignment of addresses to support structures associated with RF taps. Each parcel contains a cross with an “R,” which is the geocoder assigned location of the address. For comparison, the estimated drop location of the building is the plain cross. The pink circle, square, and hexagon connected by a pink dashed line are RF Taps, representing taps with 2, 4, and 8 ports, respectively. The small red circles with “X” connected by solid red lines are support structures (poles and strand).

The RF taps are physically located on the adjacent support structure. Notice that the two-port tap in the center of the image has two connections. There is an address below it which should connect to the two-

port tap based solely on shortest distance. However, since the RF Tap already has both ports occupied, the address must connect to the more distant RF tap to its "northeast."

Figure 10 - Address to Support/Tap Assignment by Proximity and House Count

The proximity algorithm requires a sorted list of distances for each combination of address and support structure with an RF tap. The algorithm uses this list to assign the next address based on shortest distance. The pseudo-code to track distances is shown below:

- Create an empty distance list that will store objects with the triplet of distance, address ID, and support ID.
- For each combination of address and support:
 - Calculate the distance from the address lat/lon to the support lat/lon; and
 - If the distance is less than max drop distance (e.g. 500'), add the triplet of distance, address ID, and support ID to the distance list.
- Sort the distance list by distance value in ascending order.

Support structures may contain multiple RF taps. It does not matter how the addresses are distributed across these RF taps if the RF taps are on the same bus leg. This is because the goals are determining address assignment per bus leg and determining the device and homes passed counts aggregated at amplifiers and splitters.

Each support will have a maximum number of addresses that can be connected. This will be the smaller of the total output ports of the RF taps on the support and the house count associated with the support. For example, a support may have 2 RF taps - one with 2 ports and one with 4 ports. The support may also have a house count of 5. The maximum number of addresses that can be connected is 5, since the total RF tap port count is 6, but the house count is 5. The converse may also occur. If the house count was 7, then the maximum number of addresses would be 6 since there are only 6 ports available between the 2 RF taps on that support.

The algorithm to assign addresses to supports by proximity will iterate over the sorted list of distance calculations. If the address has not yet been assigned to a support, and the referenced support has space for another address, the address shall be assigned to the support. The available capacity for the support is decreased by one.

There is no actual pruning of addresses from the distance list when assigning the address to an RF Tap. Each address appears multiple times in the list. Removing each address would require sequential traversal of the list to find all address instances. It is more efficient to traverse the distance list once and keep track of assigned addresses in the hash map of assigned IDs.

The following pseudo-code assigns addresses to RF taps based on support distance and capacity:

- Create an assigned hash map to store the list of assigned addresses. It is simply a lookup table whose key is the address ID but contains no data.
- For each element in the distance list (distance-address-support triplet) traversed in order of ascending distance:
 - Search assigned hash map. If a match is found, go to the next element in the distance list.
 - If support does not have capacity (assigned address count \geq max address count), go to next element in the distance list.
 - Find an RF tap for this support with available ports (connected address count less than port count):
 - Assign the address ID to this RF tap;
 - Decrease the support's available capacity by one; and
 - Add the address ID to the assigned hash map.

It is possible that some addresses cannot be assigned when there is insufficient RF tap port or house count capacity. It is equally possible that some RF tap ports do not have assigned addresses.

Below is an example of the data model used by the algorithm:

- **Distance List** - List of distances between an address and a support. List is sorted by distance in ascending order. Every combination of address and support distance is included in this list if the distance is less than the maximum drop distance.
- **Address Hash Map** – Stores the service addresses retrieved in the boundary and node segment queries above. The hash map uses the Address ID as a key. It contains the geolocation of each service address and may also store the node segment (if determined by device association).
- **Support Hash Map** – Stores the support structures on which the RF taps reside. The hash map uses the support ID as a key. Each support structure entry contains the list of RF taps on this support, maximum address count, and assigned address count.
- **RF Tap Hash Map** - RF tap lookup table using RF tap ID as a key. Contains all RF taps downstream of a node housing. Each RF tap entry stores the port count and the addresses associated with its support based on distance. The assigned address count must not exceed the port count.

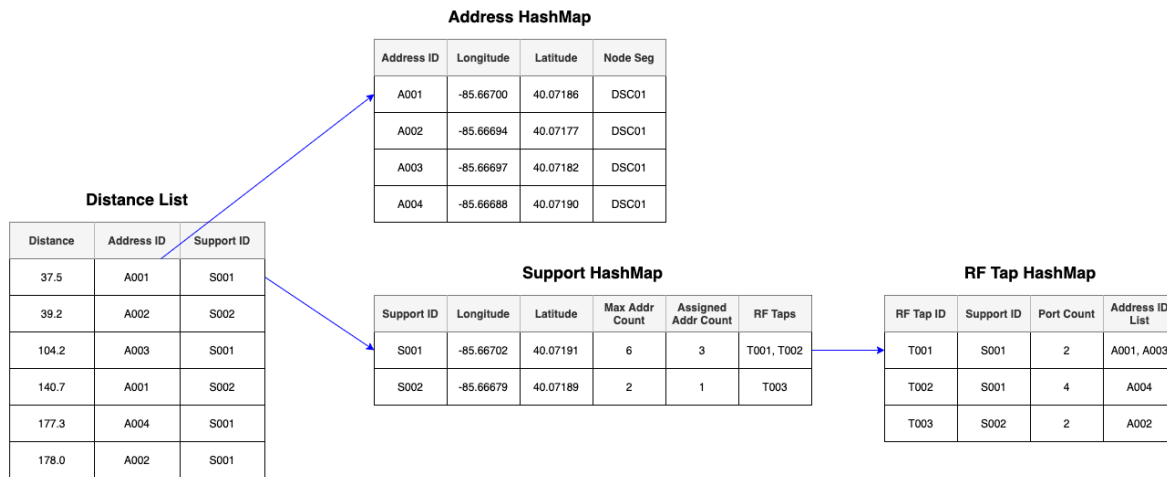

Figure 11 - Example Data Model to Associate Addresses to Supports/Taps

Use the results in the RF tap hash map to update the RF network graph with the RF tap to service Address association. Create a new vertex for each assigned address and create an edge between the address Vertex and the RF tap vertex.

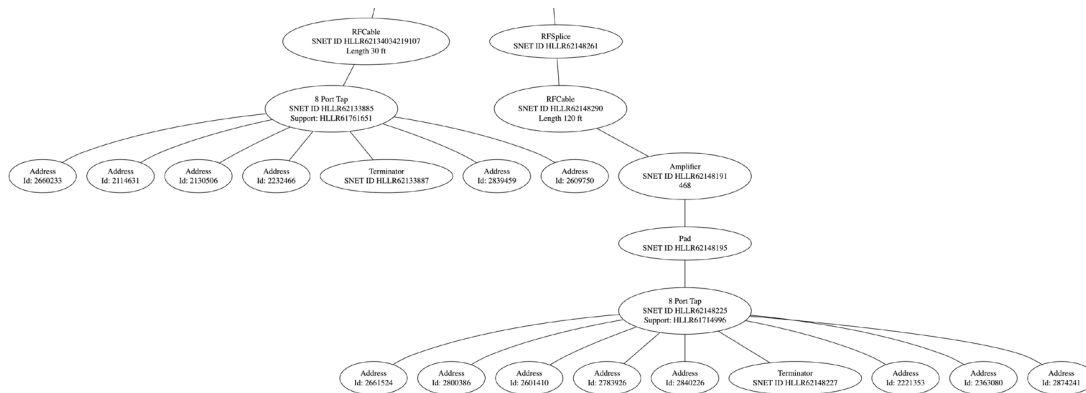

Figure 12 - Address Locations in RF Network Graph

2.3. Linking Devices to RF Network Graph

With the service address locations linked to the appropriate RF taps in the RF network graph, it should be possible to link the service locations to subscriber accounts and obtain the provisioned HSD devices for those accounts. A similar operation occurred above when identifying the possible node segments for the node housing. Remember that not all homes passed are subscribers and therefore only a subset of the service locations will have associated HSD devices.

The provisioned HSD devices may be added to the RF network graph as vertices connected to the address vertices. However, for the Comcast implementation, the devices were simply added to the address vertex itself as additional data.

Note that the graph contents are never provided to the designer since it identifies individual subscriber service locations. The device count data will be aggregated and anonymized before being presented to the user.

2.4. Data Aggregation

HSD device counts and homes passed counts are aggregated at each of the node housing RF ports as well as output RF ports for amplifiers and splitters. The equipment where the data is aggregated shall be referred to as “aggregators” in this document. The device and homes passed counts provide the designer a view into the distribution of devices and service locations across the network, which will assist in the node segmentation or node split operation. Each of these elements will track both “local” counts and the “cumulative” counts. The local counts are the device and homes passed count from the specified aggregator to the next downstream aggregator for each of the output ports. The cumulative counts are the device and homes passed count from the specified aggregator to all downstream components and branches.

The figure below shows the port level data aggregation. Focusing on amplifier A1, there are two output ports: port-1 and port-2. The local counts are based on the device and homes passed counts on all RF taps from output port to the next aggregator (amplifier A2 and Splitter S1 for A1 port-1 and A1 port-2, respectively). The cumulative counts for a given output port is the summation of device and homes passed counts of all RF taps downstream of the port.

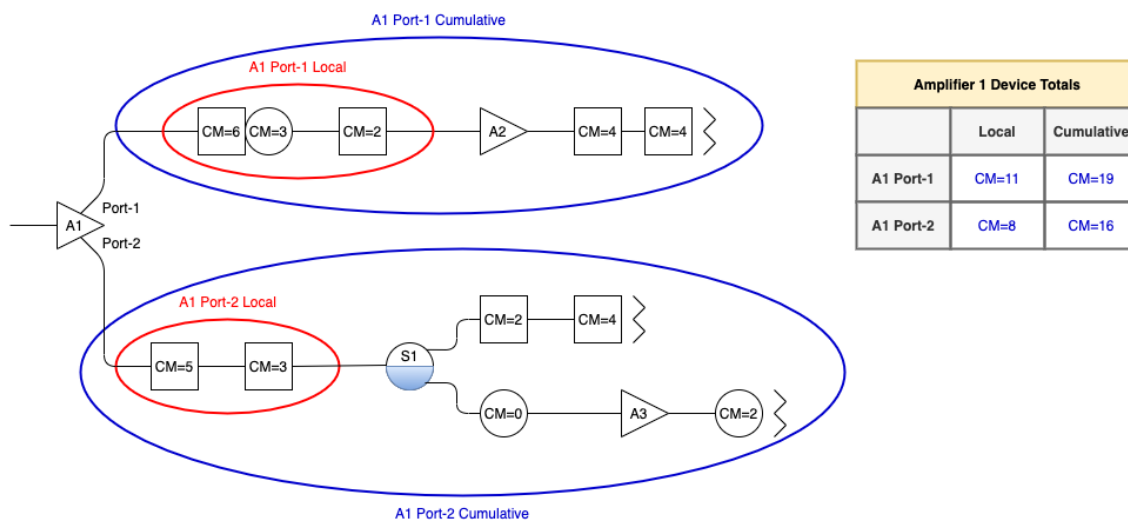

Figure 13 - Aggregating Device Counts at the RF Output Port of Amps and Splitters

MSOs can divide HSD device counts into multiple categories. Comcast uses 3 categories for device counts: cable modem (CM), set-top box (STB), and media terminal adapter (MTA). Homes passed can also be categorized as well, such as residential or commercial properties.

The algorithm to calculate the device and homes passed counts of each aggregator in the RF network uses a depth first search (DFS) to visit each of the vertices of the graph. A stack data structure keeps track of

the visited aggregators during the search. The last aggregator placed on the stack will be used for updating local counts. All aggregators on the stack will be used for calculating cumulative counts.

The DFS executes for each bus leg on the node housing. It visits each vertex in the graph, traversing as deeply as possible along one path before backtracking to visit alternate branches in the graph. When a DFS passes in the downstream direction through the RF output port of an aggregator, the RF output port of that aggregator gets pushed onto the stack. Conversely, when the DFS passes in the upstream direction through an RF output port on an aggregator, that RF output port pops off the stack.

When the DFS reaches an RF tap, it will traverse into the connected addresses. Each address contributes to the aggregated homes passed. If the address has associated provisioned HSD devices, these devices contribute to the aggregated device counts. The aggregator at the top of the stack will have its local counts updated. All aggregators in the stack will have the cumulative counts updated.

The figure below shows an example bus leg for a node housing. It includes a set of amplifiers, splitters, RF taps, and addresses. The RF equipment highlighted in red shows the elements traversed in a depth first search and the resulting stack at a point in the DFS when visiting vertex T11.

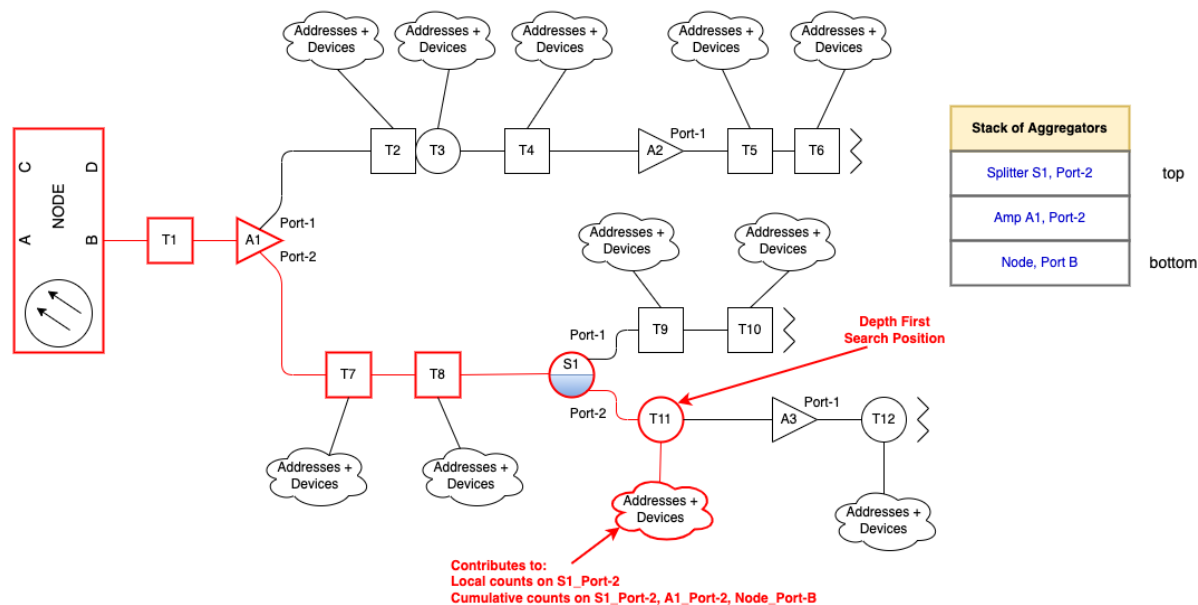

Figure 14 - Depth First Search to Calculate Device and Homes Passed Counts

The DFS began at Bus Leg B on the node housing. This RF output port is the first entry on the stack (bottom of the stack). The DFS proceeds to visit vertices T1 and A1, following the edge connected to Amp A1 Port-2. Amp A1 Port-2 shall be added to the stack since amplifiers are aggregators. The DFS proceeded to vertices T7, T8, and through Splitter S1 Port-2. Splitter S1 Port-2 shall be added to the stack since splitters are aggregators.

When the DFS traverses the address vertices connected to T11, each address contributes to the local homes passed count of S1 Port-2. Each address contributes to the cumulative homes passed counts for all elements on the stack, which include S1 Port-2, A1 Port-2, and Node Port B. Any provisioned HSD devices associated with the addresses will contribute similarly to the elements on the stack.

The DFS can also be used to calculate total amplifier counts and maximum amplifier cascade per bus leg. Each time an amplifier is encountered in the DFS, the amplifier total for that bus leg is incremented and the number of amplifiers on the stack are counted to update the maximum cascade count.

The pseudo-code for the local and cumulative device and homes passed count calculations are shown below. There will be an initialization function to kick off the processing of each bus leg. Aggregation begins at the node housing's RF output ports, which define each bus leg.

- For each node housing RF output port (bus leg), perform the following steps:
 - Create a "visited" hash map that tracks each of the vertices that have been visited.
 - Add node housing vertex to the "visited" hash map.
 - Create a stack that tracks RF port of aggregators visited as part of the DFS.
 - Push the node housing's RF output port onto the stack.
 - Set max cascade to 0.
 - Set amplifier count to 0.
 - Call ProcessVertex function for the vertex connected to this RF output port of the node housing.
 - Save max cascade and amplifier count data for this bus leg

Depth first search is performed by a recursive function that (1) skips visited nodes, (2) aggregates data from addresses connected to RF taps, and (3) manages the stack contents based on RF ports of aggregators that are visited.

- ProcessVertex function (SourceVertex)
 - Add SourceVertex to "visited" hash map.
 - If SourceVertex is a power supply, return without processing its connections.
 - If SourceVertex is an address:
 - For tracking local counts, add device and homes passed count from this address to the top element on the stack; and
 - For tracking cumulative counts, add device and homes passed count from this address to all elements in the stack.
 - If SourceVertex is an amplifier:
 - Increment amplifier count.
 - For each vertex connected to the SourceVertex:
 - If connected vertex is in the "visited" hash map, go to next connected vertex.
 - If SourceVertex is an aggregator:
 - Get RF output port from edge between this vertex and SourceVertex;
 - Add RF output port to aggregator stack;
 - Count the number of amplifier RF output ports on the stack;
 - If amplifier count on stack > max cascade,
 - max cascade = amplifier count on stack.
 - Call ProcessVertex function for this vertex.
 - If SourceVertex is an aggregator,
 - Pop stack.

The “visited” hash map is required so that searches do not loop back on themselves. Although this should not happen, it is good to have logic to prevent that case.

After executing the algorithm, the bus legs of the node housing and the RF output ports of amplifiers and splitters will have local and cumulative counts of devices and homes passed. The maximum number of amplifiers and maximum amplifier cascade will be known by bus leg.

The table below shows example device and homes passed counts for the aggregators in on Bus Leg D of a node housing:

Table 4 – Example Device and Homes Passed Count by Aggregator³

Type	Device ID	Port	Local				Cumulative			
			Homes	CM	STB	MTA	Homes	CM	STB	MTA
Node	UTAARMC18121634	D	0	0	0	0	96	39	43	69
Amp	UTAARAMC18121825	1	4	2	1	3	55	23	21	39
Amp	UTAARAMC18121825	2	3	1	2	2	41	16	22	30
Split	UTAARPMC18121923	1	2	1	1	1	21	8	8	17
Split	UTAARPMC18121923	2	0	0	0	0	30	11	12	19

Local device counts and homes passed counts may be zero if there are no RF taps between aggregators.

2.5. Bus Leg to Node Segment Identification

The set of node segments for the node housing has been discovered based on the service address locations linked to the RF network graph and the association of provisioned devices to accounts. The next step is to determine the actual node segment assignment by bus leg. All devices on the same bus leg must communicate with the same CMTS or RPD port. Therefore, they will share the same node segment.

Proximity based assignment of address locations to RF Taps is not deterministic, providing the chance for errors. Therefore, the node segment assignment to each bus leg shall be determined based on the most common node segment of the devices on the bus leg. This can be accomplished using a depth first search of each bus leg, counting each occurrence of a node segment for the devices associated with accounts on that bus leg. Details of the depth first search algorithm are provided above. In fact, this calculation can occur at the same time as the device aggregation.

Device telemetry indicates the node segment on which each device communicates. With devices associated with accounts, and the service address of the accounts linked to the RF taps in the RF network graph, one can calculate the node segment for the bus leg.

The pseudo-code to calculate the node segment assigned to a bus leg is shown below. Perform these steps for each bus leg of the node housing:

- Create hash map for node segments; key is the node segment, value is the count.
- Perform a depth first search on the RF output port of the node housing:
 - If vertex is an address, then for each device:
 - Use the node segment of the device to search the hash map;
 - If a match is found, increment the count for that node segment;
 - Else (no match found) add the node segment to the hash map with a count of 1.

³We collect, store, and use all data in accordance with our privacy disclosures to users and applicable laws.

- Set the node segment of the bus leg to the node segment with the highest count in the hash map

The node segment assignment to the bus leg shall be used to identify areas of inconsistencies on the map.

2.6. Opportunities for Map Improvement

After assigning node segments to each bus leg and linking homes passed or service addresses to the RF taps in the access network, one can examine each of the addresses to determine whether there is any mismatched data. Common exception conditions are outlined below.

It is possible that multiple exception conditions may occur per service address location. All exceptions that occur for each service address shall be recorded for display purposes to allow the designer to interpret the quality and accuracy of the map.

2.6.1. Unconnected Subscriber

The address location is associated with a subscriber account and/or active device. However, there is no RF tap with which the address location is associated. This condition may be caused by a missed plant extension.

2.6.2. Address Not Serviceable

The address location is not connected to an RF tap. Additionally, the address location is not associated with an active account and does not have a provisioned device. This may not be an error, since sometimes homes passed by the RF network are simply too far to connect. However, large numbers of non-serviceable addresses may indicate a map deficiency.

2.6.3. Unconnected RF Tap

An address location connects to an RF tap that does not connect to the RF network of any node housing. The RF tap does exist and can be plotted on the map. However, tracing the RF cable that connected to its import port does not lead back to a node housing. This typically represents a drafting error where the RF tap input port was not connected to an RF cable.

2.6.4. Incorrect Node Segment

The address location contains one or more provisioned devices whose node segment as reported by the telemetry data indicate it is on a different node segment than any of the node segments assigned to this node housing. If there are other RF taps from adjacent node housings within a typical drop distance, then the issue is either a drafting error or the proximity assignment algorithm.

2.6.5. Node Segment to Bus Leg Mismatch

The address location contains one or more provisioned devices whose node segment as reported by the telemetry data indicate it is on a node segment for a different bus leg of the node housing. This may be a drafting error or error in the proximity-based address to tap assignment.

2.6.6. Outside Node Boundary

Address locations connected to RF taps in the graph reside outside the node boundary. This condition is minor and would just require an update to the drafted node boundary.

2.7. Pre-Vet Analysis Results

Pre-vet data collection, correlation, and analysis, generates a set of data for use by the designers to determine where drafted maps have opportunities for improvement and how to segment or split the RF network for a capacity upgrade.

- Graph representation of all elements in the RF network.
- Service locations of homes passed and the connection points into the RF network
- Local and cumulative homes passed counts and device counts for each bus leg, amplifier, and splitter.
- Number of amplifiers and max amplifier cascade per bus leg.
- Service location exceptions including incorrect node segment, no connection to the RF network, and address not serviceable.

This data will be overlaid on the drafted maps to visualize the analysis results and any inconsistencies that have been found.

3. Maps and Data Output

Visualization of the pre-vet analysis results is overlaid onto the drafted access network map. The pre-vet analysis shall be presented to the designer using multiple layers that can be individually toggled on and off. This capability permits the designer to view the overall set of results or focus on a specific aspect of the analysis.

In Figure 15, service addresses and address errors are color coded based on the associated bus leg. This helps designers identify which addresses are tied to which bus leg. It also provides a visual indication of how many addresses are on a single bus leg and identifies the opportunities for map improvements.

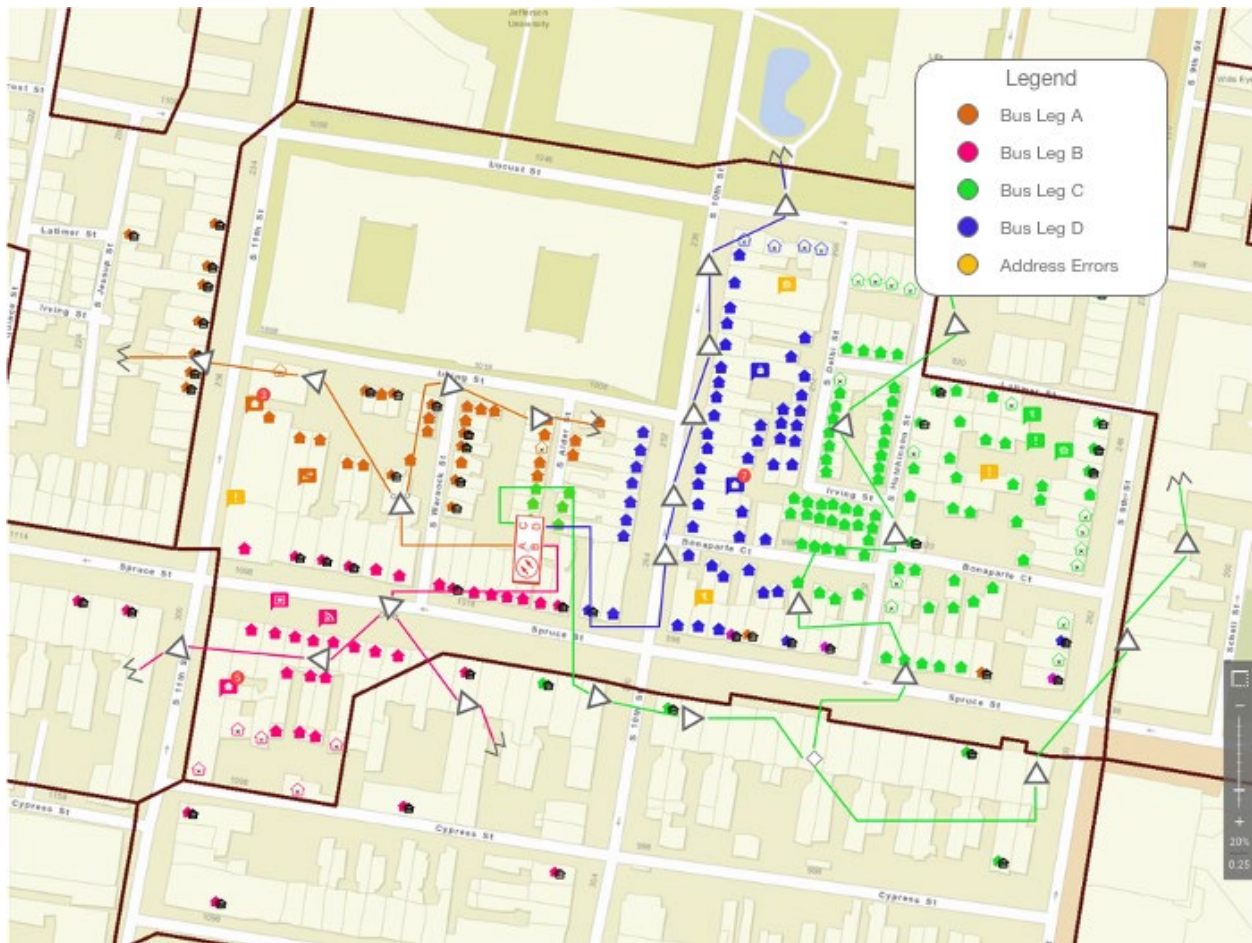

Figure 15 - Map of Plant with Bus Legs Highlighted and Address Errors

In the next two figures, users can see the device counts (aggregation of STB, CM, and MTAs) and homes passed at the amp level. The designer typically chooses an amp location to create a node split; Figure 16 shows how this view helps the user identify where there is pressure on the HFC plant.

Figure 16 – Device and Homes Passed Counts at Amp in Node Boundary View⁴

Figure 17 is a focused version of the previous figure. The image is centered on the end of a bus leg to view the cumulative and local homes passed and device counts at the amp level. Starting at the RF terminator, the cumulative counts add up the devices towards the node housing. The total number of devices and homes passed on a bus leg is shown at the node housing.

⁴ We collect, store, and use all data in accordance with our privacy disclosures to users and applicable laws.

Figure 17 – Device and Homes Passed Count at Amp (Focused View)

In addition to the map view, the user interface provides a summary table of the bus leg. Figure 18 does not reflect real data, but a representation of how the data is displayed for users to easily digest.

Bus Leg Info				
Legs	 A	 B	 C	 D
# of Amps	12	0	18	0
Max Cascade	5	0	5	0
Serviceable Passings	78	1	103	3
Not Serviceable Passings	7	1	8	0
Device Count	66	0	110	2
Active Subscribers	46	0	72	1

Figure 18 - Bus leg table

The simplification and visualization of the data helps users understand the current state of the HFC plant in an efficient manner.

4. Conclusion

The pre-vet process aggregates and correlates data from multiple sources; the results are used to analyze the drafted RF network and determine the quality and accuracy of drafted maps. If these maps are deemed accurate, the pre-vet process provides information to the designer regarding where and how capacity upgrades should be applied to the RF network.

The process to automate these steps involves building a graph model of the RF network for a given node housing based on data in the design and drafting platform. The set of homes passed by the network are determined using both USPS addresses in the node boundary of the drafted network and HSD device telemetry data. These service locations are correlated against the drafted network to identify deficiencies in the drafted map.

A depth first search algorithm is employed on the graph to aggregate homes passed and device counts at the bus legs, amplifiers, and splitters. A view of the distribution of homes passed and devices across the network aids the designer when performing the capacity upgrade design. Additional data such as amplifier count and maximum amplifier cascade is also collected. The automation system presents the results to the designer through both a map-based interface and as tabular data.

The manual pre-vet process requires 2-8 hours to complete for a single node housing. Automating many of the pre-vet steps significantly reduces the amount of time a designer dedicates to this process. Time savings of 50% or more are possible, freeing the designer to focus more on the data analysis and design, rather than data collection and correlation.

Looking to the future, additional opportunities exist to enhance the pre-vet process. One example would be to collect upstream and downstream historical utilization data by node segment; this could be presented to the designer to augment the existing pre-vet's homes passed and device count data when designing the capacity upgrades. Beyond pre-vet automation can be applied to steps in the node capacity upgrade design process. Mid split designs, node segmentation, and even node splits share many common design steps, such as node housing swaps, amplifier upgrades, and power analysis. Automating these steps accelerates the design process, permitting faster delivery of network capacity upgrade designs.

Abbreviations

Amp	amplifier

1. Introduction

Voice control of set-top boxes is becoming the norm. But voice technology needs to be able to understand non-standard speakers as well. Non-standard speech can be a factor for people affected by deafness, disabilities, medical disorders, or even foreign language speakers.

Comcast and Voiceitt, an Israel-based voice technology startup, have collaborated to explore a solution using a mobile application paired to a set-top box. In this paper, we describe how we are applying machine learning and artificial intelligence to create unique voice command models for individuals with speech disabilities to access the set-top box. In this paper, we will cover:

- Non-standard speech and how this translates to customer set-top-box control
- Solution method and architecture
- Description of our ongoing customer trial.

Offering accessible voice control for non-standard speakers can open the opportunity for all customers to experience the joy and convenience of a voice-enabled home entertainment system.

2. Non-standard Speech and the Set-top Box

This solution can be adapted to other devices besides set-top boxes (mobile, TV, computer, streaming adapter) using similar approaches and methods described throughout this paper.

2.1. What is non-standard speech

Non-standard speech is speech that is not readily understood by others or by standard speech recognition. This could be because the speaker has an accent, has deaf speech intelligibility issues, uses speech synthesis, or has a physical or neurological disability such as dysarthria. Other types of non-standard speech disabilities such as Wernicke's Aphasia create a disconnect between thought and utterance. The technological solution described in this paper will work if there is a regular, repeatable connection between the thought and the utterance.

2.2. Voice control and the set-top box

Voice-driven technologies are proliferating rapidly. Growing adoption of smart speakers and smart assistants is likely to make speech recognition a primary means to interact with the technological world around us, including home entertainment.

In 2015, the Emmy-award winning Xfinity Voice Remote Control introduced the ability to control a set-top box with one's voice. Using machine learning, Comcast's Natural Language Processing platform ensures that the remote delivers precise results. "The platform leverages machine learning to understand what customers mean when they say certain words or phrases and deliver highly relevant results."

The speech recognition engine requires understandable speech to perform speech-to-text (STT) conversion. Thus, people with non-standard speech cannot access mainstream SST voice technologies.

"Switch the channel to HBO"

For many of us, this simple, familiar voice command spoken aloud in our voice remote control is a convenient way to instruct our home entertainment system. For people with speech and motor disabilities, being able to use their voices would give them an opportunity to take ownership of their TV, increase their independence, and decrease their dependence on people around them to perform tasks such as changing the channel, recording a show, or browsing content.

In her report "Xfinity Adaptive Remote for Accessibility Audiences" Theresa Murzyn Ph.D., Lead UX Researcher at Comcast states "Not being understood takes a mental and emotional toll on users with motor/sensory challenges. The Adaptive Remote must enable users to feel understood regardless of their input method."

Customers' physical challenges, multi-sensory personas, and video mindsets inform what they expect from set-top box control technology, namely:

- Independence
- Fewer steps
- Speedier navigation through the TV/cable interface
- Less mental and physical effort
- Being valued

2.3. Current solutions for non-standard speech

"It doesn't understand me. I don't know why." (giggle)
— Comcast customer with amyotrophic lateral sclerosis (ALS)

Many of the people who can benefit from "voice first" technologies cannot access those technologies because they do not have the standard speech patterns that are recognizable to commercial automatic speech recognition (ASR) algorithms.

So what options are currently available to them to navigate this "voice-first" world?

"I have the capabilities of doing streaming if someone else is here pushing the buttons for me. But I can't do it myself. And so, I never do it."
— Comcast customer with spinal injury

Non-standard speakers may rely on friends, family, or caregivers for basic tasks, including controlling their devices for everyday tasks. Voice control for their set-top boxes can provide independence in these everyday routines.

"I use my iPad for a lot of YouTube. And I used to use a [sic] voice activation to get to it, but now it doesn't understand me any longer. So, I've kinda' lost the use of it."

— Comcast customer with ALS

Technologies such as the Xfinity Adaptive Remote are beginning to give touch and text alternatives to those who cannot speak into a physical remote control. Customers can pair the Adaptive Remote with assistive technologies (ATs) such as eye control, mouth sticks, gross-motor options for swiping and large-target tapping. This pairing gives these customers an opportunity to trigger set-top box actions or submit a text string version of the "voice" command they are interested in. Submitting this text string bypasses the ASR algorithm.

And yet, this technology often requires many steps to complete a simple task. This makes content foraging slow, tiring, and often exasperating. As one of our customers with ALS remarked, "Every click is time."

"They are already managing many challenges. let's not add more to them."

— Theresa Murzyn, PhD.

2.4. Our approach

In this project, Voiceitt's non-standard speech recognition was integrated with the Xfinity Adaptive Remote's video code (vcode) and string input capability, using Comcast's Companion App architecture as the technology bridge. This enables customers with speech disabilities to access and control their set-top boxes (and wider home and entertainment platforms) by voice.

The solution presented here was the innovation of two companies, Comcast and Voiceitt. Please note that while we will often refer to our different technologies by company or product name in this paper, this is done to keep our two companies' individual contributions and solutions clearly differentiated. Similar solutions can be developed by your organization's product team as well.

3. ASR Technology for Non-Standard Speech

Voiceitt's ASR technology is designed to recognize the speech of people with speech disabilities. The technology includes both discrete and continuous ASR for non-standard speech. Discrete ASR offers the ability to recognize a predefined list of phrases which the user with speech disabilities can customize. For example, if the speaker trains the software with the vocal pattern "uhwuh o uhah" and its meaning is, "I want to go outside," the software learns to recognize this pattern and associate it with its meaning, which it can then produce through digital speech.

Continuous ASR, now in Beta, extends this functionality to recognize the user's speech more flexibly. With the continuous ASR, there are no longer constraints to use predefined phrases from a phrase bank, thus allowing the user to speak more spontaneously and freely.

Both the continuous and discrete ASR technologies are customized solutions tailored to the individual user. As such, they rely upon enrollment data (training data): samples of the user's speech. This enrollment data is used to adapt the acoustic model to provide a more accurate representation of the individual's speech.

Further, hands-free activation is supported using the Voiceitt wake word technology, extending further accessibility for users with disabilities.

In the case of the discrete ASR solution, this customized model is downloaded onto the edge device as illustrated below.

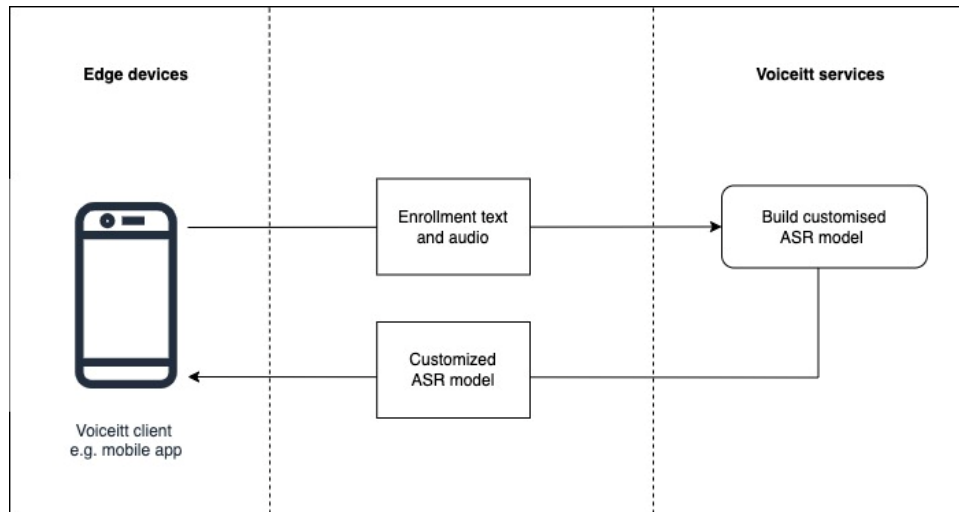

Figure 1 – customized model downloaded onto the edge device

Once the enrollment phase is complete, the user may use the edge device to recognize his/her speech. This recognition takes place on the device in the case of the discrete ASR solution. Importantly, a feedback loop is implemented which continuously improves the accuracy of the solution. This feedback loop is illustrated below.

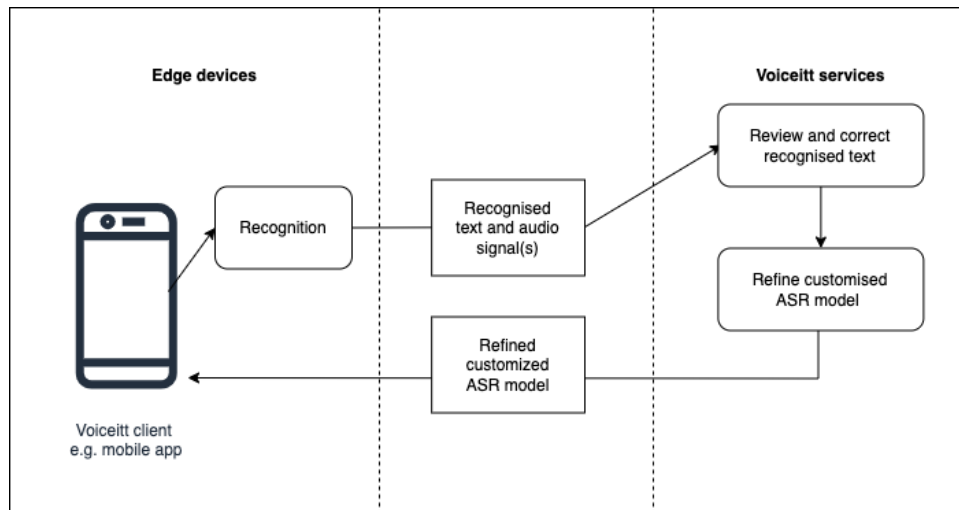

Figure 2 – feedback loop

Recognized text and its associated audio signals are sent to the backend database. The text and signals are reviewed and potentially corrected by a team of skilled annotators to provide additional training material to the model customization procedure. A further customized model is then delivered to the edge device for future recognition. This process iterates while the user engages with the technology, creating a virtuous machine learning cycle which delivers improved ASR accuracy.

A very similar workflow of enrollment, recognition and feedback is deployed in the case of continuous ASR. The primary difference is that continuous ASR uses a combination of an acoustic model and a language model to add the ability to recognize free speech using words and phrases that were not pre-trained, as well as phrases that are not in the pre-defined order.

This method could also be integrated with speech-based technologies such as those found on voice-controlled interfaces such as set-top boxes and smart home devices, effectively enabling users to access such technologies.

4. Adaptive Remote Technology

The Xfinity Adaptive Remote (<https://remote.xfinity.com/>) is a web application written in NodeJS which allows users to control their set-top boxes with various ATs such as the Tobii Eye Gaze solution.

The original project motivation was to provide remote tuning capability for our customers with ALS (also known as Lou Gehrig's disease) using an eye-tracking device such as the Tobii Eye Gaze. Later, features such as support for voice commands and voice-as-text commands were added.

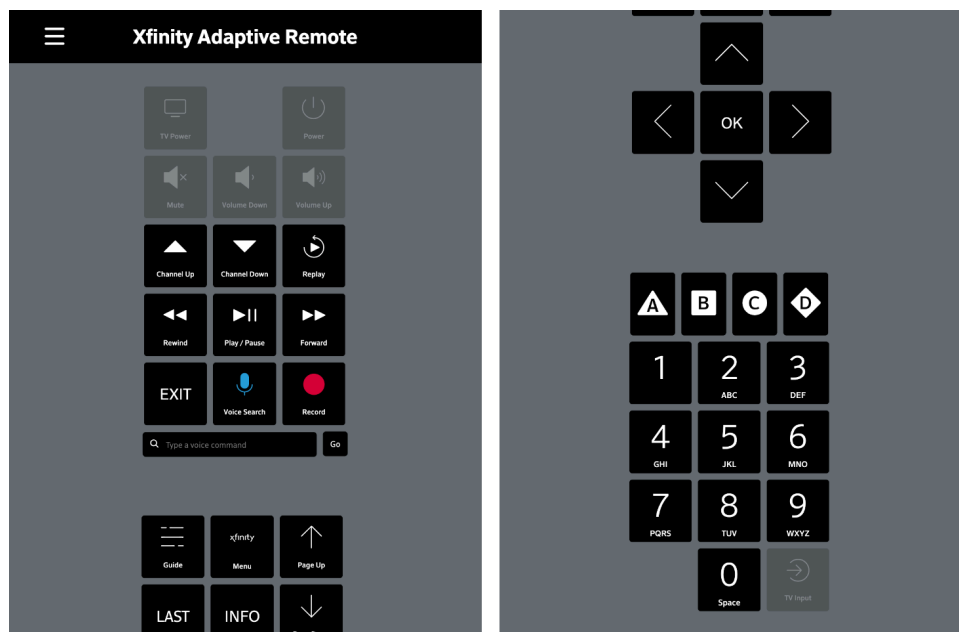

Figure 3 – adaptive remote on iPad (top and bottom scroll)

Tapping buttons on the adaptive remote simulates the press of one of the keys on the physical remote by sending the same vcode to the set-top box that the physical remote would send.

As an alternative to voice control, the adaptive remote has a field to enter a text string that would mimic the desired spoken command. Examples of voice commands include: “NBC”, “Peacock”, “Show me comedy movies”, “Guide”, “Channel up”.

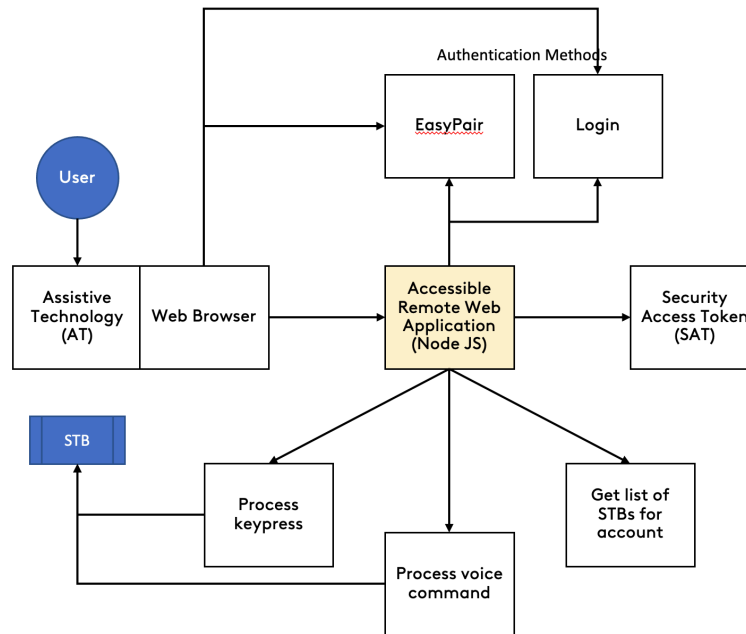

Figure 4 – adaptive remote architecture diagram

5. Companion App

The Adaptive Remote (AccRem) architecture supports “companion applications”. These companion apps use the existing AccRem app for login and TV Box selection and then use an AccRem web service application programming interface (API) developed specifically to support these companion applications. This AccRem architecture enabled the Voiceitt companion application to control the Xfinity set-top box.

Cross-Origin Resource Sharing (CORS)

CORS is an HTTP-header based mechanism that allows a server to indicate any other origins (domain, scheme, or port) than its own from which a browser should permit loading of resources.

Companion IDs

Each run / instance of a companion app must uniquely identify itself by a universally unique identifier (UUID). This is the value that will be implicitly passed via the adaptive remote app when submitting key presses, sending custom text commands, etc.

User Flow

The overall flow for an end user with speech disabilities will typically go something like this:

1. User visits a companion web app, hardware solution, or “fat client” app.
2. The companion app generates a new companion UUID value.
3. The companion app puts up a login button/link with a URL that contains the UUID.

4. Immediately after the user clicks on the button (which opens the AccRem app in another tab or mobile web view), the companion app puts up a “please wait” screen and begins polling using an API pairing endpoint.
5. Once the user logs in and choose her set top box, the AccRem app goes to the companion-success page which shows a message such as “Go back to your Companion App” and the pairing endpoint returns a token value in its response, which causes the companion app to stop polling and move the user to the companion app’s “main screen”, showing buttons, an input field for entering custom commands to control the set-top box.

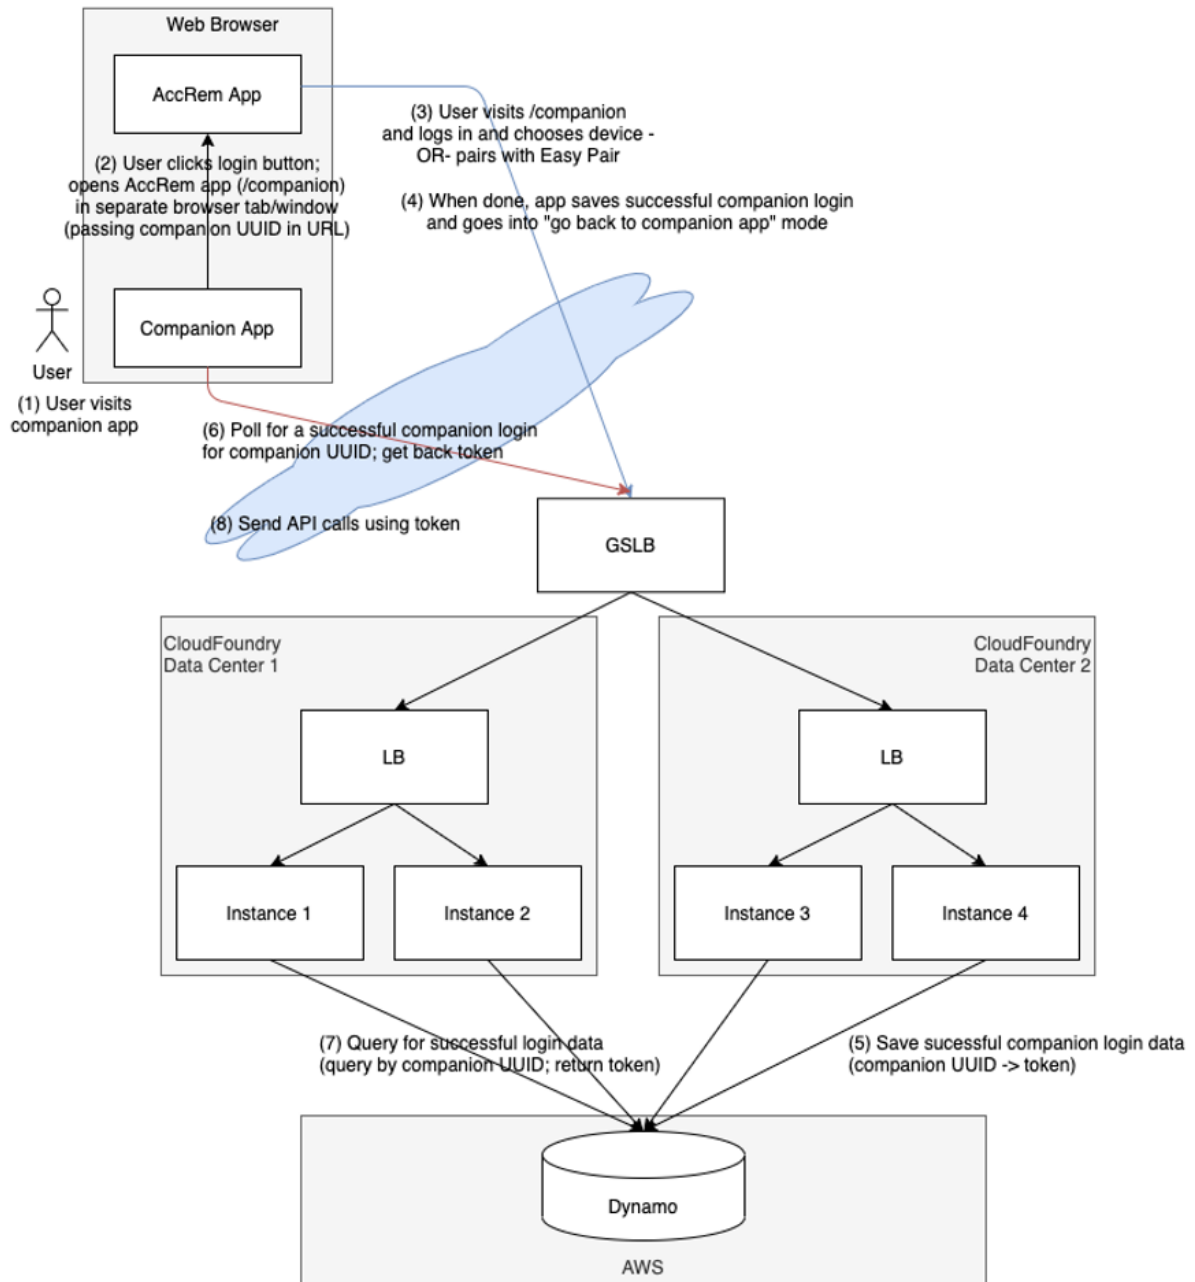

Figure 5 – companion app architecture

6. Integrating the Technologies

Comcast's Companion App was written in NodeJS, therefore Voiceitt translated this to C++ to work with their iOS mobile app. Personal identifiable information (PII) privacy was key in our joint solution.

(We are using our company/product names here to illustrate how we integrated the different technologies while ensuring the privacy of each company's customers. Again, similar solutions can be developed by your organization's product team as well.)

6.1. Customer authentication

To ensure PII privacy for Comcast customers, authentication is done on Xfinity-domain interfaces rendered in the Voiceitt app's web view. No authentication is done through the app itself.

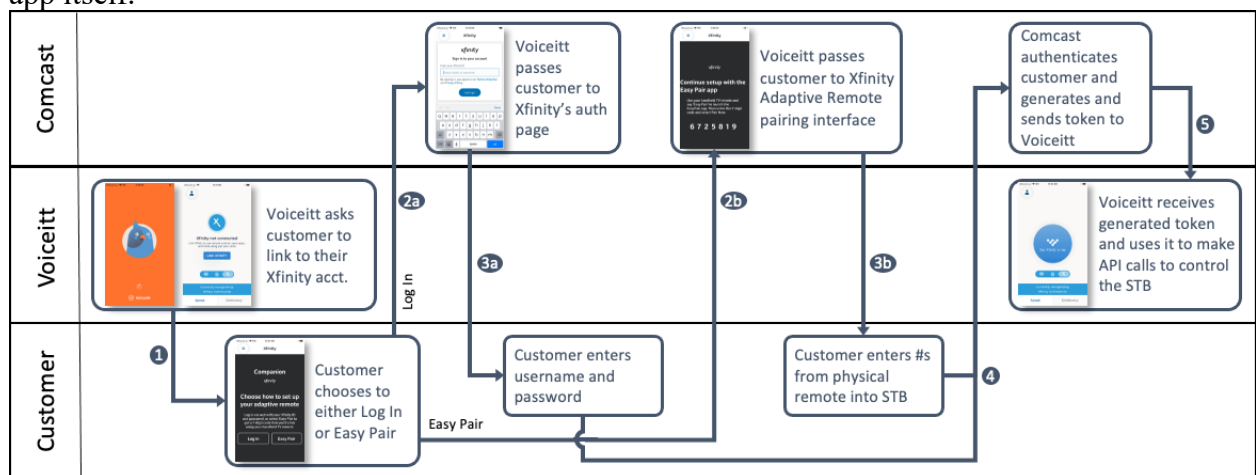

Figure 6 – authentication model

6.2. Voice imprint

To ensure PII privacy for Voiceitt customers, no voice recording is ever shared with Comcast, and moreover is compliant with international data privacy protocols.

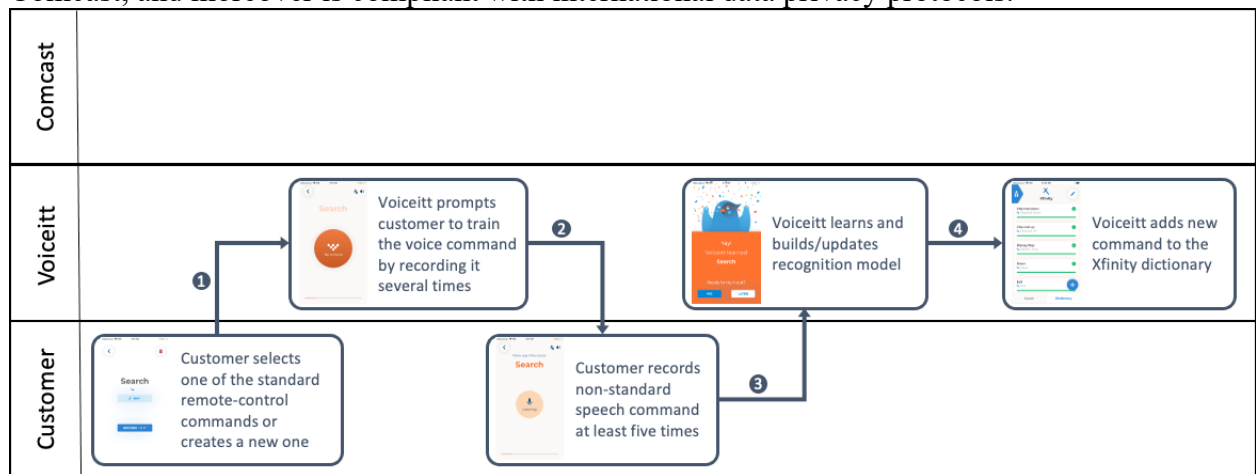

Figure 7 – voice imprint model

6.3. Set-top box control

The cable customer with non-standard speech is now able to control their set-top box with their voice.

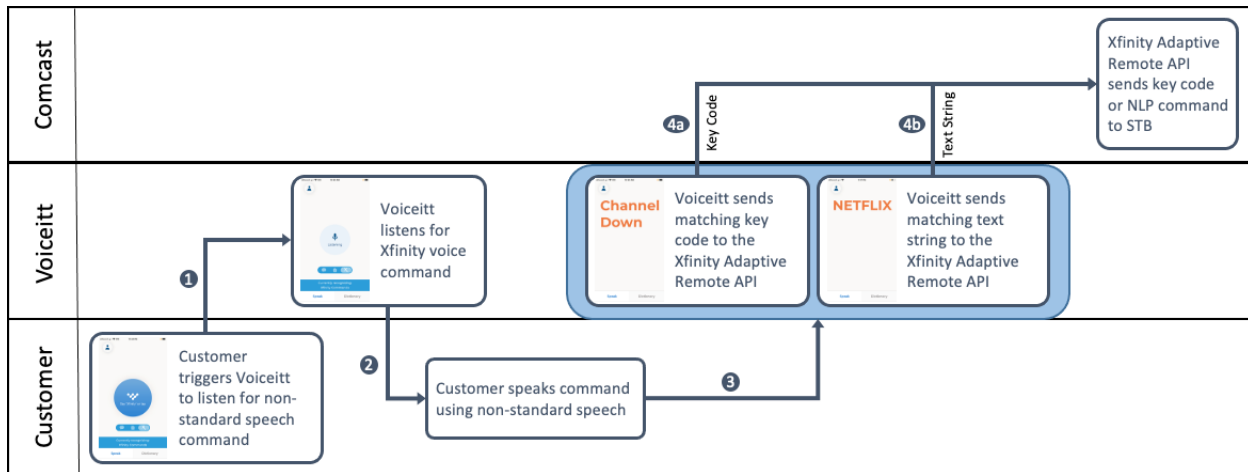

Figure 8 – set-top box control model

6.4. Compatibility with iPhone accessibility options

Any app should be compatible with OS accessibility settings and ATs so that those with disabilities can use it. We ensured all content was readable and in order when using a screen reader. We ensured all actionable items could be reached via finger swipe or AT and were labeled properly. We made sure that all [World Wide Web Consortium \(W3C\) Web Content Accessibility Guidelines \(WCAG\)](#) were followed at the AA level.

The companion mobile app is also designed and developed with innovative accessible user experience and design so that individuals with motor control impairments, cognitive, and dexterity challenges may access it as independently as possible.

7. Evaluating Impact of Integrated Solution with Customers

Comcast and Voiceitt have collaborated with a specialty nursing care facility in Philadelphia to evaluate the integrated solution described in this paper with end users with dysarthric speech.

The objective of the pilot is to evaluate how the Voiceitt app, which has integrated Xfinity's Adaptive Remote technology, improves independence and quality of life for individuals with dysarthric speech.

In an ongoing pilot, participants with highly atypical speech patterns correlated with cerebral palsy use Voiceitt's customizable speech recognition engine to activate a series of voice commands to their Xfinity X1 set-top box via Voiceitt's consumer application. The participants may not have had prior experience with voice devices or speech recognition; or, they may have previously tried to use these devices but without success. The available voice commands are chosen by each participant, sometimes with the help of a caregiver. The user calibrates the system by recording their voice, following prompts on the screen of their mobile device.

The pilot, now ongoing, will include input from participants, their caregivers and support professionals. Recognition accuracy and daily usage is measured through the companion

application. Impact on customer satisfaction, engagement, and usage, as well as quality of life and independence will be evaluated through a series of interviews and questionnaires with participants, facility administrators, and their daily support professionals.

8. Conclusion

The opportunity to give customers with non-standard speech (especially those whose speech is impaired due to neurological or physical disability) the ability to use their natural voices to control their entertainment system returns to them a sense of independence that offers fewer steps, speedier navigation, less mental and physical effort, and greater overall enjoyment of these offerings.

By integrating two solutions via a companion app bridge, we may serve not only those in the disability community with non-standard speech, but also those with accents, age-related tonal changes, etc. In short, while accessible solutions are necessary for some, they can be helpful for everyone.

We would like to acknowledge Theresa Murzyn and Mike Fine at Comcast. Theresa's user research on how those with ALS and Spinal Injury use media and home entertainment has been invaluable. Mike Fine's assistance in understanding the architecture behind the adaptive remote and companion app APIs has been vital to this technical paper. We would like to give special thanks to our partners at the facilities who provide help in recruiting and supporting individuals with speech disabilities participating in this collaborative pilot.

As our joint pilot progresses, further input from customers with disabilities will inform refinements to the technological approach described here, which will make our solution even more impactful and effective.

Definitions and Abbreviations

ALS	amyotrophic lateral sclerosis, also known as Lou Gehrig's disease, is a progressive neuro-degenerative disease that affects the brain and spinal cord.
Aphasia	The inability to understand what is being said, find the necessary word for something, or formulate sentences due to damage in the brain, often from a stroke or accident.
API	Application Programming Interface
ASR	Automatic Speech Recognition
Dysarthria	A speech disorder caused by either muscle weakness or the inability to control speech muscles due to brain damage.
Content foraging	entertainment system navigation and searching techniques to find content via direct retrieval or orienteering
Easy Pair	A method to connect a remote control to a set-top box by typing the numbers shown on the set-top box interface using the keypad on the remote to be paired.
IoT	Internet of Things
ML	Machine Learning
NLP	Natural language processing
PII	personally identifiable information such as name, address, streaming content history, etc.
RDK	Reference Design Kit (https://rdkcentral.com). RDK is a fully modular, portable, and customizable open-source software solution that standardizes core functions used in video, broadband, and IoT devices.
RDK-V	Reference Design Kit for Video.
STB	Set-top box
Speech synthesis	Artificial production of human speech by computer or speech synthesizer.
UUID	universally unique identifier. A 128-bit alpha-numeric to identify a person, peripheral, etc. without PII (personally identifiable information).
Vcode	Video code. The code sent to the set-top box when a remote-control button is pressed.
Voiceitt	Voice technology startup that has developed automatic speech recognition for non-standard speech.
W3C	World Wide Web Consortium
WCAG	Web Content Accessibility Guidelines. Guidelines written by the W3C's Web Accessibility Initiative directing designers and developers of web applications on accessibility requirements and standards. There are three levels of compliance: A, AA, AAA.
Wernicke's Aphasia	Seemingly fluent speech which is made up of unrelated words (schizophasia, often termed "word salad") or even non-words.

1. Introduction

In the monotonic drive for ever-greater bitrate consumption posed by the increased variability and sheer number of home dweller-facing digital network services (particularly immersive experiences and IoT-anchored emergency services), a review of the balancing act between WAN and LAN capacity and responsiveness begs execution. Such review seems particularly warranted at this point in the cable distribution and home Wi-Fi development epochs, given that the recalculation of transmit and receive capacities posed by the DOCSIS 4.0 WAN upgrade nearly coincides with the adoption of in-home Wi-Fi 7 LANs (themselves also potentially enhanced by higher EIRP /AFC-enabled Standard Power).

This paper will examine the implications of emerging network demands in a post-pandemic home services environment and attempt to evaluate the impact to WAN and LAN infrastructure; identifying behavioral, economic, or capacity mismatches which may alter the scope and rate of proposed network evolutions. What seems solicited is an advisory to network stakeholders on the scope of WAN and LAN futureproofing and a weighting of appropriate investment required to adequately meet anticipated mounted service connection needs in a moderately near-term adoption horizon.

Note that the exclusion of OTT WAN inroad is an intentional artifact of the constrained scope of this paper, but such competitive dismissal assumes minimal impression (consumer exploitation) in the 5-year consideration window. A brief sidebar is included for future reference and study, however, given the threat's higher global accessibility than fiber (PON), modest capability and cheaper entry ticket.

2. Bitrate and Latency, Averages and Peaks

Both the network WAN and the in-home LAN exhibit effects of mixed-flow data stochastics, though with the obvious contrast of WAN versus LAN data endpoint counts (clients and upstream sources). The WAN's high end client count and dedicated multicast video channel assets guarantee that its carry-to-capacity during peak use exhibits a higher average ratio than the bursty (though still largely video-based ABR data consumption) associated with adaptable-rate Wi-Fi traffic bound for on-premises distribution. In fact, in terms of raw bitrate capacity, Wi-Fi airtime capacity is typically leveraged to a much smaller fraction of its upper limit in the average US household (which is obviously not the case with the wireline WAN, especially during peak use periods). This begs questions around the required number of contending Wi-Fi clients (or competing in-range, interfering APs) which would render the LAN incapable of meeting its QoS aspirations – especially given next generation Wi-Fi MAC market penetration.

From the wireline WAN standpoint, DOCSIS 4.0 (in one or more of its species) promises improved duplex signaling capacity via modified exploit of the wireline's duplex split (including dynamic management of same in FDX instantiations), jettisoning video's SC-QAM in favor of full OFDM leverage and ESD (initially to 1.8 GHz) to accompany higher spectral efficiency modulation schemes. All these improvements promise higher bitrate support in both directions over the WAN.

2.1. The Wi-Fi (LAN) environment

The summary standard of on-premises network performance is Wi-Fi bitrate, and its singular comparative assessment is “the higher, the better”. And while raw delivery speed makes up for many signal distribution sins, it is worthwhile to recognize that data movements between Wi-Fi endpoints lever orchestrated solicitations of clear airtime in one or more radio bands to guarantee transfer of packets, the integrated view of which amounts to flows of varying bitrate and waypoint latencies. Contention in the airtime space – especially from native-mesh-asynchronous radio sources – compounds the access issue and confounds the negotiating parties; this serves to reduce delivery determinism and inject noise into the

packet goodput in the form of varying latency (jitter). In pathological cases, it can result in intermittent service interruption (if not outright failure) for any given link.

Fundamentally, Wi-Fi has evolved to include methods for framed exchange (RTS, CTS) and priority handling (WMM with its varying backoff counts) and now with the advent of MAC 7, features much broader channel BWs, higher spectral efficiency (denser QAM), cross-band channel aggregation, bi-directional MIMO and inherits OFDMA, BSS coloring and TWT from MAC 6, all of which serve to give its scheduler more tools to rapidly – and with low latency and higher dependability – transfer packets across endpoints even under challenging interference conditions. The goal, of course, is “responsive immersion” for end users in cases where content is being consumed or interacted with; and immediate cloud network connectivity for those services which operate on emergency care or home security tiers within a given residence.

Wi-Fi responsiveness has two components – bitrate and latency. The twitch gaming community (and simulation scenarios in general) have drawn attention to roundtrip command processing latency and the specific requirement of predictable, low jitter – given that now the issue of raw data pumping capacity has moved well past a 25x surfeit of capability for any mounted service in the home wireless domain. In other words, since we seem to be able to burst data to/from endpoints with low enough airtime duty cycle, it now becomes more critically important to remove queuing shims from the transfer process and more appropriately address tiers of delivery priority for the packets themselves.

On the Layer 2 front, the typical resolution for latency issues comes in the form of different priority queues (with delivery deferral of, and pre-empted delivery for, lower versus higher priorities respectively), clever multi-receiver packing of right-sized data payloads (OFDMA) and hold timeouts (buffer truncations) capping the maximum dwell time for lined-up packets. The Layer 1 mitigation involves identifying surplus airtime in underutilized Wi-Fi channels (in bands mutually supported by the attaching endpoints). Further, these types of solutions may be reactive (algorithmic responses to particular link telemetric triggers like airtime capacity or buffer lengths) or anticipatory (via managed pre-emptive adjustments given TOD and stored prior successes). Condensed, the Layer 1 consideration involves the capacity calculus of the given band and channel (so, typically, MCS x BW x SS) versus any steering options on the band/channel front for the affected client(s). If better spectrum efficiency (shorter burned airtime) is available in an alternate channel or band, the scheduler chooses that more optimal solution. And by leaning on MCS as one of the calculus components, the EIRP benefits of alternate spectrum choice will automatically receive an accounting (more power meaning better received C/N and hence higher MCS). A key leverage here is the 6 GHz spectrum, where even simple single user round-robin (non-OFDMA) scheduling can achieve 2 msec link latencies provided the served spectrum client count does not exceed a half-dozen or so participants.

The initial step in effectively handling latency expectations is to either infer requirements based upon some period of traffic observation or have the user explicitly designate a particular client/service binding which sets priority expectations for its data needs. The inferential determination can be done autonomously (and aligns with “fingerprint” methodology necessary when MAC randomization becomes a fixture in home wireless LANs – certainly likely during our study horizon). To mitigate startup jitter – and during the period when client traffic inference is still pending, the default priority handling should be set to highest (least latency and jitter). Over some initial transfers, the traffic from AP to client will establish its stochastic metrics (fingerprint) and “graduate” to the appropriate priority and latency setting. And while WMM provides a Wi-Fi mechanism which suggests leverage of 4 different priority queues, tremendous improvement for jitter comes with just the first parsing of traffic from “first-come, first served” to “warrants special handling”.

Once the traffic is parsed for latency priority, the scheduler can then employ various buffer, payload packing and spectral leverages to manage the latent aspects of data connectivity for the impacted services. In the case of a low latency need, for example, a PHY optimization would consider the immense spectral width of the 6 GHz band. This large greenfield spectrum makes it straightforward to select a wide BW channel (to enhance burst speed) and locate it such that CCI is not measurably present (to guarantee a C/N which maximizes MCS and hence, bitrate); the Achilles' heel is the obvious requirement that both ends of the wireless link must support the 6 GHz band. The upside is that Standard Power and Wi-Fi 7 – both due within a year's time (or so) -- will both serve to catalyze adoption of devices which can lever that band.

2.1.1. Wi-Fi 6, Wi-Fi 7 and Standard Power

Briefly, Standard Power 6E allows the AP to paint the home expanse with up to 9 dB additional EIRP (over LPI at 160 MHz BW in the 6 GHz band) and essentially walks all 6 GHz clients up the MCS bitrate cascade (for downlink delivery), reducing consumed transmit airtime for a given packet size.

Wi-Fi 6E

LPI to SP Benefits

Figure 1 – Standard Power Benefit over LPI at 6 GHz in Arris Wi-Fi House

For its part, Wi-Fi 7 allows the AP to bind data delivery over multiple bands, with more granular BW leverage (think: spectrum puncturing, fractional RU use and multiband exploit), than any prior Wi-Fi MAC – and so can more cleverly leverage gaps in contested spectrum (in up to 3 bands, at that) to increase delivery rate and reliability over that of a single monolithic channel/single band at best-case C/N.

Figure 2 – Effect of MLO on Goodput at Various Bonding Options

The Wi-Fi 6E stranglehold on operations in the 6 GHz band will not even be fully two years old before Wi-Fi 7 devices will debut, beginning late this calendar year/early next. And it appears this landmark will also (roughly) coincide with the availability of Standard Power for AP devices in that same band. The significance of these coincident events manifests in outstanding bitrate reach throughout even large footprint estates – and couples this with multiband robustness and unprecedented levels of predictable, low latency signal distribution. As previously alluded, APs with Wi-Fi 7 will be able to implement schedulers which have at their disposal broader channel bandwidths than those offered by Wi-Fi 6 (320 vs 160 MHz), spectrum puncturing, MLO, OFDMA, bidirectional Mu-MIMO and TWT operations. Orchestrated data exchanges to the heterogeneous MAC limitations of respective client devices should be possible. This bonanza in Wi-Fi 7 additions to 6E – and their so-proximate release to the first 6E-capable devices – has largely rendered 6E a moot (OBE) waypoint proposition (succeeding only in fragmenting the 6 GHz Wi-Fi market in its early days, unfortunately). There exist two exceptions to this proclamation on 6E early obsolescence: “virtual wireline”, low-latency dedicated 6 GHz Wi-Fi channels between AP

and gaming endpoint and AP:AP (non-backed-off power and maximum BW on a dedicated channel) trunk links for wireless extension within the premises.

Regarding the former, addition of Ethernet (or USB)-to-6E dongles to AP and client on opposing ends of a dedicated-channel 6E link provide an instantaneous means of running a (virtual) Ethernet cable between those devices and establishing near-wireline delivery latency on said link. Regarding the latter, for large-footprint homes, Wi-Fi extension via a dedicated 4SS 6E link between gateway device and mid-home can provide Wi-Fi extension with trunk capacity easily exceeding 2 Gbps – again with low single digit millisecond latency over the link. And by doubling down on this arrangement via leverage of AFC-enabled standard power, 4W EIRP at both ends of the link will be allowed; this trumps the power footprint for APs in any other Wi-Fi band. Boutique solutions, certainly – but also worthy of note in the time horizon under study.

2.2. The DOCSIS (WAN) Environment

Though (for some) glacier-paced, the onset of a DOCSIS 4.0 era has nonetheless proceeded and now finds itself well into commercial chip implementation phase within the development domains of the two most pedigreed commercial participants in the DOCSIS legacy. However, the end game – as regards deployment particulars and timing – is very much undetermined. There exist multiple permutations of DOCSIS wireline epoch which could conceivably meet network needs in the coming few years with rather steep implementation costs for some weighing on the solution calculus. Relief for the restrictive legacy return path is the only identifiable common element at this juncture, with the trunk diplex split, continued exploit of SC-QAM for video and final forward bandwidth still under evaluation – as well as the MAC subtype(s) to be exploited across the full band (such impacting the effective spectral density and hence capacity of the total spectrum).

Regarding the latter, a “budgetary” approach to upgrading the DOCSIS network might be to move to DOCSIS 3.1, slide the diplex frequency up to 204 MHz and set the forward band limit to at least 1.2 GHz. Such a conservative approach might attract some attention from (and provide temporary relief for) capex-bound systems, but for the purposes of analysis we will focus on the DOCSIS 4.0 variants matrixed with more future-proofed options on diplexer frequency and upper band edge (in anticipation of a higher adoption rate which better describes the coming WAN environment for the greatest population of NA subscribers). A brief summary of DOCSIS 4.0 options follows, in order of increasing implementation complexity.

2.2.1. DOCSIS 4.0 Enhanced Spectrum DOCSIS (ESD)

The following pictogram illustrates diplex split operations for DOCSIS 4.0 ESD in either 5x5 or 5x7 formats (referring to number of OFDM 96 MHz blocks of upstream traffic):

Figure 3 – DOCSIS 4.0 ESD Variants

These are but two examples; the spec lists five different diplexer options in up/downstream operation. Note the corresponding shift in the diplex corner frequencies in these two cases and the option to shift the full band forward cutoff up to 1.8 GHz if desired. If we conjure full exploit of the 1.8 GHz bandwidth with only OFDM carriage (no video SC-QAM) and maximum upstream bandwidth (so closest to most symmetric wireline operation), the EOL performance of a cascade would be capable of a downstream PHY rate exceeding 10 Gbps for all but the highest diplexer splits.

2.2.2. DOCSIS 4.0 FDX

ESD pushes the forward spectrum out and eliminates less efficient SC-QAM, but FDX goes a step further (and more complex) – shiftable duplex signaling bands (adjustable diplex frequencies). The CableLabs visualization of this looks as follows:

Figure 4 – DOCSIS 4.0 FDX Variants

The clear benefits on the flexibility front fall into the category of adaptable duplex ratio. Post-pandemic in particular, it is not entirely clear whether the traditional 10:1 split (in the US) for downstream:upstream capacity will continue to make sense. (The SOHO, IoT and data-sourcing aspects may see relatively higher growth rates than traditional lean-back video consumption, for example.)

3. Managing E2E Packet Latency Across WAN and LAN

Proper stewardship of packet delivery across the concatenated DOCSIS and Wi-Fi networks involves a synonymous mapping scheme for the various packet priorities within the two domains; anything less promotes thrash in the queuing arrangements on one side or the other, resulting in jitter increases as the packet queues are spasmodically serviced. Fundamentally, synonymous mapping involves marrying the wireline LLD (low latency DOCSIS) – where appropriate -- with Wi-Fi's WMM and assigning sensible, staggered priorities for the client services drawing data connectivity support from the two networks.

3.1. Low Latency DOCSIS

Pre-DOCSIS 4.0 already features an unevenly implemented technique for minimizing forwarding delays for certain priorities of packets called Low Latency DOCSIS (LLD). This is an evolutionary endpoint along a vector of buffer management trials which produced the following signatures:

(CM/CMTS RTT)			
	<i>When Idle</i>	<i>Under Load</i>	<i>99th Percentile</i>
<i>DOCSIS 3.0 Early Equipment</i>	<i>~10ms</i>	<i>~1000ms</i>	<i>~1000ms</i>
<i>DOCSIS 3.0 w/ Buffer Control</i>	<i>~10ms</i>	<i>~100ms</i>	<i>~100ms</i>
<i>DOCSIS 3.1 Active Queue Management</i>	<i>~10ms</i>	<i>~10ms</i>	<i>~100ms</i>
Low Latency DOCSIS 3.1	~1m	~1ms	~1ms

Figure 5 – Evolution of DOCSIS pre-4.0 Roundtrip Time Latency

Fundamentally, LLD calls for a parsing of duplex service flows into LL and Classic – with a management function to apply service classifier membership to discharge data flows identified as not requiring rapid forwarding from the LL flow into the Classic mix. It also monitors queue health along both flows to make sensible, weighted exploit of the low latency path under dynamic loading conditions.

Figure 6 – 2-Component Flows in DOCSIS Pipe, Low Latency and Classic

With this simple expedient of a second, shunt buffer queue for high priority/low latency traffic, the following remarkable results are obtained in the DOCSIS domain:

High Classic Traffic

p99 Latency vs USSG Utilization
(90% classic Traffic)

Tmax: 20 Mbps

USSG Capacity: 200 Mbps

High Classic Traffic

Jitter vs USSG Utilization (90% classic Traffic)

Figure 7 – Differential Flow Performance Upstream for Latency and Jitter

As can easily be identified, both latency and its deviation (jitter) are remarkably constrained once LL discipline is applied in a second service flow (typically 10 msec RTT latency with 1 msec jitter, across a service group loading from 25% to 90%).

So what services require low latency assistance? The following attempts a parsing of typical home data services into “LL” and “non-LL”:

Flow Mapping for Typical Data Services

Low Latency	Bulk/Background
Web	Software Updates
Videoconferencing	Dropbox
Audio Streaming	Email
VOIP	VPN*
Gaming	Video

** may also require LLD treatment*

Figure 8 – Candidate Service Mounts for Low Latency Grooming

Essentially, then, rate tiers provide a means of selectively monetizing progressively more aggressive user bitrate demands and this type of selectivity can now be applied to the latency domain and enhance those services requiring preferential, low latency handling.

4. Extant and Emerging Premise Services Landscape

Any well-founded attempt at aligning network data delivery to, and scavenging from, home premises necessarily must consider both present (established) service mounts and those calculated to emerge and mature – or wither and go dormant -- over the five-year consideration horizon posed in this paper to supply foundation for modification of network behaviors. A general expectation seems to be that data flows will increase (and on a duplex basis) between premise and cloud; but as always there needs to be sober justification for the timing and magnitude of capex investment to enhance data flows versus the life cycles of legacy and emerging services and the migration of opex balance sheet operating points (typically subscription revenues against licensing or other service origination/maintenance costs). This

section will attempt to assign relative values to services which are expected to populate the network application service palette in the postulated time window.

4.1. Consumer Impressions of Wi-Fi Performance and Feature Value

A proper sampling of present network performance service levels and features – as perceived by the end users themselves – seems an appropriate and necessary first consideration in establishing any motivation for alteration of the current state of network data operations. This can also provide the rational basis for critique of the relative end perceived value of various modification strategies. And providing a voting mechanism on alternate value strategies would help establish success vectors (from the users' standpoints) regarding where to steer the performance of the combined cloud-to-ground (and back) environment experienced by these end users. Such a survey was constructed and the details of the canvassed topics – and the recovered results from 546 global participants – follow.

The regional breakout for the data – which sources from the CommScope associates database – exhibited the following detail:

Asia-Pacific	250
North America	187
Carib./Latin America	21
Europe	80
Africa	2

Figure 9 – Regional Basis for User Network Impressions

The survey attempted to identify users' appreciation of the common metrics used to described network data attachment and assess those parameters and values which resonated from a value standpoint. To orient some of the subscription realities, users were asked their broadband speed tier:

Figure 10 – Users' Broadband Speed Tiers

Note the gross preponderance of sub-Gbps subscription, with the plurality lying in the 200-1000 Mbps bucket. Cost for this privilege was solicited:

Figure 11 – Budgeted Monthly Cost for Network BB Data

Note that globally, caps appear at 1 Gbps speed and \$100/month cost. In terms of satisfaction with this service exchange rate, nearly 79% of respondents indicated they were happy with the value proposition – perhaps underpinned by the fact that just over ¾ of the users had an alternate supplier handy (so,

presumably, might have done a “best offer” type of alternative analysis). To add to the inertia, nearly 87% of those answering defined themselves as not actively looking for replacement broadband services.

However, in terms of total network support, just over half (56%) of respondents felt that their home Wi-Fi matched the performance of their WAN attachment – and 62% felt that, were investment in their total networking were to be made, that investment would fall to the Wi-Fi side. (There appears to be some legacy ill will or suspicion associated with Wi-Fi – perhaps created in bygone single-band days, or with a preponderance of 2.4 GHz based, single antenna clients. Certainly, Wi-Fi beyond dual-band MAC 5 – 802.11ac – has no problem with disposition of packets at the less than 10 Mbps throttling rate which represents average WAN attachment pace for dwellings!) And it is true that, wherever network issues arise, the human proximity of Wi-Fi CPE lends itself to that nearby equipment shouldering blame for connectivity issues (whether or not they originate there).

In the next section of the survey, users were tested as to specific opinions on upstream and downstream data – the latter both regarding speed and latency/jitter. First, as regards upstream connection speed:

Figure 12 – Upstream Bitrate Rating

Note that nearly half the results peg the upstream as being either “good” or “excellent”; whilst an uplifting opinion, one wonders if users understand how little of their connectivity traffic is actually carried upstream – or how to quantify its “goodness”. Still, their resolution on this point was tested by the alternative to either stay with their current provider at a 10% price cut or move to another provider for twice the speed at the same cost they currently experience. The result was telling:

Figure 13 – The Upstream Value Challenge

Only about a third of respondents could see the worth in switching up suppliers for twice the speed at identical cost to them; still, this shows some fair sensitivity to upstream performance value – so it is noteworthy the majority push would be for less cost. (This opposite view holds in high connectivity speed regimes, so clearly even when satisfied with downlink speeds, there is opportunity to mine interest in better upstream capability). Next, the same question was posed regarding downstream performance. The response shift is interesting:

Figure 14 – The Downstream Value Challenge

Note that roughly 10% of respondents opted up for more downstream speed than were prepared to do so for upstream improvements. This suggests that they are aware of some correlation between DS bitrate and in-home services performance (while perhaps not being convinced that it is worth that much more than getting a quick 10% service cost rebate for the extant DS rate). Note that the higher the subscription speed, the more likely the user was to push for cost mitigation than more bandwidth (obviously viewing their connection as at least adequate).

The survey then shifted to probing users' feel for the value of latency and jitter in their network performance; first, as to latency:

Figure 15 – Where Latency Fits for Users VS DS Bitrate

It is difficult to infer anything here: the plurality of users would have latency rank equally with bitrate as regards connection “goodness” but the weighted average of value from this chart produces no other insight – other than high bitrate users REALLY appreciate their high bitrate tier more than latency. Perhaps unsurprisingly, the jitter evaluation by users produces a near-mirror copy of the latency result:

Figure 16 – Where Jitter Fits for Users VS DS Bitrate

If these results were perplexing, perhaps they appear less so when a litmus test for the magic effect of high bitrate labeling is concocted. Users were asked if, rather than receive a guarantee of bitrate, they would instead prefer a promise that all their equipment would be set to operate under the best bitrate, latency and jitter conditions possible, an astounding 2/3 replied “No”. When this offer was sweetened with the inducement of a 10% rate reduction, the “yes” responses did increase – but only about 10 percentage points (to ~44%). So there is obviously a great deal of marketing value to network connectivity distilled to a single rate tier value. Given this reality, the respondents were quizzed as to what speed grades they looked for: the lowest to do the job, the highest offered or something in between. The responses came down as follow:

Figure 17 – BB Connection Rate Impetus to Shopping

To add a layer to this query, the users were asked if new broadband services (specifically like VR) factored into their purchase thinking for network connectivity. The responses came thus:

Figure 18 – VR impact to BB Connectivity Requirements

Nearly 70% of users indicated a high level of sensitivity to high bitrate demanding services emerging in their homes and appeared prepared to include consideration of these in present and future BB purchases. (This is a critical leverage point, as VR developments will very shortly push higher bitrates into the home, as we detail in following sections).

The users were then asked to rank the top attributes they examined when looking for broadband services; the rank order of the number 1 responses was distributed as follows:

Figure 19 – Most Important Broadband Network Attribute

Cost, reliability and topline bitrate were noted – but oddly enough, Wi-Fi performance was seen to count for inclusion in broadband network performance as well. In terms of home uses for WAN services, the following were cited:

Figure 20 – Broadband Network Enabled Home Services

Unsurprisingly, watching streaming video set the bar, but in the post-pandemic world, working from home and teleconferencing received high notice. Not yet too noteworthy, but of interesting acknowledgment are the votes cast for remote healthcare; expect these to rise significantly as AIP takes hold.

A final query had to do with concurrent users in the home. Given the US household average of 2.6, perhaps these numbers are not too far-fetched:

Figure 21 – Simultaneous User Leverage of WAN

The overall impression of users seems to be that they are very satisfied with their broadband investment; they value cost, speed and reliability highly (but are largely clueless on the value of latency and jitter); spend the largest chunk of time ingesting streaming video (still) and are curious about the impact higher-value video services may have on their networking environment (in which they link Wi-Fi performance directly to that of the WAN).

4.2. Premises Services Data Payloads

For the next five years (and in fairness, the conceivable future) video services will continue to represent the largest tranche of downstream service data consumption. This is not one's grandparents' video experience; broadcast channels have morphed to applications, with the appended '+' symbol an indicator of viewing options which exist underneath a brand headliner. But however the content is catalogued and presented, it is clear that lean-back video consumption will remain a lynchpin service for almost every subscriber given that current consumption metrics peg video as burning close to 80% of premise-bound downlink data payloads. And while the present HD resolution norm for premium video meters at ~ 5 Mbps given present codec efficiency and common rendering devices, growth of in-home 8K-capable TVs promises to boost the video data appetite to something in the realm of 50-100 Mbps per screen (at coming codec efficiencies and higher frame rates) in the very near future. (It is, in fact, the rate of consumer uptake of higher quality video services which most challenges the forecast of any premises data consumption budget.) In terms of perceptible wireless impact, video picture quality is also the most relatable quality metric of wireless performance accessible by the average non-technical user and provides an obvious marketing leverage point in side-by-side comparisons of network bitrate value. (Imagine the marketing penalty associated with the realization that network A can mount the latest VR

headset and network B cannot.) Pegging an inflection point for adoption of super-resolution and frame rate rendering devices seems fraught with false starts, but perhaps an understanding of what is implied (in terms of network performance) might serve to frame the coming expectations:

Bandwidth Requirements of Cloud VR

- The estimated per-user bandwidths required by strong-interaction services in the three phases of Cloud VR development are as follows:

[1]

Phase		Fair-experience Phase	Comfortable-experience Phase	Ideal-experience Phase
Typical content resolution		2K (equivalent full-view resolution: 4K)	4K (equivalent full-view resolution: 8K)	8K/16K (equivalent full-view resolution: 12K/24K)
Typical terminal resolution		2K	4K	8K/16K
FOV		90° to 110°	120°	120° to 140°
Color depth (bits)		8	8	10~12
Coding standard		H.264/265	H.265	H.265/266
Compression ratio (I-frame/P-frame)		25/75	38/165	50/255(8K), 83/585 (16K)
Strong-interaction VR service	Typical bitrate	40 Mbit/s	90 Mbit/s	Full-view: 290 Mbit/s (12K) 1090 Mbit/s(24K) FOV: 155 Mbit/s (12K) 580 Mbit/s(24K)
	Typical bandwidth requirement	80 Mbit/s	260 Mbit/s	360 Mbit/s (8K) 1.5 Gbit/s (16K)

 **Note relentless increase in video bitrate**

Figure 22 – Stacked Bitrate Increases Driving VR Simulation Immersion and Super-Resolution Screens

A distant, if otherwise distinct, common second service type which may be reasonably expected to continue (if not grow) its ranking among services is network gaming. (This includes immersive AR/VR equipment such as Oculus – the 80% market share leader – which is projected to exhibit a CAGR between 40 and 60% over the time period 2018 to 2025). This compound growth suggests an exit value from our 5-year window at north of \$20 billion dollars of sales revenue for AR/VR. The desired network attachment profile for these types of gaming services includes a latency component which is two orders of magnitude tighter in tolerance than that required for ABR delivery of video packets for lean-back viewing. The desired jitter descriptor is a further order of magnitude more restrictive than that (so low single-digit milliseconds). Present Oculus data burn mimics that of a moderate resolution planar video

screen but upcoming versions (described above) seem to intend on increasing resolution and pushing frame rates, *a la* 16K TVs. (And recall that VR/AR equipment paints not just frame content straight ahead, but also prospective adjacent frames to the sides, above and below, to reduce rendering stutter in rapidly moving head exercises). As such, it should be expected that near-term-available Oculus II and III headset gear will exhibit an even higher data appetite (from 50 Mbps to perhaps as much as 400-500 Mbps) than those 8Kp120 UHD screens which lie largely unexercised in present home viewing rooms.

AR/VR systems aside, dedicated gaming stations and PCs with legacy planar rendering surfaces will continue to see heavy use in the residences of end users during the projection period. As is the case for immersive (head-worn) rendering systems, the twitch aspects want for predictably low latency with corresponding small amounts of packet delivery jitter. In terms of raw bitrate support, however, network gaming peaks at 150 MB/hour (~ 300 kbps). As regards pipe demand, this is on the same order of magnitude as listening to streaming audio services or conducting an IP-based phone call.

An emerging video option, yet ungraduated from boutique levels of interest and deployment, is holographic imaging. Requiring multiple video planes to construct, it represents the largest potential downlink consumption in the residence (if such is so equipped). Although not yet representing notable consumer interest, it seems an inevitable (if expensive) extension along the vector of greater immersive simulation or learning. Current state-of-the-art requires a data downpipe of nearly 2 Gbps capability – several multiples of present-day “full up” home services network attachment – so when adoption becomes real, such will manifest a huge uptick in network connectivity. However, given the abbreviated window of expectations for this study, the marketing outlook for holographic support in the home may be presumed to be beyond the time scope of this analysis.

Five other, lower bitrate and less stringent latency-invoking, service profiles can easily be identified: website browsing, digital assistant interplay, live streaming, SOHO teleconferencing and IoT telemetry forwarding. Of these five, the latter three represent the largest upstream bitrate generators: camera feeds. Depending on video resolution and codec, these can vary from 500 kbps to 2 Mbps per feed and (constant rate teleconferencing aside) the common use case involves intermittent (triggered) operation, involving transfer of perhaps 7.5 MB of video/audio clip data over a 30-second capture window. From a security standpoint, it would not be unusual to expect camera coverage of all premises ingress/egress points, resulting in perhaps 4 streams worth of randomly triggered data per dwelling. In general, however, the total contribution to network connectivity (and upload at that) might only see 5 or 6 episodes dispatched per 24-hour period (so 40 MB total security payload). The teleconference load depends on meeting times (naturally), but six hours of daily meetings would contribute 5.4 GB/day worth of upstream traffic. Live streaming (Tik Tok and the like) can vary from short bursts to sustained use on the order of a teleconference hit per mounted instance.

Digital assistant interactions process audio clips of typically 48 kbps sampling rate. Assuming a multichannel far-field array capture, one could budget 400 kbps uplink and perhaps 200 kbps downlink traffic, representing around 6 Mb uplink and 1.5 Mb of downlink utilization over a 2-minute, randomly occurring interaction cycle. As with security cameras, assistants will be sprinkled throughout the home (and recall these can be apps on multiple types of CPE, including phones, remote controls, audio players and TVs). A dozen of these “conversations” among all household members might be a reasonable estimate for maximal usage during a day, which yields much less than 10 MB uplink / 2 MB downlink total payload over the course of a day.

Smart home IoT command exchanges and telemetry uploads over Wi-Fi tend to be even less of a network burden than smart assistant interchanges. If we exclude the voice-ordered aspects and consider their impact captured above, telemetry and commands might amount to no more than 30kB (up and down)

worth of daily interactions; though what is critical is timely forwarding of these exchanges into, and out of, the premises, given the potential emergency nature of security or health alerts included in the payloads. (From a behavioral point of view, persistent and rapid-rate-signaled “alarm clamoring” – until such is acknowledged by the cloud receiving entity – would seem to make sense). This also presumes verbose loop-in of a cloud element, though what is expected is that routine executive control of the premises (as regards IoT) would not likely exit the home edge (and such would be hardened for loss of power and wireline WAN connectivity, at that).

4.3. Data Demands of a Model Smart Home in 2027

Combining several of our expectations, expressed above, for data interchange between home LAN and network WAN, allows us to posit the following model for a smart home in 2027. Note that we will be leveraging Arris’ 5300 square foot Wi-Fi house as the representational challenge and will outfit its ~ 2x average home footprint with a full array of CPE Wi-Fi (including sub-mesh Matter support for SED – battery powered -- IoT devices, arranged so that Wi-Fi acts as aggregating long haul for the Thread edge routers commanding these distributed resources). Note that MLO triband capability will be assumed to be implemented in all link endpoints (AP and client alike). We will also liberally equip the home with A/V kiosks (2 per floor, say – though representationally, these might well be phone applications) to support voice control of IoT devices from throughout the premises.

From a human-centric viewpoint, we can suppose nine concurrent clients at peak network utilization, perhaps arranged with the following locations and application demand profiles:

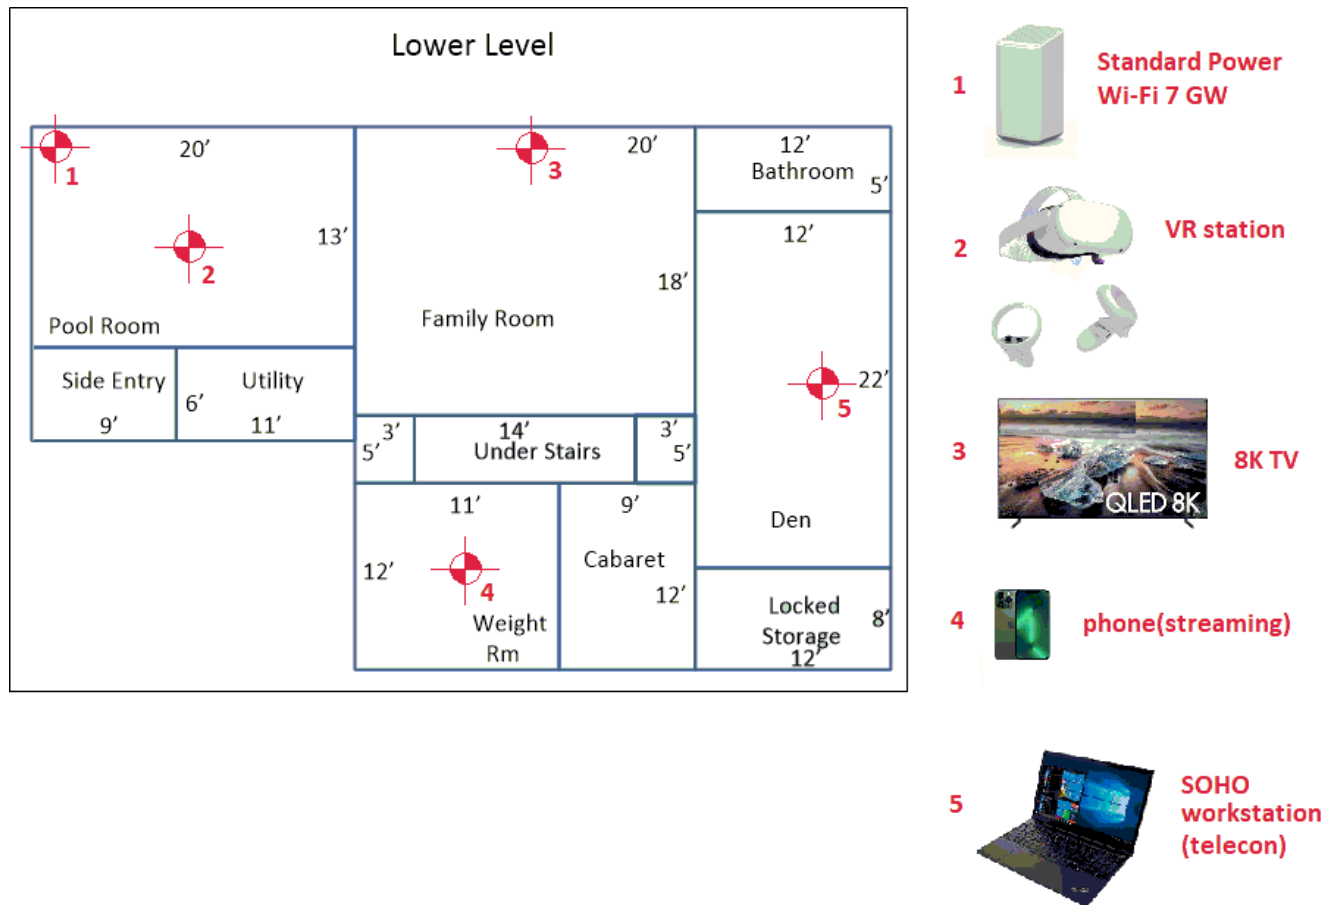

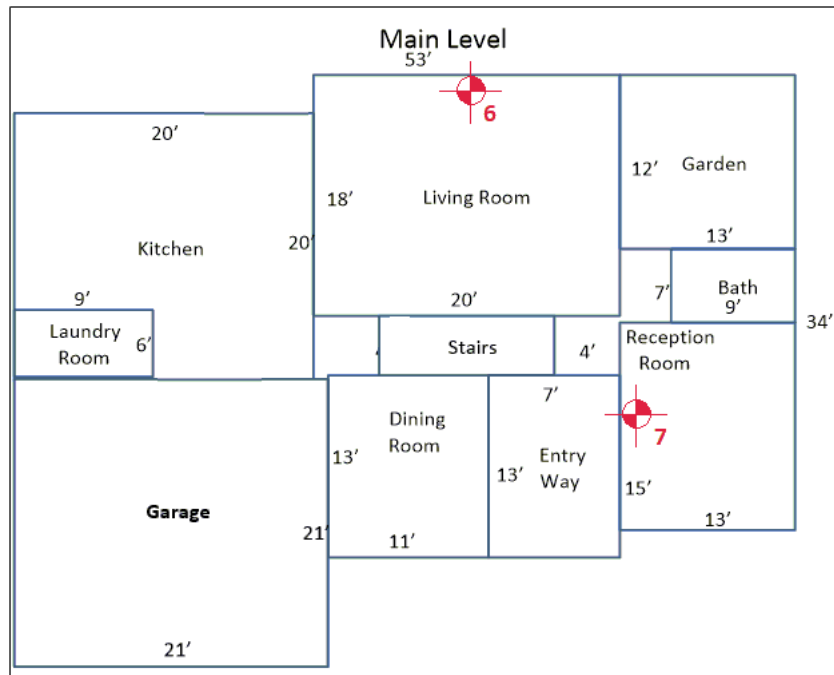

Figure 23 – Wi-Fi House Basement Device Outfitting

6

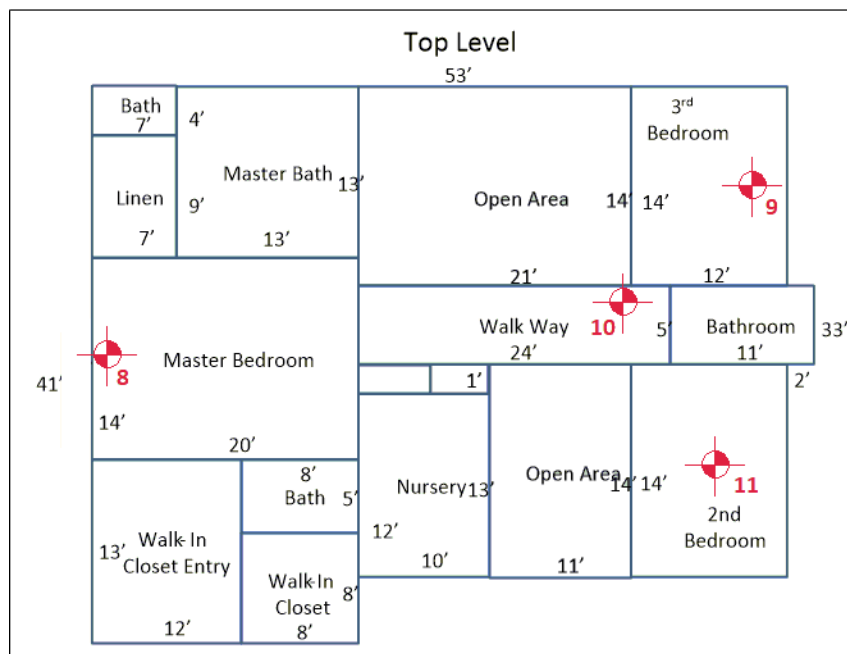

8K TV

7

iPad gaming

Figure 24 – Wi-Fi House Main Level Device Outfitting

8

8K TV

9

Playstation

10

Extender

11

phone

Figure 25 – Wi-Fi House Top Level Device Outfitting

So we can imagine just north of 250 DS Mbps in mounted services, roughly half of which would require the attentive grooming of low latency flow management. In addition to these dynamic client mounts, the home features external security family feeds, internal kiosks for voice command capture and a multi-drop

Thread mesh (for Matter IoT support of automated home security items such as door locks, lighting and garage door control, among others). Note that this latter, alternate-PHY mesh seeks backhaul support via Wi-Fi to the hub (edge) control functions set up in the WAN gateway.

The model home network infrastructure will adopt forward-leaning technologies and so will exhibit a main trunk extension from WAN entry point in the basement game room corner up to the third-floor juncture between the Jock and Jill bedrooms. This will feature a Standard Power and 320 MHz BW channel leverage (at 6 GHz) which will be time-split for attached client MLO/MRU support (essentially dividing client servicing duties with the WAN GW, such split determined by best sustained MCS between AP and client). As all clients will be presumed '11be capable, scheduling behavior will be expected to optimize (minimize) Wi-Fi airtime burn through exploit of appropriate BW in each of the three Wi-Fi bands. Note, however, that for MLO operations, only bonding of 5 and 6 GHz bands will be considered (conservatively capping the available Wi-Fi 7 connections).

5. Performance of the Adjoined Networks

Now we arrive at a discussion of our highly outfitted model home networked to the cloud via its DOCSIS 4.0 WAN wireline attachment. For the purposes of stressing the network attachment, the intention is to array the model with a rather large assortment of Wi-Fi dependent CPE (as described above) and amplify this data aperture by indulging multiple concurrent users with disparate services. We will examine the network behaviors in reverse order, starting with the LAN.

5.1. Stressing the Wi-Fi 7 Home Network

Given the described locations for the types of clients and their respective service mounts, the predicted airtime distribution costs for support of the services array gives us the following:

Device	Location	AP	Path Loss	Link Capacity	Service Bitrate	Service Latency	Service Jitter	Airtime %	Low Latency?
VR station	downstairs pool room	Gateway	10.8 dB	6500 Mbps	100 Mbps	5 msec	2 msec	1.54	yes
8K TV	downstairs family room	Gateway	24.2 dB	5250 Mbps	50 Mbps	250 msec	50 msec	0.95	no
phone (streaming)	downstairs weight room	Gateway	35.5 dB	1800 Mbps*	2 Mbps (up)	15-20 msec	5 msec	0.11	no
laptop (SOHO, teleconf)	downstairs den	Gateway	33.3 dB	2850 Mbps*	2 Mbps (up)	5-10 msec	2-3 msec	0.07	yes
8K TV	middle level, living room	Gateway	33.8 dB	4500 Mbps	50 Mbps	250 msec	50 msec	1.11	no
iPad, gaming	middle level, reception room	Extender	25.5 dB	4950 Mbps	350 kbps	10 msec	3 msec	0.007	yes
8K TV	upstairs, master bedroom	Extender	26.1 dB	4900 Mbps	50 Mbps	250 msec	50 msec	1.02	no
Playstation gaming	upstairs, bedroom 2	Extender	13.1 dB	6500 Mbps	350 kbps	10 msec	3 msec	0.005	yes
phone (streaming)	upstairs, bedroom 3	Extender	18.1 dB	4500 Mbps*	2 Mbps (up)	15-20 msec	5 msec	0.044	no
4SS MLO Trunk (5G+6G)	pool room to upper landing	AP/EXT	35.9 dB	8250 Mbps	52.7 Mbps	< 2 msec	< 1 msec	0.64	yes
Total, Gateway:				*client upstream EIRP limited				4.42	
Total, Extender:								1.716	
Client Bitrate Service					256.7 Mbps				

Figure 26 – In-Home Wi-Fi 7/Standard Power (with Extender) Network Performance

As can be seen, even restricting the Wi-Fi 7 MLO to bonding only 5 and 6 GHz channels (albeit, at 160 MHz and 320 MHz bandwidths, respectively), the in-home network is not at all appreciably taxed by the 256 Mbps worth of mounted client services. And it should come as no surprise that the intermittent demands of multiple security camera feeds and periodic polling of the Thread subnetwork do not impinge on operations in the measurable slightest. The leverage of standard power along with a quad-band Wi-Fi 7 extender amounts to extreme futureproofing; the WAN gateway commits to just over 4% airtime serving all its clients and the 4SS trunk to the upper far end of the home, while for its part the extender located there commits less than two percent of its time transmitting. Note that, excepting the trunk peer-to-peer 4SS link, all other links amount to 2SS connections (given client radio restrictions); and the 3

uplink feeds' bitrate capacities are all bound by client EIRP limitations (battery-driven, in the two phone cases).

These distribution costs seem extremely well controlled. What if we restrict the gateway and extender to only LPI levels at Wi-Fi 7? The following results:

Device	Location	AP	Path Loss	Link Capacity	Service Bitrate	Service Latency	Service Jitter	Airtime %	Low Latency?
VR station	downstairs pool room	Gateway	10.8 dB	6500 Mbps	100 Mbps	5 msec	2 msec	1.54	yes
8K TV	downstairs family room	Gateway	24.2 dB	4500 Mbps	50 Mbps	250 msec	50 msec	1.11	no
phone (streaming)	downstairs weight room	Gateway	35.5 dB	1750 Mbps*	2 Mbps (up)	15-20 msec	5 msec	0.065	no
laptop (SOHO, teleconf)	downstairs den	Gateway	33.3 dB	2900 Mbps*	2 Mbps (up)	5-10 msec	2-3 msec	0.055	yes
8K TV	middle level, living room	Gateway	33.8 dB	3425 Mbps	50 Mbps	250 msec	50 msec	1.46	no
iPad, gaming	middle level, reception room	Extender	25.5 dB	4500 Mbps	350 kbps	10 msec	3 msec	0.008	yes
8K TV	upstairs, master bedroom	Extender	26.1 dB	4500 Mbps	50 Mbps	250 msec	50 msec	1.11	no
Playstation gaming	upstairs, bedroom 2	Extender	13.1 dB	6025 Mbps	350 kbps	10 msec	3 msec	0.006	yes
phone (streaming)	upstairs, bedroom 3	Extender	18.1 dB	2250 Mbps*	2 Mbps (up)	15-20 msec	5 msec	0.089	no
4SS MLO Trunk (5G+6G)	pool room to upper landing	AP/EXT	35.9 dB	6000 Mbps	52.7 Mbps	< 2 msec	< 1 msec	0.88	yes
Total, Gateway:				*client EIRP limited				5.11	
Total, Extender:								2.093	
Client Bitrate Service					256.7 Mbps				

Figure 27 – In-Home Wi-Fi 7/LPI only (with Extender) Network Performance

Note that all considerations are still very well met, with only a slight ballooning in airtime for the two AP devices (certainly acceptable, given that the limits at ~ 5% and 2% are still low single digits). So it appears that, with extender, the use of Wi-Fi 7 at the two endpoints of a trunk link limited to LPI EIRP would still work very well. This begs the removal of the extender, coupled with bumping up the single gateway AP (at the WAN injection point to the home) to Standard Power to see if coverage would still be possible:

Device	Location	AP	Path Loss	Link Capacity	Service Bitrate	Service Latency	Service Jitter	Airtime %	Low Latency?
VR station	downstairs pool room	Gateway	10.8 dB	6500 Mbps	100 Mbps	5 msec	2 msec	1.54	yes
8K TV	downstairs family room	Gateway	24.2 dB	5250 Mbps	50 Mbps	250 msec	50 msec	0.95	no
phone (streaming)	downstairs weight room	Gateway	35.5 dB	1750 Mbps*	2 Mbps (up)	15-20 msec	5 msec	0.11	no
laptop (SOHO, teleconf)	downstairs den	Gateway	33.3 dB	2900 Mbps*	2 Mbps (up)	5-10 msec	2-3 msec	0.069	yes
8K TV	middle level, living room	Gateway	33.8 dB	4500 Mbps	50 Mbps	250 msec	50 msec	1.11	no
iPad, gaming	middle level, reception room	Gateway	38.0 dB	3700 Mbps	350 kbps	10 msec	3 msec	0.0095	yes
8K TV	upstairs, master bedroom	Gateway	41.5 dB	2575 Mbps	50 Mbps	250 msec	50 msec	1.94	no
Playstation gaming	upstairs, bedroom 2	Gateway	42.3 dB	2450 Mbps	350 kbps	10 msec	3 msec	0.014	yes
phone (streaming)	upstairs, bedroom 3	Gateway	47.6 dB	355 Mbps*	2 Mbps (up)	15-20 msec	5 msec	0.56	no
Total, Gateway:				*client EIRP limited				6.3025	
Client Bitrate Service					256.7 Mbps				

Figure 28 – In-Home Wi-Fi 7/Standard Power (no Extender) Network Performance

As can be seen, whole home coverage is still doable – though note the noticeable burn of airtime just to enfranchise the Tik-Tokker in the far upper bedroom. This type of airtime stress will always be the worst – trying to reach a battery-powered device a large distance from the AP and mounting a service thereon which produces upstream data (instead of consuming downstream) – hence being limited to the link MCS achievable with the relatively weak transmitter of the client device.

Still, in all these solution cases, a relatively pathological mix of concurrent services can be mounted and supported by the in-home wireless network built of Wi-Fi 7 componentry. Now the question shifts: can the DOCSIS 4 WAN adequately support these client mounts in reasonably scaled service groups – and of what particular DOCSIS 4 species must we avail ourselves?

5.2. Taxing the DOCSIS Wireline Network

From historical trends, the appearance of a 250 Mbps persistent (and pervasive) home network demand in a DOCSIS service group (SG) is not remotely projected through 2037, based upon current modeling. (Reference ULM et al 2022). Which is not to say it could not exist, merely that capacity planning using present tools has no historical basis to predict the arrival of multiple CPE with bitrate service demands at, or exceeding, 50 Mbps each. This is cataclysmic disruption, relative to present architected capacity and projected bitrate growth; at issue is whether the weighted take-up of these types of bitrate demands within multiple homes comprising a SG produces statistical impact on network service structure before historical trends suggest it might. The best way to judge the scale of this impact, perhaps, is to note that with our present Tav_g value of 3.5 Mbps, UHD TV video consumption (the major single data sink per home in the network) produces SG sizes of perhaps 250 subscribers (with a forward BW of < 1 GHz). 250 Mbps represents an 80-fold increase in persistent home data consumption which would have to be defrayed by the combination of increased BW, denser spectral modulation leverage and smaller service groups. Succinctly, even the most aggressive deployment of DOCSIS 4 would find this an untenable challenge. So a bit less of an impact needs to be bitten off on first chew. (In fairness, nine concurrent users with four huge concurrent service consumers of DS data in a single HH is simply much-too-much of a service stretch example when it comes to taxing the WAN – especially if we claim prevalence in a SG, so we will be more circumspect from here on out.)

To establish a more realistic perspective (and to suppose that even 25 Mbps represented a reasonable Tav_g DS service goal – note the current value is 3.5 Mbps), we can refer to the Cloonan DOCSIS capacity planning tool for the impact to SG scaling. For reference purposes, we will suppose an ESD solution to 1218 Mhz with a diplex split at 204 Mhz. This gives us roughly 1 GHz of forward BW which, if committed to OFDM parsing only (no SC-QAM) at 9.7 bps/Hz, gets us fairly near the magical 10 GBps downstream capacity.

If we further conjure a top advertised SLA of 5 Gbps, the SG scaling is then set:

N_{sub} (the SG size) $\leq (10^9 - 1.2 \cdot 5^9) / 25^6$, or $SG \leq 160$ (if all are at the premium SLA tier – an admittedly unusual occurrence).

This is on the smallish size (range typically varies from 100-400) but at least reads as a very workable number. The 250 Mbps Tav_g, on the other hand, would produce an SG of only 16 under the same spectrum and SLA assumptions. To drive home the difficulty of this proposition, if we instead applied even a full 1.8 GHz DOCSIS network with only a modest diplex split of around mid-UHF (say 400 MHz), we would end up with forward capacity in the region of $9.7 \cdot 800 \text{ MHz} + 8.5 \cdot 600 \text{ MHz}$, or just shy of 13 Gbps. At the same SLA tiering, this would put us at an SG of roughly 28 – still untenable without reworking expectations. Doing so, however – perhaps looking to support a Tav_g of 50 Mbps and top SLA tier of 10 Gbps (a magical enough marketing icon) -- the SG moves to 60 (certainly a reasonable asymptote given that not all subscribers will select the premium tier, and the actual number will push into perhaps the 120+ range).

Without doubt, however, WAN network capacity becomes quickly tested when high resolution simulation environments become the norm on the client side; and the capacity “fat” at this juncture in the distribution network lies almost wholly within the LAN environment.

6. An OTT Sidebar

A brief acknowledgement of competitive (5G) forays into OTT connectivity for residential CPE in the US seems in order, if for no other reason than to inject some compounding considerations which might resolve teetering wireline network strategy decisions. As of this writing, two cellular ISPs have introduced 5G home gateway solutions, one a sub-6 GHz band version and the other a more urban-centric mmWave band variant. Given the full-USA coverage of these MNO/ISPs, it implies that both urban and suburban customers are to be granted immediate (as opposed to fiber's buildout-paced) access to premise internet coverage (as a 5G/Wi-Fi composition) which also exposes cable video consumption to co-option via streaming services.

Cable MSOs have carefully marked – and reacted to – telecom rollout of fiber. With fiber's pitch of symmetric 10Gbps connectivity (despite a lack of evidential service need for such BW) and further marketing forays into 25 and even 50 Gbps service tiering, cable has dutifully ramped up development of FDX DOCSIS 4.0 to at least place a bookmark in the derby for bragging rights to what – to-date -- may be called an unreasonably thick data pipe to the residential home. But competition for network connectivity bargains (and perhaps more concerning, in lower tiers of QoS) is already everywhere to be found, courtesy of OTT plays.

The appeal in both OTT cases lies in mining interest among these ISP budget-aware shoppers. The sub-6 GHz solution, for example, features a lowest bitrate tier which produces roughly 150 Mbps down/30 Mbps up with 25 msec latency inclusive of one Wi-Fi hop (one floor vertical) off of the modem for around \$50/month (the modem being a GW device which provides dual-band Wi-Fi coverage to the premises). Via contractual agreement for a couple of years, such attachment can produce similar performance at half that subscription rate. A typical midafternoon Ookla SpeedTest sample follows:

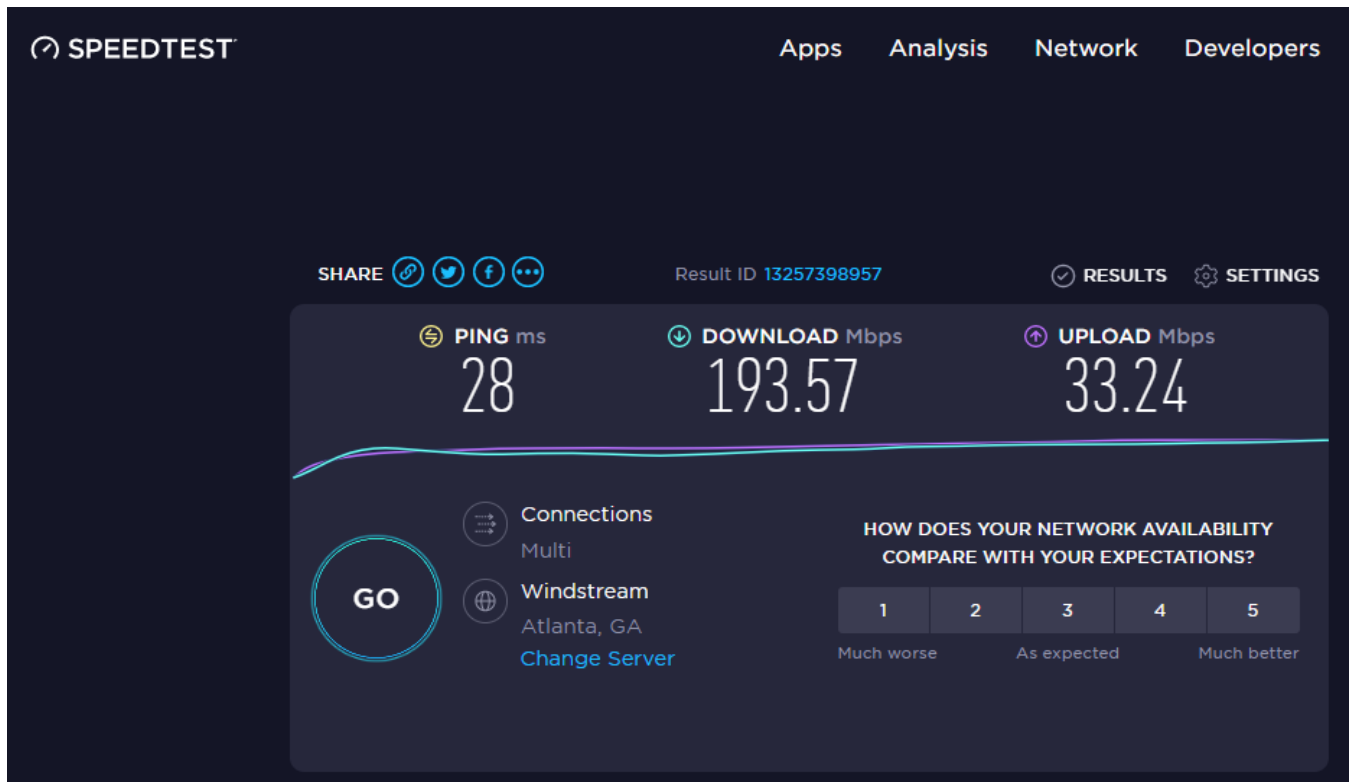

Figure 29 – Mid-day, one Wi-Fi hop OTT modem performance

In MDU and small home scenarios (with perhaps only 2 active Wi-Fi devices concurrently operating), such an arrangement can be seen to provide perfectly adequate internet connectivity, with the benefit of a single point of contact for both phone and network support and logistics. Awareness of this potential for internet fulfillment at less than eye-popping performance numbers ought to serve as a cautionary reminder to not ignore lowest QoS/bitrate markets, as opportunistic competition stands prepared to infiltrate same.

7. Conclusion

As has been shown, Wi-Fi premises bitrate budgets are much more than adequately covered for the near (and coming) term; even pathological, simultaneous adoption cases for extremely high resolution and high frame rate video displays are easily accommodated by home Wi-Fi emerging MACs during the coming five years. With proper leverage of low latency planning and scheduling tools – applied synonymously across the concatenated networks -- immersive simulation environments at modest resolutions can be created which suitably interdict artifacts in the constructed virtual domain(s) and facilitate mounting of rich gaming and instructive services. And there does not yet appear to be widespread adoption of an application or service which swamps the up- or downstream user bitrate flows over home Wi-Fi to the extent that inadequate QoS could be asserted; the home LAN, it seems, is extremely well positioned for all anticipated service mounts.

Packet latency conditioning seems acceptably met in both domains, with LLD capable of dual-piping the WAN and both WMM and buffer congestion management (by virtue of highly flexible scheduling) dissolving any congestion clots within the LAN; married, the E2E performance advertises itself to easily meet sub-20 msec type of E2E latencies just across these networks.

When it comes to raw bitrate, however, WAN prep seems perhaps not congruent with immediate market acceptance of high resolution, high scan rate immersive simulation environments becoming the sudden norm. If this type of precipitous advance in simulation entertainment occurs, then a stepped two-orders-of-magnitude increase (from a *sustained* sub-10 to multi-hundred Mbps) in on-premises average downstream bitrate demand will transpire and network capacity will be challenged as never before -- perhaps tainting even planned 10G/10G FTTP with an “inadequate” QoE estimation.

It's a gambler's paradise, perhaps; truly immersive entertainment options challenge the average home entertainment budget and so might be expected to suppress rapid adoption of the most compelling of lean-back media environments. We have been 8K-capable and pending appropriate source material for several years now, after all – granting WANs some respite in the process. And the CAPEX for system upgrades begs a lag-lag type of adoption curve, certainly. But the penalty for substandard network data support of high-end CPE involves an experiential litmus test which will be difficult to spoof if the long-awaited video nirvana does, in fact, take root. And, to be sure, just as the in-home distribution infrastructure of a very near adoption horizon seems easily capable of underpinning these viewing and gaming experiences, the wireline WAN which most commonly serves it seems, as-yet, resolutely under-capable.

Why, How, and Where to Converge Fixed and Mobile Networks

Bob Hallahan
Global Head of Cable Strategy
Nokia

AGENDA:

- ✓ Introduction
 - ✓ Current state of cable fixed and wireless networks
 - ✓ Drivers of convergence
 - ✓ Cable moves to 5G, and problem to be solved
- ✓ Why you should converge fixed, and wireless networks
- ✓ How to look at convergence
- ✓ Where and how to converge to achieve maximum value
 - ✓ Converging MVNO with cable 5G MNO Cores
 - ✓ Using the access gateway function (AGF) to converge broadband
 - ✓ Converging fixed and wireless voice services
 - ✓ Using a 5G adaptive core to achieve access network agnostic service delivery
- ✓ Why converging networks requires a new approach
- ✓ Summary

- Current State of Cable Fixed and Wireless Networks
 - **Network Centric Service Access:**
 - Fixed and wireless networks have historically been built with separate access, cores and OSS, making the job of managing and assuring services and customers experience in near real time exponentially more complicated and costly as services begin to span networks.
 - Services are not easily accessible seamlessly across network access technologies today

- Drivers of Convergence

- **Bundling:** Services and applications are becoming more bundled and agnostic to network access technology
- **Network Agnostic Services :** Network services need to be decoupled from the network access, to enable network agnostic delivery through a multitude of access technologies, devices, and locations with mobility at the center.
- **FMC (Fixed Mobile Convergence) :** The Distinction between fixed and wireless access will be blurred into a seamless blended access capability.
- **Improving Opex :** Initial driver behind network convergence in 2022 and beyond will be the need to offload wireless data from the MVNO 4/5G MNO network on to the MSO's 5G network
- **Market pressures and Digital Divide :** FWA (Fixed Wireless Access) Broadband with OTT (over the top) applications and content to out of network footprint residential and business customers, and Government subsidized network builds (RDOF)

- Cable Moving to 5G problems to be solved
 - **Cable Goes 5G :**
 - Deploying 5G networks is further complicating the need to manage access to Fixed/Wi-Fi, MVNO, 5G, Private, and partner networks.
 - Managing service assurance, reliability, quality, devices, and customers experience as service access becomes networks agnostic and devices are intelligently switching networks.
 - **Reducing complexity and cost:**
 - With the advent of 5G service oriented open architecture, it is now possible to eliminate redundant network and OSS functions and costs, while achieving service and device network access agnosticism

Why you should converge fixed and wireless networks

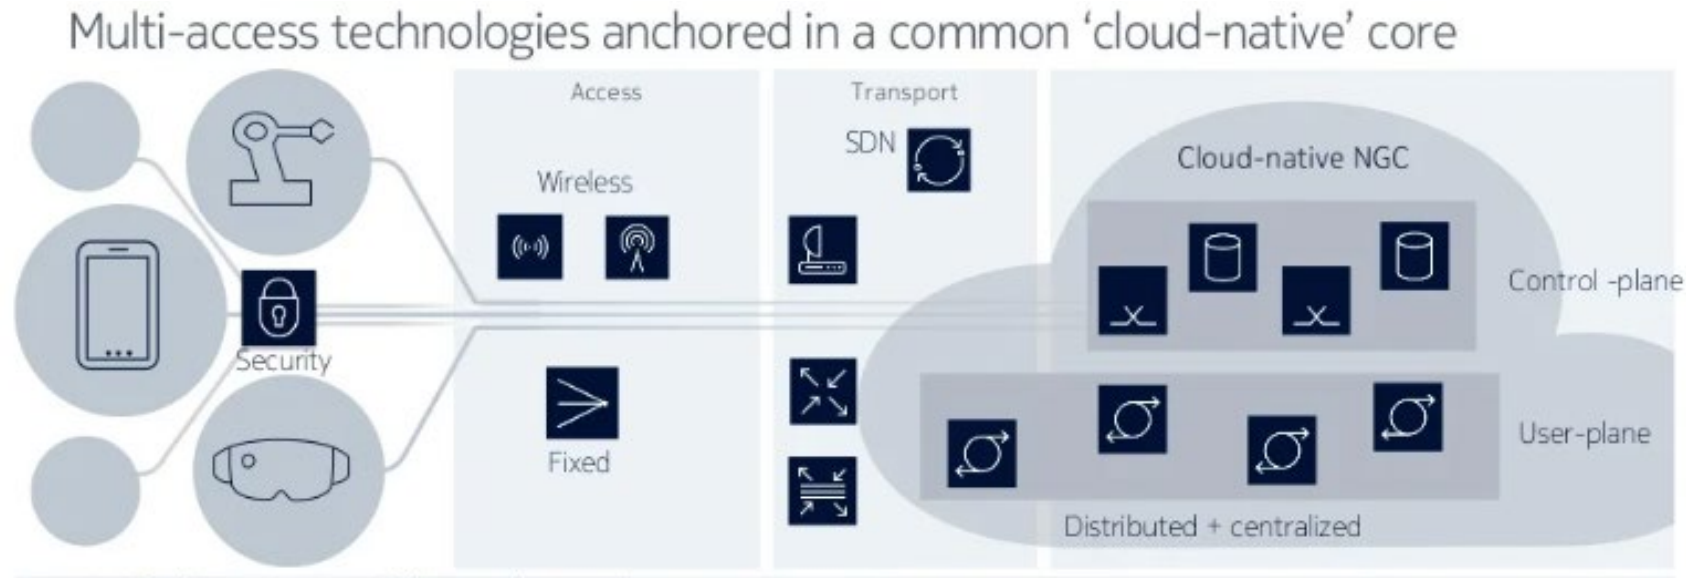

- **Understanding the Benefits of Convergence**
 - **Improve Opex** : Reduce high level of redundancy, cost and complexity in common converged layers
 - **Improve Service Quality** : Seamless service control and resilient continuity for all devices Improving ability to assure service quality and customer experience resulting in reduced churn and increased revenue, loyalty, monetization and retention.
 - **Improve Top/Bottom Line** : New Revenue generating opportunities in the enterprise market for converged private wireless, and the delivery of low latency applications at 5G speeds.
 - **Fast TTM** : In the Residential market it means for example new revenue streams from cloud gaming at the edge accessed through 5G slices, 4/5G MVNO and Wi-Fi seamlessly

How to look at Convergence

- **Agnosticism:** Cable fixed and wireless services and applications should be agnostic from the network access types fixed or wireless
- **The COREs :** Stitching Cores together enables session and management continuity, and moving to a universal adaptive core enables optimal convergence.
- **The Data :** Enabling fixed and wireless network operations to create and measure a universal set of KPIs (key performance indicators) will require a common shared data layer (SDL) containing an aggregated blended set of operational network data from Wi-Fi, 5G SA, MVNO, DOCSIS, PON, for all services under a single management umbrella.
- **B/OSS :** Fixed and Wireless OSS/BSS systems can be normalized via convergence of specific O/BSS functions to support multiple network and access types enabling Network agnostic customer experience management (CEM), Device Management (DSDS, eSIM/iSIM, and common service profile, entitlements, policy and assurance management.

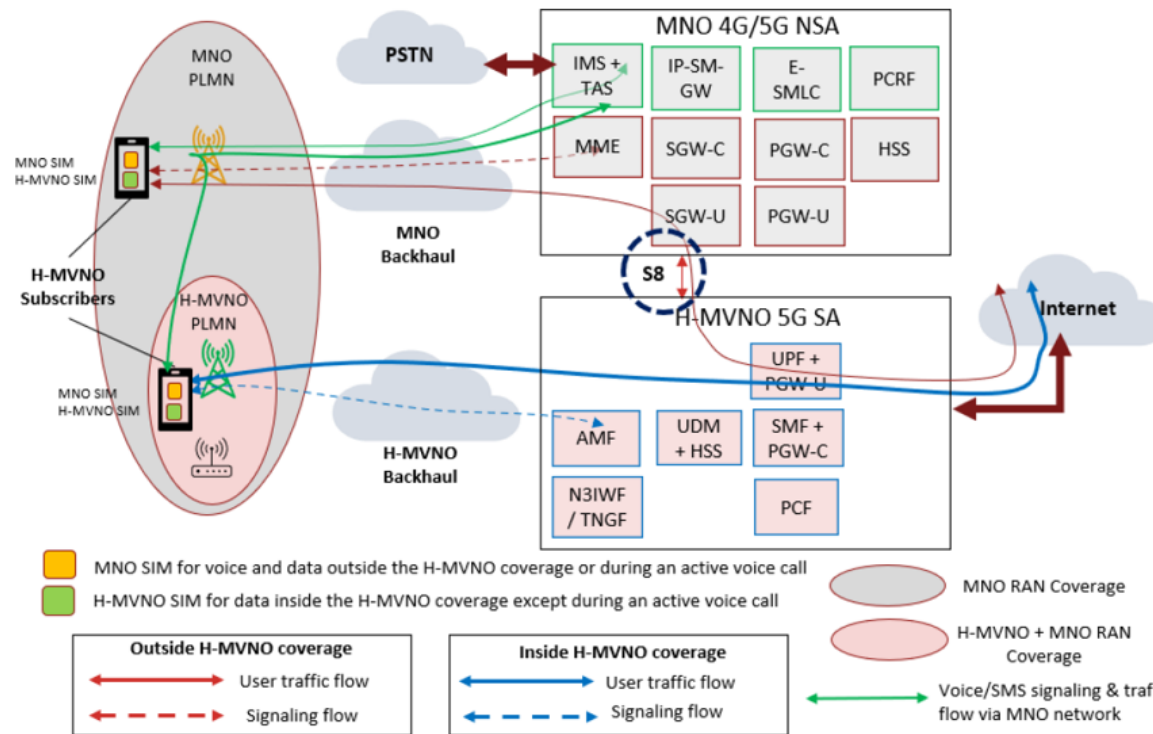

- Where to Converge for maximum Results and Value
 - **Convergence between the Cores**
 - Converging MVNO and MNO 5G Cores
 - Thin vs Thick MVNO models, enable “more knobs to turn”
 - Using AGF to Converge Data services Wi-Fi and 5G
 - Converging Fixed and Wireless Voice at the IMS Core
 - Achieve access network agnostic service delivery via universal adaptive core
 - **Convergence at the Data Layer**
 - Leveraging SDL to optimize network agnostic service access
 - **Convergence at the B/OSS layer**
 - Service Assurance Profiles and entitlements
 - Customer service experience Insights

- **Converging Fixed and wireless network Cores enables..**
 - Unified Session, mobility, and security management
 - Multiple simultaneous connections
 - e2E policy Service Profile management
 - Enhancing service QoS with core automation
 - Converged common multi technology transport layer

Where and how to converge to achieve maximum value

- Converging MVNO with Cable MNO 5G Cores

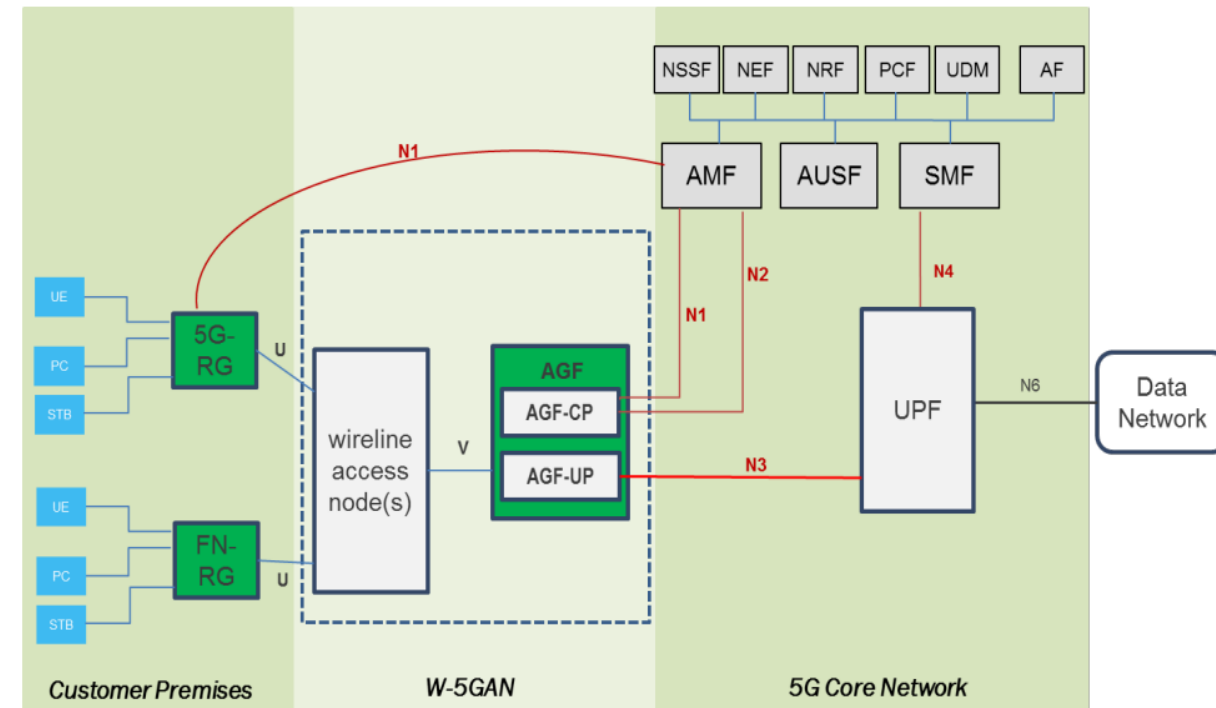

Recommendation from CableLabs using the S8 interface between SGW-U and the UPF/P-GWU to maintain session control and management.

Figure shows MNO network to be a 4G/5G NSA, but the architecture also applies to a scenario where both MNO and H-MVNO networks are 5G SA
The core network elements shown within the MNO and H-MVNO networks will use standardized interfaces

2021 SCTE Fall Technical Forum : Evolved MVNO Architectures for Converged Wireless Deployments

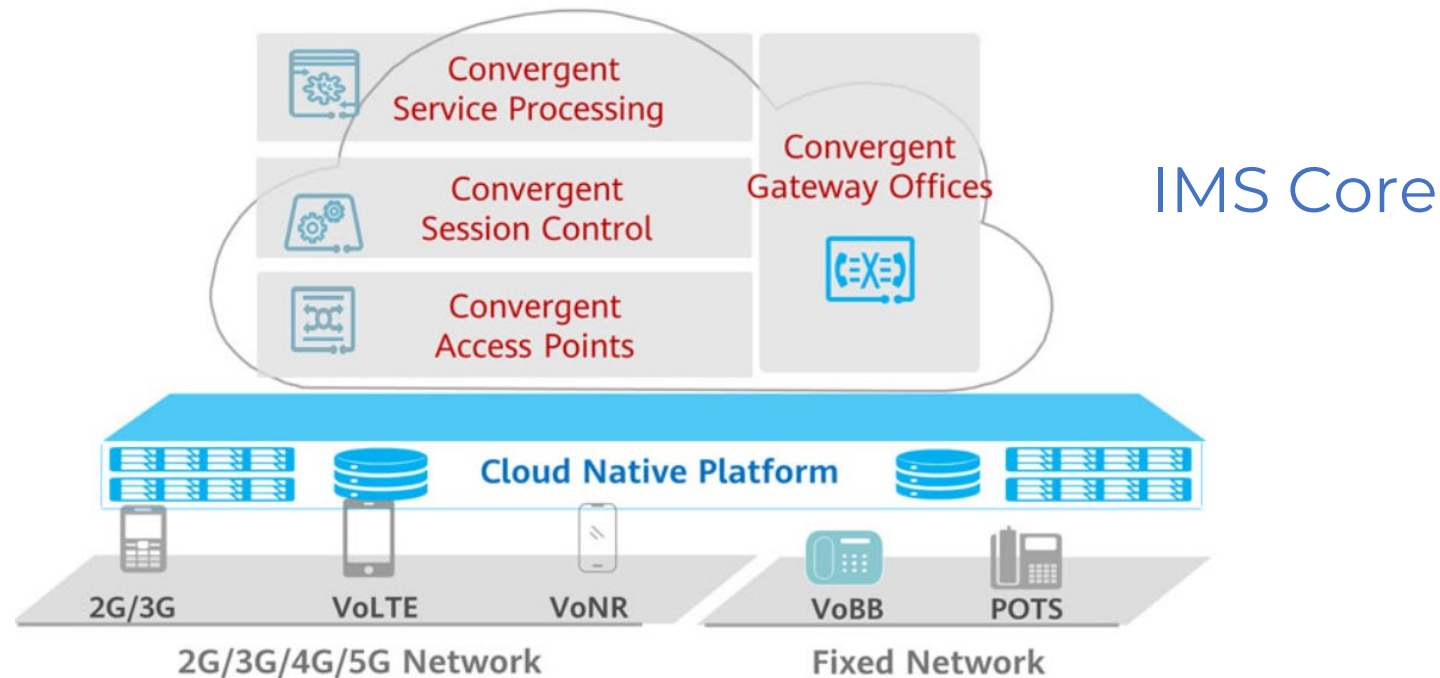

Where and how to converge to achieve maximum value

- Using the access gateway function (AGF) to converge broadband
- One of the main points of convergence is where devices access the networks.
- A key network function which enables fixed and wireless convergence is the access gateway function (AGF),
- The AGF controls network access for fixed networks to the 5G core, and is critical to the success of any network convergence initiative

Where and how to converge to achieve maximum value

- Converging fixed and wireless voice services
 - Convergence should be achieved at the IP Multimedia Subsystem (IMS) core level to bringing together wireline and wireless voice services across all access networks, which will enable centralized management and control of voice services access thru and spanning fixed and wireless networks.

Where and how to Converge to achieve maximum value

- Using an Adaptive Core to enable network access agnostic service delivery

Future Evolution to 5G Universal Adaptive Core
Flexibility to deliver any service over any access

Fixed-Mobile Convergence

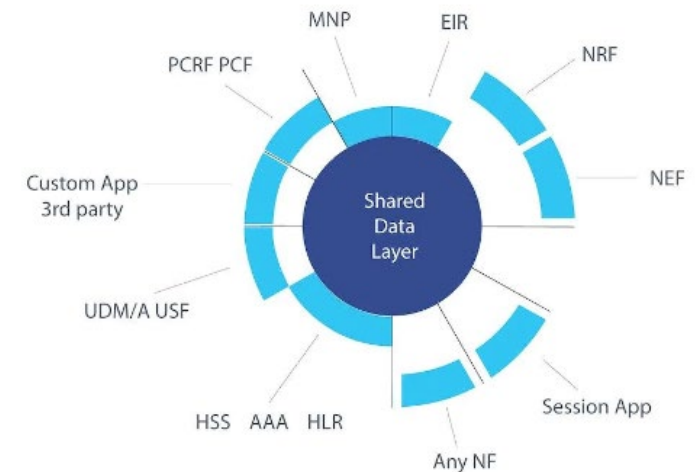

Fixed-Mobile Access Gateway

- Common SMF for fixed-mobile converged interworking
- UPF Packet Forwarding Control based on 3GPP Sx/N4 interface
- Dynamic UPF selection based on APN/DNN
- 5G services over any access!

- New services will require complete “connectivity agnosticism” with subscriber expectation of seemingly infinite service quality and ubiquitous connectivity.
- Enabling a massive scale in access, coupled to an evolved converged core, or new universal adaptive core control function that provides seamless service control and resilient continuity for all devices and associated flows..

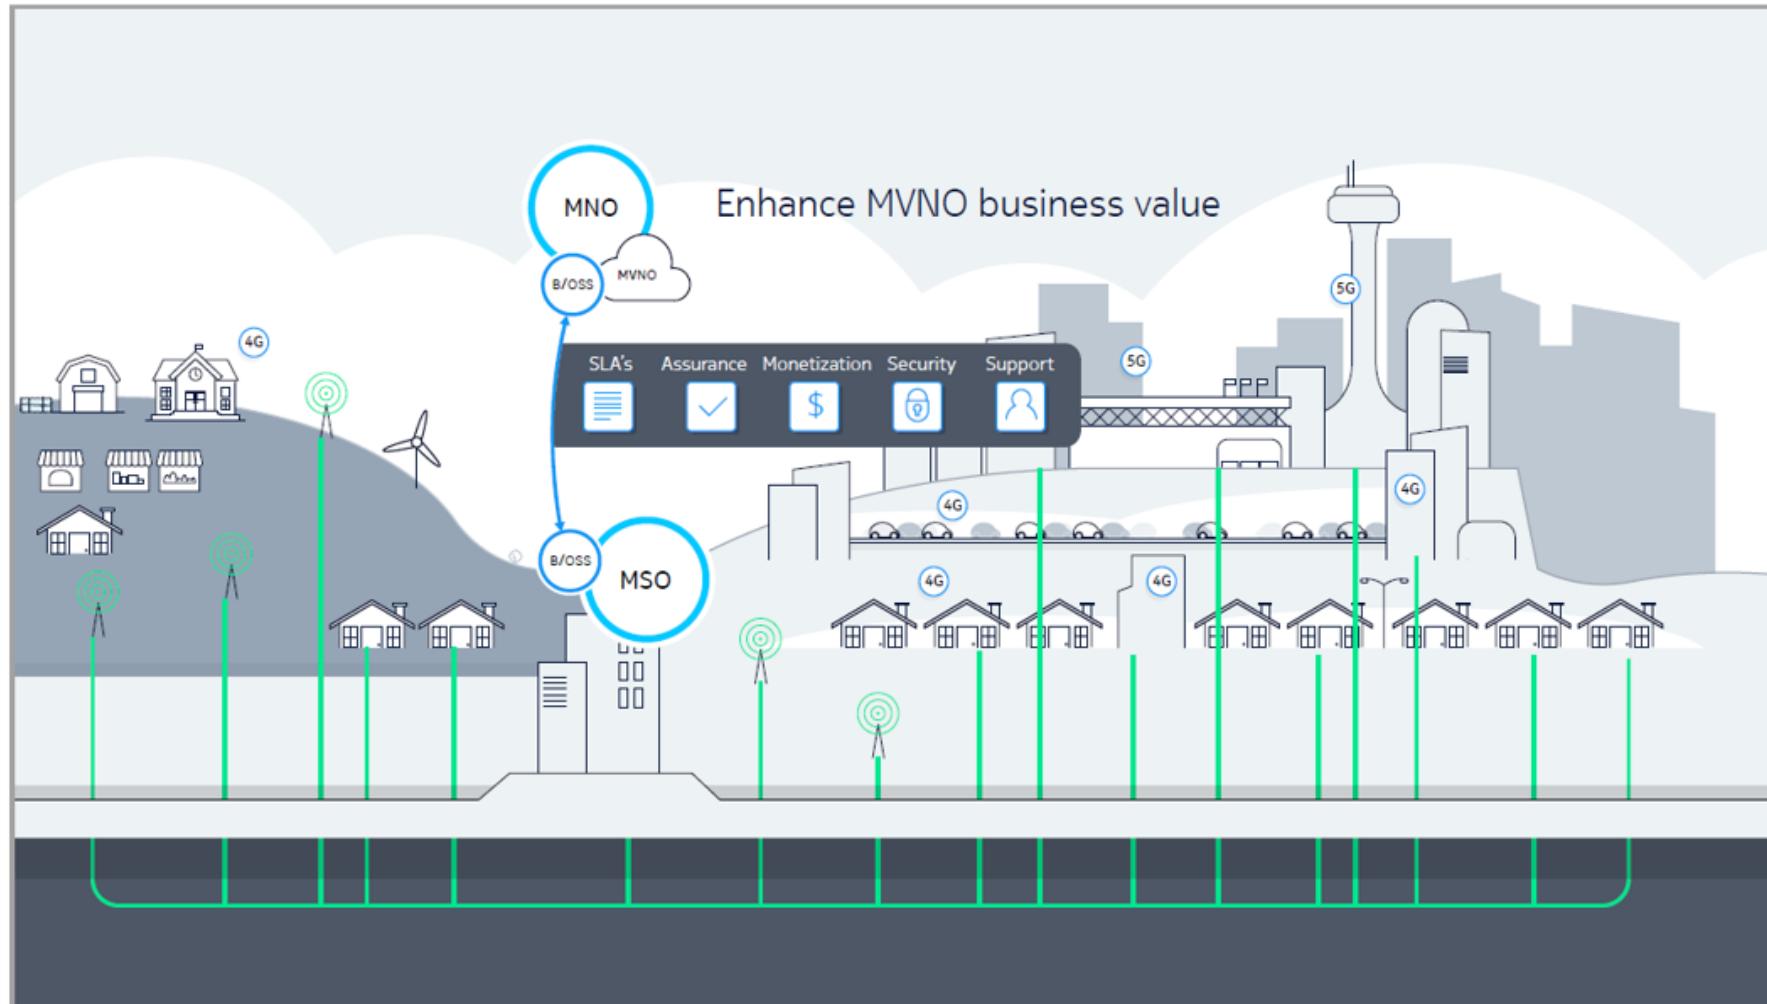

Why Converging networks requires a new approach

- Convergence of network and user data
 - Achieving the right convergence of fixed and mobile networks will mean rethinking the way you currently collect, aggregate, and normalize service and experience data from different access networks
 - Leveraging a User Data Repository (UDR) eliminates data redundancy, error, complexity and operational inefficiencies
 - The shared data layer (SDL) will enable optimal fixed wireless convergence of network and subscriber data

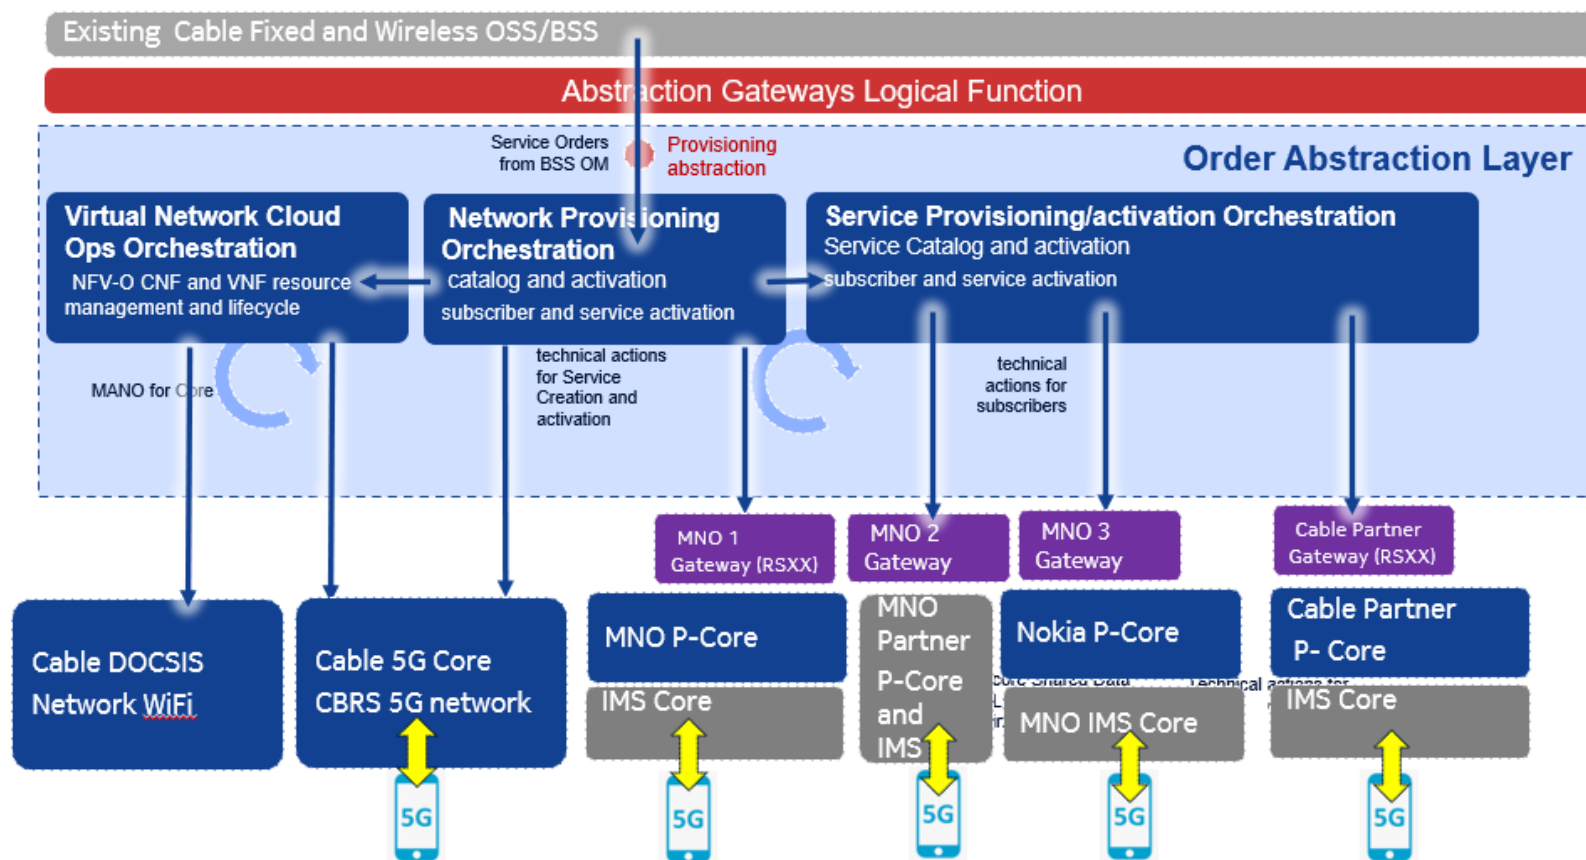

Why Converging networks requires a new approach

- Getting a converged view of subscribers on multiple networks

Why converging networks requires a new approach

- Simplifying Order management for multiple network service access

- **Not all convergence is the same** : Cable operators with multiple Fixed and Wireless networks will need to execute the right convergence architecture to offer, manage and assure network agnostic services
- **True Network Agnostic Services** : Customers will expect to access services and applications regardless of the countless dynamic handoffs which will occur between Wi-Fi, MVNO 4/5G, and CBRS 5G core and RAN owned or partnered.
- **Isolate Current Complexities** : An affective strategy is isolating B/OSS and normalizing network and subscriber data of current fixed and networks from services, devices to enable universal customer experience and situational awareness.
- **Its Convergence at the Network, Data and IT that counts** : Converging at the right points across multiple Cores enables an aggregated umbrella management architecture to provision, activate, assure, control, and measure customer experience via analytics insights, while enforcing entitlements, managing devices, service profiles and policies of services for customers across all fixed and mobile network domains.

Creating Infinite
Possibilities.

1. Introduction

Wi-Fi sensing uses functionality already present in Wi-Fi radios to detect motion. The immediate use cases for home security are certainly valuable by themselves, but the future of sensing holds immense promise for elder care, aging in place, advanced medical applications, IoT control, immersive gaming, and more. Imagine being alerted to a change in behavior of a remote relative, or even potentially detecting a fall or other life-threatening condition. Imagine a doctor being able to have real-time information about a patient's breathing or heart rate - all with the patient comfortably at home with no expensive, dedicated medical hardware. Imagine these solutions not requiring a professional installation, relying solely on the devices already deployed in a customer's home. This paper covers the base technology behind Wi-Fi sensing, current applications, deployment best practices, and near-future use cases.

2. Wi-Fi Sensing Technology Overview

Wi-Fi sensing is the ability to detect motion inside an area covered by Wi-Fi. Current implementations use Channel State Information (CSI) to detect this motion.

“CSI characterizes how wireless signals propagate from the transmitter to the receiver at certain carrier frequencies. CSI amplitude and phase are impacted by multi-path effects including amplitude, attenuation, and phase shift. Each CSI entry represents the Channel Frequency Response (CFR)”

$$H(f; t) = \sum_n^N a_n(t) e^{-j2\pi f \tau_n(t)},$$

where $a_i(t)$ is the amplitude attenuation factor, $\tau_i(t)$ is the propagation delay, and f is the carrier frequency” [1].

In short, CSI is the sum of all information needed by an access point (AP) or station (STA) in order to decide how best to transmit a wireless frame. In a completely static environment (e.g., an AP and a STA in a shielded chamber – see Figure 1), CSI should have extremely low variability, as all direct and reflective RF paths are constant and there are no external interferers. In this simplified example, CSI is on a scale from 1 to 10, with 10 being perfect signal conditions.

Figure 1 – RF Shielded, static environment, demonstrating constant CSI

If a person were to walk through this chamber (Figure 2), these RF paths would encounter attenuation, reflection, etc., thus affecting the CSI. By observing the changes in CSI on the receiver, one can infer motion.

Figure 2 – RF absorption of a human walking through the environment causes changes in CSI

Wi-Fi sensing relies on significant Wi-Fi utilization over multiple devices. It is not currently good enough to have a single AP and a mobile device to enact sensing. An “ideal” residential deployment would have several static APs and STAs (e.g., smart speakers / Wi-Fi doorbells / Wi-Fi thermostats) deployed at the boundary of the coverage area. Mobile devices within this area currently cannot participate in sensing, other than to provide a user interface for configuration or motion reporting.

2.1. IEEE 802.11bf

Current Wi-Fi Sensing deployments, while based on 802.11 standards, are all unique in their implementations as the process for turning CSI information into inferred motion is proprietary. The IEEE has formed a task group to standardize sensing. This will be a critical step in helping wide adoption and has the potential to include moving STAs into the sensing cluster. Additionally it will enable a cross-platform mix of devices to participate seamlessly.

“Task Group bf is expected to develop an amendment that defines modifications to the IEEE 802.11 medium access control layer (MAC) and to the Directional Multi Gigabit (DMG) and enhanced DMG (EDMG) PHYs to enhance Wireless Local Area Network (WLAN) sensing (SENS) operation in license-exempt frequency bands between 1 GHz and 7.125 GHz and above 45 GHz.

This amendment enables:

- *Stations to inform other stations of their WLAN sensing capabilities*
- *Request and setup transmissions that enable WLAN sensing measurements to be performed*
- *Exchange of WLAN sensing feedback and information” [3]*

Draft 0.1 for initial comment collection was released in April 2022, and final 802 EC approval is scheduled for July 2024.

3. Wi-Fi Sensing Use Cases

The uses cases listed below are presented in chronological order from where we are today, to where this technology could take us in the future.

3.1. Home Security

Home security is the simplest implementation of Wi-Fi sensing, as it merely detects some level of motion in the coverage area. While it will be the most basic use case described here, it is not without significant challenges – primarily in false signal detection. These include:

- Fans, robotic vacuums, or other household devices that move on their own
- Pets
- Outdoor motion (e.g., a tree on a windy day)

Addressing these false detections is achievable. Fans and devices with consistent repetitive motion can be identified and filtered out. Most pets will have a much lower effect on CSI than a human, so a minimum motion level could be set. Outdoor motion can be an issue but could also be useful in the proper context. For example, outdoor motion on the second floor of a house may be ignored, while outdoor motion on the ground floor could trigger an alert as a possible trespasser.

3.2. Aging in Place

The next evolution of Wi-Fi sensing will address aging in place, which is the ability for people to retain independence and stay in their homes for longer than is currently possible. There are currently 5.8 million people over age 65 in the United States with Alzheimer's or related dementias [2]. These diseases are progressive in nature, with increasing levels of care needed the further along the person is. Technology designed for aging in place can help delay the transition to memory care facilities by offering minimally invasive remote monitoring by a relative or healthcare professional. Several specific uses for Wi-Fi sensing include:

- Fall detection
- Sleep monitoring
- Lack of motion alerts
- Boundary crossing alerts

3.3. Advanced Medical Applications

Wi-Fi sensing is also being developed for dedicated medical applications, beyond the residential deployments covered above. Heart rate and breathing detection have already been shown as achievable, but these have deployment considerations that initially make them only appropriate for controlled environments. For example, envision a hospital bed with an AP on the ceiling above the patient and a STA directly beneath them on the floor. These APs would not be used to service other non-medical STAs and would exist as a separate network from anything providing data services.

While this level of medical application is only possible today in a specific healthcare environment, Wi-Fi sensing technology should advance to the point where these same services are achievable in the home.

3.4. Future Innovations

We've only begun to glimpse the full potential of Wi-Fi sensing, as we're only in the very first years of innovation. And considering there are over 20 Billion Wi-Fi devices deployed today, there's an incredible base upon which to develop new uses for Wi-Fi sensing. The following represents a small sample of what is technically possible.

3.4.1. Gesture Sensing

As seen in section 2.1 above, the 802.11bf task group is working to enable sensing at frequencies above 45 GHz. In this range, gesture recognition becomes possible at very small motion ranges. We've seen advances in IoT control where most home devices can be controlled with a voice command, and sensing will enable an even more natural level of control. If you want all the lights off in a room, just gesture towards the light switch as if you were turning it off.

3.4.2. XR Integration

The natural evolution from gesture recognition is full XR (AR/VR/MR) integration, without the need for on-body sensors or dedicated tracking systems. This will increase immersivity while decreasing hardware costs and battery utilization, making XR systems lighter and more powerful. Potentially, the only hardware needed would be the head-mounted display (HMD).

4. Conclusion

Wi-Fi sensing represents a paradigm shift in how we leverage existing and future Wi-Fi deployments. Home security applications available today are just the very beginning. The biggest impacts will be in home healthcare, granting more independence and a better quality of life for far longer than ever possible before. On top of home and health, the potential value to entertainment markets is enormous, and the field for not-yet imagined sensing innovations is limitless.

1. Introduction

The coaxial network that is the backbone of the Cable Broadband industry was designed with a simple, ingenious powering scheme that allows multiple “actives” to be powered from a single point of connection to the utility grid. This tried-and-true powering strategy allows operators to minimize their points of interaction with an unpredictable utility grid and create a more reliable HFC grid to power network actives that support customer connectivity.

However, unlike the utility grid, the coaxial network’s primary functions are both optimizing the flow of data to customers and transporting energy. As we continue to move toward 10G and beyond, exponential progress has been made in speed and volume of data that can be delivered over HFC, often by developing new architectures that increase dataflow with only minimal increases to power. But, as our industry seeks to be more sustainable and reduce operational energy spending, what should we be doing to improve power usage efficiency? Are there network efficiency gains that can be applied to all architectures to reduce energy usage and further improve the amount of data per dollar that the network can deliver?

This paper will first give a brief overview of network powering as we move toward 10G and beyond to understand the urgency of developing more efficient network powering. From there, the goal will be to map the power consumed by the network from the point of connection to the utility, through every transition point where the energy is transformed, transported, split, or ultimately consumed, to identify where energy is being used without creating value for customers. Finally, with our map in hand, we will discuss where efforts can most effectively be applied to reduce energy consumption and associated cost from the Access Network.

2. Powering Challenges into the Future

One operator recently commented that their outside plant (OSP) coax installed in the 1980s will meet DOCSIS 4.0 performance requirements with only passive component upgrades (splitters and taps). Similarly, OSP powering elements such as enclosures, power inserters and ferro-resonant transformers can function for decades. And while OSP power electronics and batteries will require expected periodic replacement resulting from normal use, the components that currently comprise coaxial network can support network demand into the foreseeable future. The question that needs to be addressed is how the OSP network can deliver power to the network more efficiently and sustainably. To fully understand the impact of the OSP on overall industry power usage, the SCTE Energy 2020 subcommittee recently updated the “Power Pyramid” showing that OSP power usage makes up nearly half of the overall consumption in the Cable Broadband industry.

Figure 1 - Cable Operator Power Consumption Pyramidⁱ

The urgent need to increase power efficiency is inherently connected to not only an understanding of the past and present of the HFC network, but also the future. The trek to 10G requires us to understand what the network of tomorrow will look like in order to plan for optimum power efficiency. Access network evolution has created unique powering challenges that must be addressed to assure that network powering upgrades will endure for decades to come. Let's review some of our powering challenges from the lens of the evolving access network with some help from CableLabs.

2.1. Powering 10G Vision

The CableLabs 10G initiative is the catalyst behind several technology innovations designed to deliver future proof internet speeds up to 100 times faster than most consumers are experiencing today. 10G aims to provide 10Gbps symmetrical, secure, low latency data services. 10G innovations will affect every aspect of the broadband network including headends, the access network and the customer's premises. The access network specifically must undergo enhancements to support new performance levels. Underlying technologies used to move network performance towards and beyond the 10G vision requires power. Assuring the availability of additional, reliable, and intelligent power for the 10G capable network is both essential and challenging since network architectures are evolving and much of the 10G enabling technology is still being developed. To approach this dilemma, let's review the 10G architecture vision as it exists today to ensure we're planning the appropriate powering infrastructure to support this near-future vision. For our 10G powering discussion, refer to this CableLabs 10G network architecture shown in Figure 2.

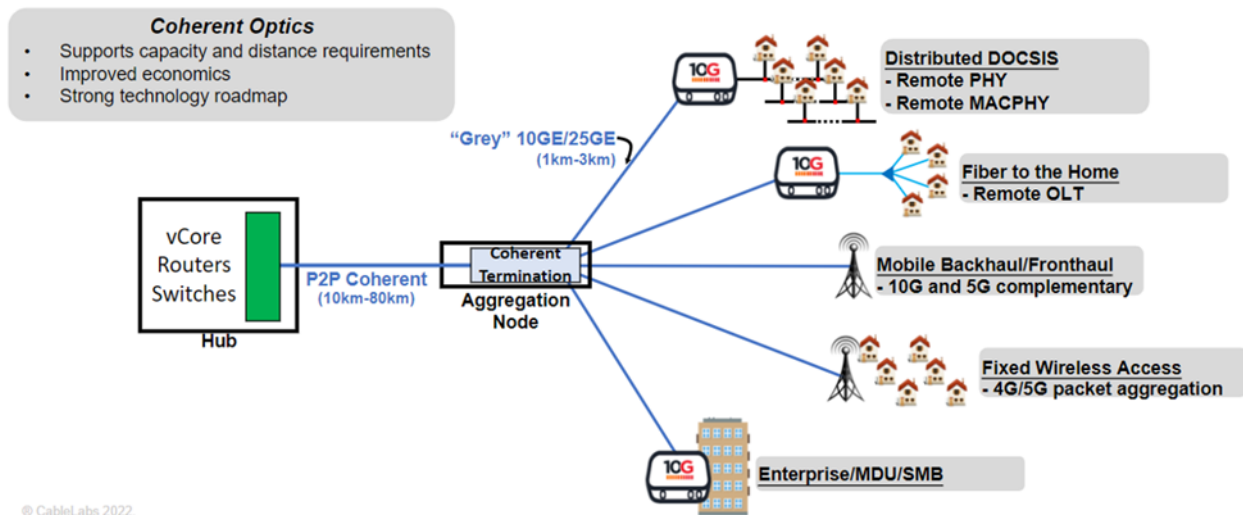

Figure 2 - Diagram of the Access Network in the near future

This near-future network contains several new concepts all combined into a single diagram. Let's review these network elements through the lens of power.

Aggregation Node: Fiber leaving the headend is routed to a new network component, the aggregation node (AN). In this architecture, new high speed fiber communications are pushed deeper into the network by use of high-speed coherent optics between the hub and the new AN. This link could be 50Gb, 100Gb or faster. The AN will act as an optical Ethernet switch providing 10Gb (or higher speed) optical links to downline elements such as DAA nodes and OLTs. The result is higher capacity services deeper into the network and closer to subscribers. From a powering vantage point, we've simply added another remote active element to the mix. Although the AN concept is new, one likely implementation would be a clamshell enclosure with fiber ports for upstream and downstream links, with a traditional node power port connecting to a standard 90VAC HFC power source. Once AN units begin to be deployed, power requirements will need to be analyzed. Given today's state of coherent pluggable modules combined with known high-speed switching elements, we anticipate that the AN may require approximately 200W in a fully configured state. This estimate remains highly speculative until actual architectures using AN prototypes are deployed.

DAA Nodes: Today's DAA nodes are fed from 10G Ethernet backhaul. Future DAA nodes may utilize 50G, 100G or faster backhaul links from an AN. These higher capacity links would be implemented using pluggable coherent optic modules. DAA node outputs support four DOCSIS 4.0 RF QAM channels over coax. Future looking, fully loaded DAA nodes may approach 180W power requirements.

R-OLTs: PON networks are deploying at increasing rates. The RDOF initiative is contributing this increase. Today's strand-mount R-OLTs support up to 512 subscribers using either 10G-EPON or XGS-PON protocol. Higher speed PON architectures are being discussed. 50Gb coherent optics support is planned for next generation PON implementations. Current R-OLT units can consume up to 140W. Future 50Gb PON R-OLTs will likely require up to 165W.

Wireless Backhaul: Wireless backhaul for 5G using the existing HFC infrastructure is expected to grow significantly in the near term as 5G scaled rollouts continue to increase. Coax powered radio units (RU), access points (AP) represent a significant incremental power draw to the coax plant.

Enterprise/MDU: high-capacity enterprise applications as well as large MDUs have historically used P2P dedicated optics for backhaul. DOCSIS 4.0 may be used for many new commercial applications when coax already exists in the region. New ANs providing P2P services or utilizing 10G or 50G PON to commercial and MDU customers are anticipated in the future.

Having this vision in mind of the near-future HFC network and its ability to support the data and backhaul demands for 10G and beyond, let's now discuss how to make the future more energy efficient.

3. Power Mapping the HFC Grid.

Reducing energy use and OpEx spend from the access network starts by understanding where power is used in the plant. More specifically, identifying and reducing or eliminating energy waste is the key to optimizing the effectiveness of the network. By mapping the flow of power from the point of connection to the grid and cataloging how each Watt of energy is consumed or wasted, we can develop data-driven strategies to optimize network sustainability and significantly reduce utility spend.

As we look to understand how to save energy, it is important to keep in mind these simple conversions based on the US average utility cost and CO₂ impact per Watt:

1 Watt of power savings = 8.76 kWh annually

8.76 kWh @ \$0.119 per kWhⁱⁱ = \$1.04 of savings = 7.45 Lbs of CO₂ⁱⁱⁱ

So, every Watt of savings yields a dollar of annual savings on energy bills, with the potential for 2 to 3 times that in regions with higher utility rates. This combined with the fact that there are more than 750,000 power supplies in North America alone, help to emphasize the value that can be gained by reducing wasted power in the OSP.

3.1. Where does the power go?

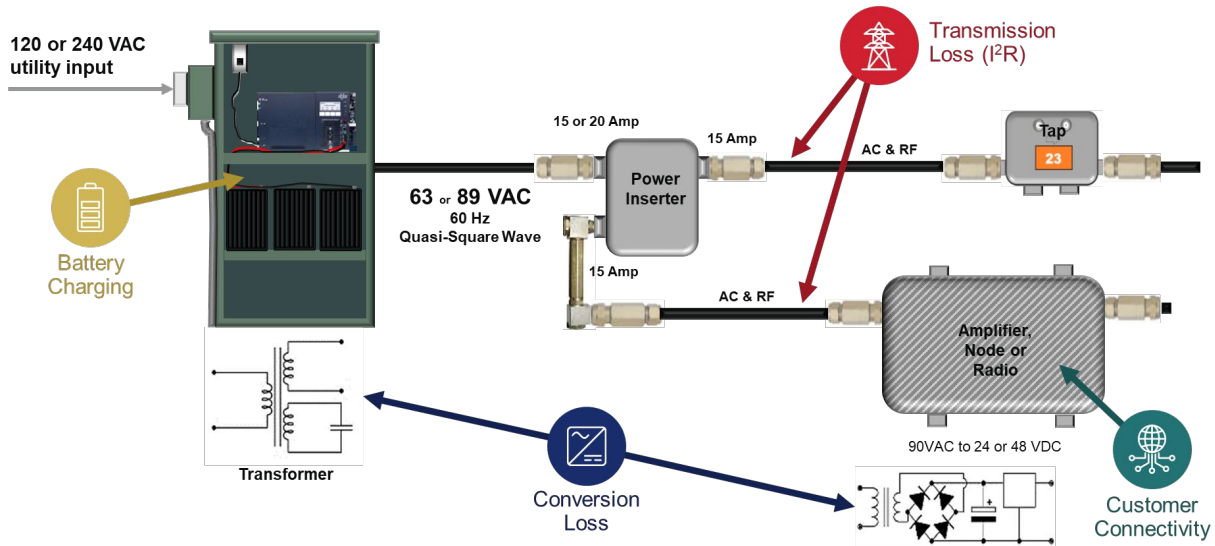

Figure 3 - Areas of power consumption in the HFC Grid

From the point of connection to the utility, power in the HFC network is essentially consumed in 4 ways:

1. **Customer Connectivity** – Powering equipment necessary to transport data through the network and connect customers to the digital world requires energy
2. **Conversion Loss** – Converting electrical power to a different voltage or from AC to DC and back
3. **Transmission Loss** – Power loss inherent from moving power across the network (I^2R loss)
4. **Battery charging and management overhead** – power used for operation of the network power supplies including the cable modem (transponder) and battery charger

Understanding the reasons behind each of these areas of energy consumption and the locations where they happen will allow us to develop strategies to greatly reduce them. Because the plant is a complex electrical circuit, changes to any of the four elements of power consumption above can often have an additive effect. For example, conversion loss in actives can have an impact on transmission loss throughout the plant. We will discuss this in more detail later.

It is also necessary to consider power usage in the network holistically, as in some cases small power sacrifices in the Access Network are made to make the network more robust or intelligent, and often are offset by significant power savings in other areas of plant operations. In order to better quantify the impact of each of the four types of power consumption for comparative analysis against operational impacts we will build a model network and observe the impact of changes to each of them. But first, let's dive a little deeper into each of these four types of power consumption in the network.

3.2. Customer Connectivity

The HFC network is the central nervous system of the connected world. The actives that extend the reach of the network or increase the speed and bandwidth of data that flows through it are the reason that the HFC grid exists. Significant effort is consistently being invested into network actives to enable them to do more with less power. While these efforts have significant impacts in reducing network power consumption, for the purposes of this paper we will view their power draw as a mathematical given within

our power calculations, understanding they are a non-negotiable within the network. We will discuss potential savings from maximized conversion efficiency within actives as a piece of Conversion Loss.

3.3. Conversion Loss

When converting electrical power from one form to another there will always be some power loss. The method by which that power is transformed can have a significant impact on power consumed in the HFC network. However, any conversation around transformer efficiency needs to be had with a more wholistic view considering effects on plant resiliency and operating costs. Currently in the HFC network there are 3 main points of conversion where loss needs to be considered.

3.3.1. Converting utility voltage to plant voltage

The first point of conversion is at the utility input to the power supply that feeds power to the plant. At this point utility power at either 120VAC or 240VAC is converted to plant voltage of 60VAC or 90VAC. In the overwhelming majority of powered coaxial plant in the world this conversion is done by a power supply with a **ferroresonant transformer**.

3.3.1.1. A Brief description of ferroresonant transformers

“Ferroresonance” is a phenomenon associated with the behavior of iron transformer cores, which in the instance of broadband power supplies, have two separate sections. The input core section is designed to prevent saturation at the maximum utility input so it cannot trip the input circuit breaker. The output section is designed to saturate in a controlled manner to provide tight output voltage regulation. The core is designed to optimize the efficiency at full load and allow the saturation loss only at lower load for output voltage regulation.

Normally, a ferroresonant transformer causes distortion of the output sine wave shape at lower load to regulate the output voltage. Ferroresonant transformers also have a magnetic shunt between the input winding and the auxiliary secondary winding, which is paralleled with one or more capacitors, forming a resonant circuit tuned to the power supply frequency. This resonant LC or “tank” circuit amplifies the input voltage and drives the output core to saturation to regulate the output voltage. In addition to providing isolation from input to output windings, this tank circuit provides additional filtering of input noise and resilience against high utility energy surges, such as lightning and industrial surges. The tank circuit also limits the output current during plant short circuit conditions to prevent tripping the input circuit breaker.

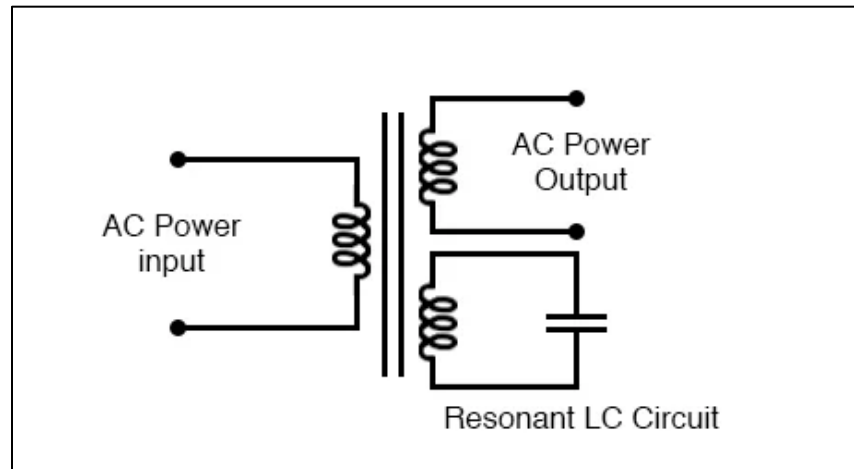

Figure 4 - Simple circuit diagram of a ferroresonant transformer

Because of their unique design, ferroresonant transformers provide several key benefits in powering the OSP network. First, they provide network equipment protection for surges and other transients as well as filtering out input noise that might otherwise be passed on to the plant. Additionally, they provide significant protection from shorts on the plant by current limiting to protect other equipment, and no-touch recovery once the short condition has been repaired. Finally, their relatively simple design, with minimal component count makes them extremely reliable and resilient to the uncontrolled environmental conditions in the majority of OSP locations.

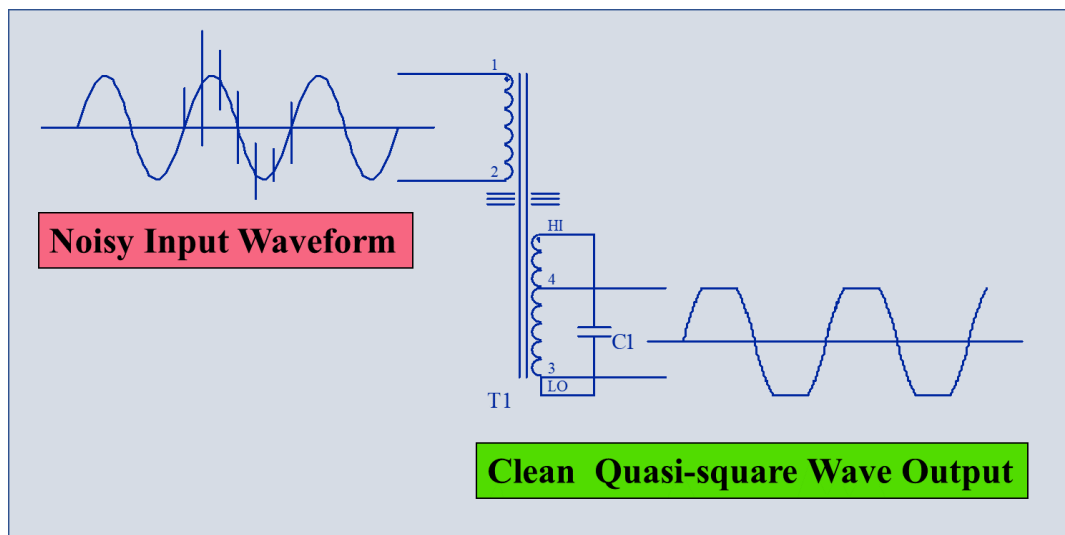

Figure 5 - Noise and transient reduction capability of a ferroresonant transformer

Figure 6 - Current limiting of a ferroresonant transformer during a short-circuit condition

However, with the additional power required for both the tank circuit, and the iron core saturation, the benefits mentioned above come at the cost of some efficiency loss. Since these elements of a ferroresonant transformer are optimized to handle a peak load, there is an inherent overhead to running these transformers that generally makes them significantly less efficient at lower loads. For example, in a power supply that is rated for up to 18A of output, there may be an inherent load of 100W or more to ensure resiliency up to peak load. At 3A of output at 90VAC or 270W of load, an additional 100W of inherent load means the transformer is operating at just under 73% efficiency.

Fortunately, much has been done over the past 30 years to gradually decrease the inherent load required for a ferroresonant transformer and make these devices more efficient. For example, a standard 15A power supply outputting 700W before 1999 would have had an efficiency of around 82.5 %. In the 2000s the standard 15A power supply was up to around 86% efficient at that load and today it is an additional 2% higher. Additionally, as the peak rating of a ferroresonant transformer is lowered so is the inherent load required to support that peak rating. Therefore a transformer that was rated for 5A, for example, would have an inherent load significantly lower than the 18A transformer.

3.3.1.1. Load Matching

It is important to note that when loaded to 50% or more of max rating, ferroresonant transformers can reach efficiencies of 85% to 94%. Knowing this, one strategy that could be deployed to reduce energy usage without losing the operational benefits of a ferroresonant transformer-based power supply is **Load Matching**. This strategy uses power supplies designed to tiered peak capacities in order to lower the inherent load on power supplies at lower amp draws. For example, if power supplies designed to peak loads of 5A, 10A, and 18A are deployed in an operator's network, power supplies can be targeted to unique plant loads between 2.5A and 18A so that all power supplies operate at efficiencies above 85%, with many above 90%. While this strategy comes with some added management operationally, it could be an effective strategy to deploy during regular replacement cycles that shows moderate improvement for little added cost. We will model the potential impact of this strategy later on.

3.3.1.2. Linear and Switch-mode transformer efficiencies

While other transformer architectures, such as linear or switch mode, may be able to achieve conversion efficiencies of 95% or greater, these efficiency gains need to be weighed against either lost operational

benefits, or the energy cost to add intelligence or redundancy into their architecture to achieve desired resiliency targets. For the purposes of this paper, we will model potential energy efficiency gains from increased efficiency of moving to these architectures, but thorough analysis should be done on real-world impacts of switching to a non-ferroresonant transformer.

3.3.2. AC to DC battery charging or DC to AC battery backup

The next conversion to be discussed briefly is the conversion in the standby power supply from AC to DC for battery charging, or DC to AC to power the plant during utility outages. These conversions have very little impact on overall power consumption since they happen very infrequently. And, while there is a constant float charge generally being applied to lead acid batteries in a standby power system to keep them healthy and ready for discharge, even in the worst-case scenario a 20% change in the efficiency of this conversion would yield less than a Watt of savings.

3.3.3. Conversion of plant power to DC power for actives

Another location in the plant where conversion loss is notable is at each active. Plant actives are generally powered internally by 48VDC or 24VDC which means that conversion from 90VAC plant power to the required DC voltage is necessary. Most actives do this conversion through small voltage conversion devices which, generally have low losses with efficiencies generally ranging from 95% to 98%. The presence of the ferroresonant transformer providing power to the network allows these higher efficiency transformers with less resiliency against transients and surges to be safely used in network actives. The efficiency of these, and all transformers, does tend to decrease with age as transformer insulation wears down and more energy is lost to heat. Reducing network impact by ensuring maximized transformer efficiency of actives is key to reducing wasted energy in the network, as inefficiency of actives can also create additional transmission loss in the plant.

3.4. Transmission Loss

Transmission loss refers to the power lost from pushing current down the coax to feed actives, stated mathematically by Ohm's law, and it is one of the most important factors to understand in order to reduce the power consumption of the OSP. Depending on the particular section of plant, transmission loss can account for up to a 25% of the power consumed in the plant.

Since the plant is, from a powering standpoint, an electrical circuit with a series of loads drawing current and a series of resistors between them, in a single span of coax feeding an active we can express the transmission loss by Ohm's law as:

$$P(\text{loss}) = I^2R$$

Where:

$P(\text{loss})$ = power lost from coax line resistance, measured in Watts.

I = current through the cable required to feed an active, measured in amps

R = resistance of the length of cable, measured in Ohms

To understand the total plant load and how and where transmission loss occurs, it is also important to remember that active loads on the plant are constant power devices, or again from Ohm's Law

$$P = IV$$

Where:

P = power required for the active to function

I = current through the cable required to feed that active, measured in amps

V = voltage feeding the active

While these concepts are fairly simple mathematically, the interaction between them and a number of properties of the plant make them more complex to model in the plant.

3.4.1. Modelling power transmission loss

The layout and makeup of the HFC plant varies greatly from section to section. And while the number and type of actives in the plant are the most significant factors in the power draw of the plant, the coax and the passives have an impact on transmission loss.

3.4.1.1. Coax Loss

Everywhere that the plant is not drawing power it is resisting its flow. The resistance of any span between two actives is generally determined by three factors which, again, vary greatly from plant to plant – the length of the coax, the diameter of the center conductor of the coax and the passives in the power path. The coaxial resistance is fairly predictable as long as the cable size is known, which is not always a given especially when reaching toward last-leg actives. For modelling purposes, assuming that we know the length and diameter of coax, each span from active to active can be treated as a resistor with a certain ohmic value calculated from the table below.

Table 1 - Quick reference guide for coaxial cable resistance

P3 Cable Resistance	
Cable Dia	Ohm/Ft
0.5"	0.00172
0.625"	0.0011
0.75"	0.00076
0.875"	0.00055
625 PF	0.0003

3.4.1.2. Passive impact to transmission loss

Passives such as taps, splitters, directional couplers and power inserters are less impactful to plant resistance, but also less understood. Their per length resistance is inherently greater than that of the coax that surrounds them in the plant, but the value of this addition resistance is not well-documented and therefor hard to quantify. A cursory check of resistances for several random passives recently showed resistances from input to output ports of between 10 and 35 milliohms, which based on the table above is the equivalent of an additional 10 to 50 ft of coax depending on diameter. Assuming that approximately one passive is in each 200 ft. span of coax, this means that passives could add up to somewhere between 5% and 10% to the overall resistance of the plant.

To be clear, these results do not come from a well-organized, systematic study of a large sample of various types and manufacturers of passive equipment. They are an initial glimpse at a potential opportunity for plant savings that should be further understood. With the need to update passives to handle higher frequencies required by DOCSIS 4.0, this could be an opportune time to determine a resistance specification for passives that is not cost prohibitive.

3.4.1.3. *Constant power actives*

The vast majority of active equipment in the access network today is of a constant power nature, or simply the input current and voltage can vary as long as their mathematical product provides the requisite power for the device to operate. This is not to say the power draw of actives cannot vary moment to moment due to changes in throughput required. The principles of ‘constant power devices’ dictate that any change in voltage is offset by an inversely proportional change in current. Thus, if a 90W load initially is receiving 2A of current at 45V, and the voltage on the plant is doubled, the current through the lines will be halved. For the HFC network this has the added benefit of reducing the voltage drop through the coax, thereby reducing power loss. As you can see, this process would continue to occur until the changes in voltage and current were immeasurable and the plant voltage “settled.” In the plant this settling of voltage happens almost instantaneously. For a mathematical model of the plant, it can be more time consuming to calculate without the use of some additional calculating power.

Figure 7 - Sample network for power loss calculation

Consider the simple section of plant above. To calculate the total power draw from this section of plant you would sum the power drawn from each active (A-1,2,3) and the total transmission loss from each span (S-1,2,3.) Before calculating the loss in span S-2, you need to calculate the loss in S-3 as the power loss in that span is a factor in determining the amount of current that is drawn through S2. The same goes for S-1 where you need to calculate the loss in S-2 and S-3 before you can calculate that span.

So first:

$$P_{(\text{loss in S-3})} = (P_{(A-3)} / V_{(A-3)})^2 \times R_{(S-3)}$$

Then:

$$P_{(\text{loss in S-2})} = ((P_{(A-3)} + P_{(A-2)} + P_{(S-3)}) / V_{(A-2)})^2 \times R_{(S-2)}$$

Finally:

$$P_{(\text{loss in S-1})} = ((P_{(A-3)} + P_{(A-2)} + P_{(A-1)} + P_{(S-3)} + P_{(S-2)}) / V_{(A-1)})^2 \times R_{(S-1)}$$

For purposes of power modelling the plant later in this paper a computer model was built that sets the end-of-line (EOL) voltage at the last active to a relatively low value then calculates loss back to the point of power. The model then checks the voltage against the known output of the power supply then repeats the process iteratively by raising the EOL voltage incrementally until the calculated voltage at the power supply matches the known output voltage. From there all transmission loss in the plant can be summed and analysis performed on the impact of any power saving strategy.

3.4.2. Concepts for voltage increase in the HFC

The proportional relationship between voltage and current with regard to power opens up interesting opportunities for reducing transmission loss by raising the voltage of the plant to lower the current, and therefor transmission loss, through the coax. First, there is still roughly 25% of plant in North America that is 60V. We will show later in our model that raising the voltage of plant from 60VAC to 90VAC can yield a significant reduction in transmission loss. Second, the National Electric Safety Code (NESC), Section 2 (excerpt in Figure X below) allows up to 150VDC in the communication space and while there are details that need to be better understood with DC powering of the HFC plant, there may be some relatively simple solutions that could allow the voltage to increase to that level. This increase would not only reduce power draw on the plant, but would also increase the reach of the plant and potentially allow for the reduction of operational energy usage by reducing the total number of sites to be maintained. It could also enable easier deployment of wireless technologies powered from the HFC grid. We will model all these scenarios below to better understand their impact on reducing utility power draw.

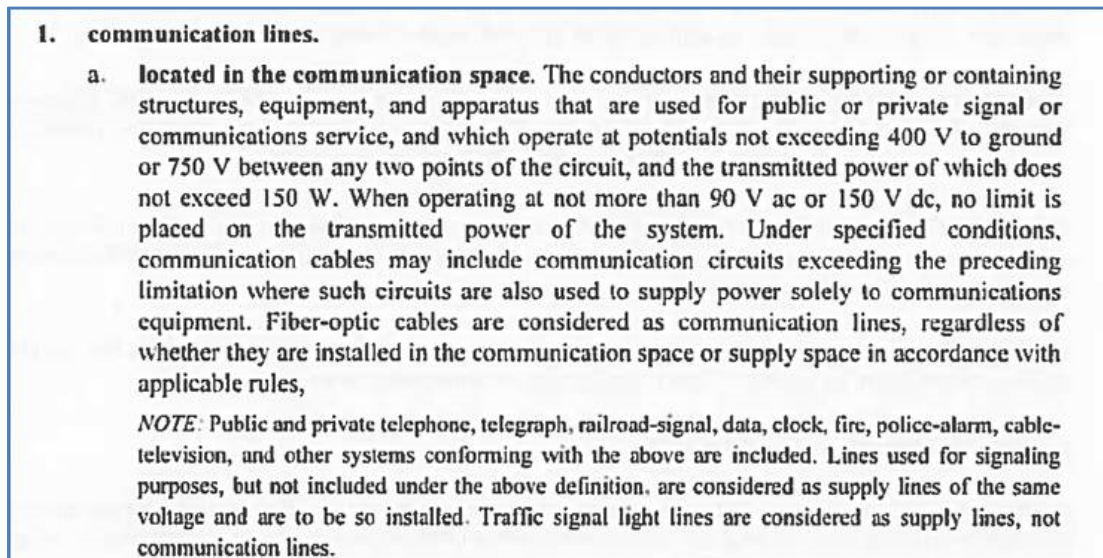

Figure 8 - NESC section 2, excerpt defining allowable voltage in the communication space

3.5. Battery Charging and Management Overhead

Standby powering has made the HFC grid an extremely resilient architecture. There are two key elements required to make standby powering such a robust architecture that draw additional power.

3.5.1. Power use from battery charging

Standby power requires batteries, battery charging can use unnecessary power if not properly managed. Typical gel cell VRLA batteries require a trickle/float charge of up to 3-4W constantly to stay healthy.

This is necessary to negate the effects of self-discharge and ensure batteries are topped off and ready for an outage. As batteries age and internal resistance increases the power used for float-charging these batteries will continue to increase. Therefore, it is important to ensure that batteries are properly maintained so that aging batteries with higher internal resistances, which are often no longer able to provide adequate back up time, are replaced regularly.

Some newer advanced AGM lead-acid batteries present a small opportunity for power savings. With lower internal resistances and self-discharge rates, these batteries have the ability to “rest” without being charged for up to 75% of their life, reducing the power needed to float charge them. Lithium-Ion batteries have extremely low self-discharge rates and, therefore, do not require float charge at all. There are small power gains of around 4 Watts to be had here, but as a part of a broader strategy it could help add up to larger total reduction of power.

3.5.2. Power use from DOCSIS status monitoring

Remote DOCSIS status monitoring of network power supplies has helped to greatly improve power reliability in the OSP by providing insight into potential issues before they become customer impacting. As our ability to extract additional data and perform more advanced analysis on these devices continues to improve, plant operations practices will become increasingly more streamlined. While these devices have become mission-critical to plant operations, they do have some draw that should be noted. Like other cable modems, the majority of devices currently in the OSP have an average draw of 5 to 7 Watts which will increase as networks advance and require higher-powered DOCSIS devices.

4. Modelling the impact of loss factors in the HFC grid

To understand how power is used in the HFC plant and more importantly where it is being consumed without adding value, we can look at an average section of plant and map the power flow. Then we can run mathematical scenarios based on targeting each type of loss and measure the impact of each strategy.

As mentioned earlier, the layout and makeup of the HFC plant varies greatly from section to section. This exercise is designed to show potential impact from loss factors, but the weighting of these factors may vary slightly depending on architectures or location of the plant—rural, suburban, urban—being viewed. The average power supply in North America has an output load of around 650W-750W so for the model it is ideal to find a section of plant with an output load within that range. Fortunately, in order to find this model section of plant all I needed to do was take two aspiring young cable engineers on a walk around my neighborhood to assist me in mapping the power flow from my local power supply. They were very engaged and helpful, until we reached the node which had an ice cream truck parked in front of it.

Figure 9 - Pictures of the model plant and the ice cream truck where I lost my assistants

For the sake of simplified mathematical modeling I used some generalized estimations of power draw for various actives and calculated the output power from my local power supply to be approximately 720W, which just happens to fit nicely into the average load range. I've mapped our model network in **figure 10**, but for the purpose of this exercise I have arranged the elements to more effectively show power flow instead of a more standard optical and RF-path layout. It is also important to note that, while loads were based on data from a cursory review of real actives of varying models and capabilities, the accuracy of the plant active power estimations used for modelling power draw is somewhat irrelevant due to the broad variation of active loads that the plant can support today and will support in the future.

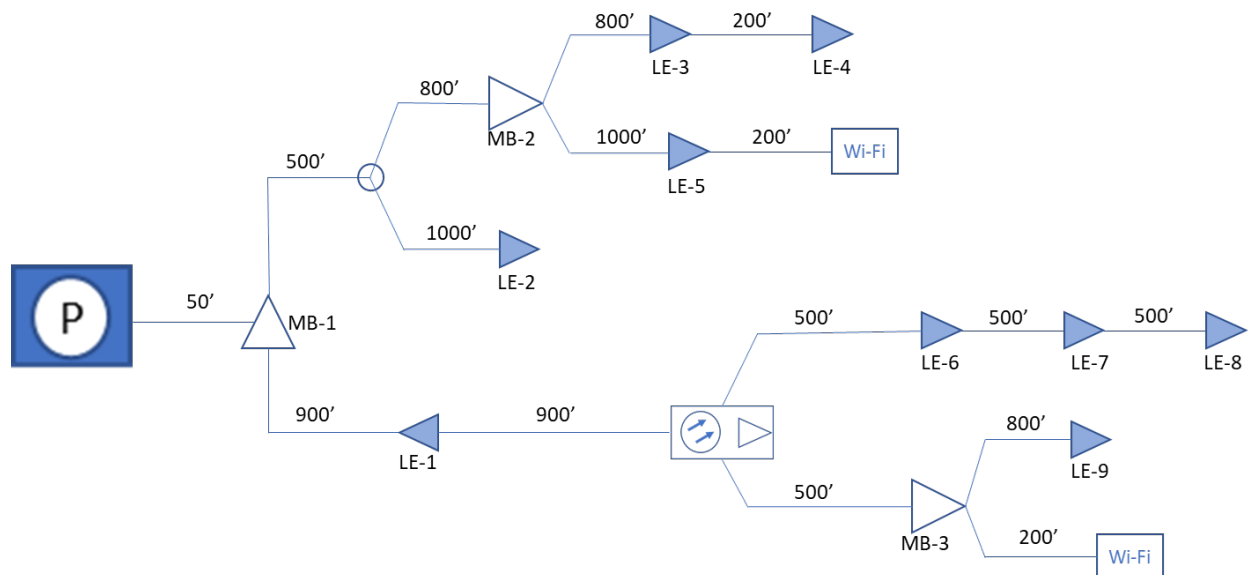

Figure 10 - Network power diagram for scenario modelling

4.1. Baseline assumptions for modelling

Below are the baseline assumptions that were used to build our initial power map.

- 1) Estimates for power draw of plant actives

Table 2 - Power draw for modeled plant actives

Active type	Power Consumed (W)	Quantity	Total Draw (W)
Legacy Node	90	1	90
WiFi Access	55	2	110
Amplifier (LE)	35	9	315
Mini bridger	50	3	150
Total Customer Connectivity Load			665

- 2) Per the chart above the total Customer Connectivity Load is assumed to be 665W.
- 3) All actives are assumed to have a conversion efficiency of 95% which is included in power consumption estimates.
- 4) Based on 2&3 above, the theoretical minimum power to run the network actives at 100% plant efficiency would be 631.75W.
- 5) Power supply conversion efficiency is assumed to be 86% based on a 15A power supply deployed prior to 2010 running at this load. This represents more than 55% of the deployed population of broadband power supplies in North America today.
- 6) Plant passives are assumed to add approximately 10% to the total plant resistance
- 7) Coax carrying power in the plant is assumed to be a 75/25 mix of .75 and .625 P3 cable to represent real-world variation in cable types.
- 8) Battery charging and management overhead is assumed to be a fixed 10W.
- 9) There is assumed to be 1 passive for every span or approximately 200 ft.

Inputting the baseline assumptions into the computer model, here are the baseline results:

Table 3 - Baseline power breakdown of modeled network

Original Baseline	
 Required power for connectivity	631.75 Watts
 Conversion Loss (Actives)	33.25 Watts
 Transmission Loss	59.48 Watts
 Battery Management Overhead	10 Watts
 Conversion Loss (Power Supply)	119.57 Watts
Total Utility Power Draw	854.05 Watts

So, based on the above assumptions, my local network has a customer connectivity load 631.75W. This is the theoretical minimal power that is needed to keep the actives in this section of plant functioning if no other power was consumed in the plant. This is impossible to attain, but the goal is to get as close as possible with reasonable investment. The annual utility usage cost of this power supply based on the US average utility price of \$0.16 per KWh is about \$892.

4.2. Conversion Loss impact scenarios

4.2.1. Power supply conversion loss

Based on our baseline above, this is the most significant loss factor so let's look at the real-world impact of improving power supply efficiencies on conversion loss. We will start by looking at the impact of upgrading to a newer 15A power supply as a part of regular planned replacements. From there we will compare the impact of load-matching a more appropriate 10A power supply to this section of plant. Finally, we will look at the impact of a theoretical power supply that can maintain a maximum efficiency of 94% across a wide range of loads. See the results in the table below.

Table 4 - Model of power consumption varying power supply efficiency

	Original Baseline	Newer 15A PowerSupply	Load-Matched 10A PS	Theoretical High-Efficiency PS
 Required power for connectivity	631.75 Watts	631.75 Watts	631.75 Watts	631.75 Watts
 Conversion Loss (Actives)	33.25 Watts	33.25 Watts	33.25 Watts	33.25 Watts
 Transmission Loss	59.48 Watts	59.48 Watts	59.48 Watts	59.48 Watts
 Battery Management Overhead	10 Watts	10 Watts	10 Watts	10 Watts
 Conversion Loss (Power Supply)	119.57 Watts	100.16 Watts	80.7 Watts	46.88 Watts
Total Utility Power Draw	854.05 Watts	834.64 Watts	815.18 Watts	781.36 Watts

Overall, strategies to increase power supply efficiency seem to have good results in our model network. Moving from an aging power supply to a Load Matched 10A power supply yields a 4.5% reduction in overall power consumption or an annual savings of around \$40 annually. Any additional economically viable efficiency that can be gained toward the maximum theoretical efficiency above should obviously continue to be pursued as well.

4.2.2. Conversion loss in active devices

Maximizing the efficiency of power conversion in plant actives is not an easily deployable strategy as it requires multiple touch points for every section of plant. For example, in our model network there were 15 actives versus just one power supply. That being said, as we transition networks from current architectures to the near-future network discussed earlier, we must remember to be vigilant about ensuring maximum efficiency in plant actives as gains or losses out the plant have a cascading effect that you can see in the table below. This scenario models hypothetical increase in efficiency of all actives from 95% to 98%.

Table 5 - Model of improved power conversion efficiency of actives

	Original Baseline	Plant actives at 98% efficiency
 Required power for connectivity	631.75 Watts	631.75 Watts
 Conversion Loss (Actives)	33.25 Watts	12.89 Watts
 Transmission Loss	59.48 Watts	55.52 Watts
 Battery Management Overhead	10 Watts	10 Watts
 Conversion Loss (Power Supply)	119.57 Watts	115.61 Watts
Total Utility Power Draw	854.05 Watts	825.77 Watts

This scenario is interesting as we get to see just how complex plant power is through the ripple effect that happens by changing the load on the plant. Gains or losses in conversion efficiency at the actives can create carry an additive change of up to 30% by impacting transmission loss and power supply conversion loss. Notice here that by reducing active load by 20W the rest of the plant load was reduced by an additional 7W, or almost an additional percentage point.

4.3. Transmission loss impact scenarios

In the prior scenario we began to see a small impact on transmission loss when adjusting slightly the amount of power drawn by actives. However, the best strategy to reduce transmission losses, as previously mentioned, is to increase the voltage at which power is delivered to actives and thereby reduce current flowing through the plant. In this scenario we will take a small step backwards to show what our model network would look like if it were running at 60VAC and then take a big step forward to the potential future scenario of powering at 150VDC.

Table 6 - Model of the impact of increased voltage on transmission loss

	Plant modeled at 60V	Original Baseline	Theoretical 150VDC
 Required power for connectivity	631.75 Watts	631.75 Watts	631.75 Watts
 Conversion Loss (Actives)	33.25 Watts	33.25 Watts	33.25 Watts
 Transmission Loss	154.67 Watts	59.48 Watts	18.46 Watts
 Battery Management Overhead	10 Watts	10 Watts	10 Watts
 Conversion Loss (Power Supply)	135.06 Watts	119.57 Watts	112.89 Watts
Total Utility Power Draw	964.73 Watts	854.05 Watts	806.35 Watts
Voltage at last active	47.2 Volts	79.8 Volts	145.3 Volts

The biggest thing that jumps out in these scenarios is the power savings going from 60VAC to 90VAC, where we see the impact of transmission loss in older sections of plant and again the additive effect that loss can have on power supply conversion loss. Fortunately, adjusting the output voltage of the plant in most locations can be done in a few minutes without an upgrade to the power supply. Unfortunately, as many operators are already aware, in some of these sections of plant actives would need to be swapped out to handle higher voltages.

The theoretical 150VDC power supply does show significant power savings due to a big reduction in transmission loss. Another key detail to note in the model is the voltage of the last active in each scenario. As mentioned earlier, potentially the biggest gain from going to an increased output voltage like this is the ability to combine sections of plant and reduce power supply locations that need to be managed by plant operations. In 60V plant not only does current need to increase to deliver adequate power, but voltage decreases much more quickly and only needs to drop 18V (from 63VAC to 45 VAC) before it can no longer power actives. In 90V plant, voltage drop toward the minimum voltage for actives is much less pronounced, but would still be impacted significantly if the powering needs of two sections of plant were combined. Additionally, as the next generation of actives with higher power draw are deployed, the additional current required to power these actives will accelerate voltage drop and power loss beyond what we see in the scenarios above. In 150V plant, voltage drops so insignificantly, and the gap between power supply output voltage and minimum voltage for actives is so great, that two sections of plant could easily be combined without adding significant additional losses or risk of dropping actives due to low voltage.

4.4. Battery Charging and monitoring overhead

Assuming that the load of the cable modem used to monitor the health of network power is a given and that these devices are at maximum efficiency, reductions in this can be modeled based on a simple binary scenario. If we can, as a part of near-future network upgrades, leverage an energy storage technology that reduces or eliminates the need to float charge, we can eliminate 4 Watts of draw on the HFC network or the equivalent of 35 KWh annually. No need to create an elaborate model for this, however, there are other strategies to leverage the existing energy storage to create additional energy or utility cost savings that we be discussed in a moment.

4.5. Cumulative effect of power savings strategies

One last scenario to look at is the potential cumulative effect of implementing all of these strategies to have an idea of how much wasted energy we could theoretically remove from the plant. In this scenario, we will optimize all the variables to the limit of their realistic values.

- Increase conversion efficiency in actives to 98%
- Increase power supply conversion efficiency to 94%
- Increase line voltage to 150 VDC
- Reduce the additive resistive load from passives to 5%
- Remove battery float charging of 4W from the battery overhead

Table 7 - Cumulative effect of power savings strategies

	Original Baseline	Theoretical Best Case
 Required power for connectivity	631.75 Watts	631.75 Watts
 Conversion Loss (Actives)	33.25 Watts	12.89 Watts
 Transmission Loss	59.48 Watts	16.48 Watts
 Battery Management Overhead	10 Watts	6 Watts
 Conversion Loss (Power Supply)	119.57 Watts	42.84 Watts
Total Utility Power Draw	854.05 Watts	709.96 Watts

While this model showing a 17% reduction in power draw is only theoretical, it is a realistic view of what is possible. It emphasizes the point that small cumulative gains will add up to significant progress in reducing our industry's footprint and drastically reducing operational costs. Using this average example as a baseline, if we could realize similar savings across all 750,000 power supplies in North America, our industry would be able to save nearly a terawatt hour of energy, 800,000,000 lbs of CO₂, and more than \$110M of utility operational cost. In addition to that, raising plant voltage and increasing reach could save millions of additional dollars in maintenance costs.

The biggest question for many of these opportunities is how to make the solutions economically viable. To achieve many of the gains we've identified, investment is required and the payback period for any of these initiatives individually often makes them difficult to justify. One solution may be to pair these concepts for power savings into network upgrades already planned for the access network of the future, specifying key power saving elements into next-gen actives and passives. Additionally, prioritization of plant upgrades for next gen architectures could factor in opportunity for power savings at each sites so that gains are accelerated.

5. Other power reduction strategies

While significant gains can be made by targeting wasted energy in the plant, that strategy is limited. In our model example our maximized efficiency scenario removes 144W of grid energy and cost but still leaves 710W of dependency. To accelerate sustainability efforts it will be necessary to find additional ways to reduce energy draw from the grid. Here is a brief overview of two other concepts that should be considered to reduce grid dependence and operational spend.

5.1. Solar power augmentation

Renewable sources of energy bring the promise of sustainability and reduction of our carbon footprint. While many sources of renewable energy don't scale well to an OSP powering installation, solar energy not only scales effectively, but also could have the additional benefit of shading installations from excess solar load.

Over the past decade, the cost of an installed renewable energy system has gone down between 60% and 70%^{iv, v, vi}, to the point where the cost of solar energy is around \$2.50 per Watt fully installed. This means that two common 370W panels would have an installed cost of less than \$1500, including permitting. In

most locations in the US these panels would generate around 3.2 KWh of power per day. With the average site drawing 700W, solar production could reduce overall energy usage by an additional 20% or around \$140 of annual savings per site, with potential upside from more intelligent implementations. This could be scaled up to four or more panels where more space is available to cover larger loads.

Figure 11 - Example of a solar augmented cable power supply

5.1.1.– Options for solar implementation in the HFC plant

There are a couple of options for installation of solar in the OSP. The first is to simply leverage the real-estate of the plant to install an AC based grid-tied solar system and sell back energy produced by the panels to the utility company. This option is generally considered the simplest to implement, but it has several drawbacks. First, most utilities buy back at wholesale rates and not the retail rate that users generally pay so the payback model is reduced. Second, the power cannot be used for any other plant benefits like increasing runtime in an outage or charging batteries with free power after an outage. Finally, this type of "unintelligent" solar production has flooded the grid and created uneven demand for utilities. Thus, utilities have begun to discourage this scenario by removing incentives and increasing costs for permitting and metering of these sites.

An alternative, patented method exists to harvest solar energy locally at the point of load. This approach, which is shown below in **Figure 12**, creatively leverages the typical powering elements already existing in the OSP and does not involve any grid interactive utility permitting. By coupling the solar power directly onto the battery (DC) bus, the harvested energy can be utilized automatically for battery charging or extended runtime in an outage. By adding supplemental battery capacity, the system can also be used intelligently for offsetting utility power consumption when it makes the most sense (e.g. higher billing hours). The key element of the system is the master controller which can tailor solar consumption to various system sizes, standby runtime requirements, and utility billing scenarios to optimize the available solar resource and minimize utility billing while still maintaining critical backup capacity.

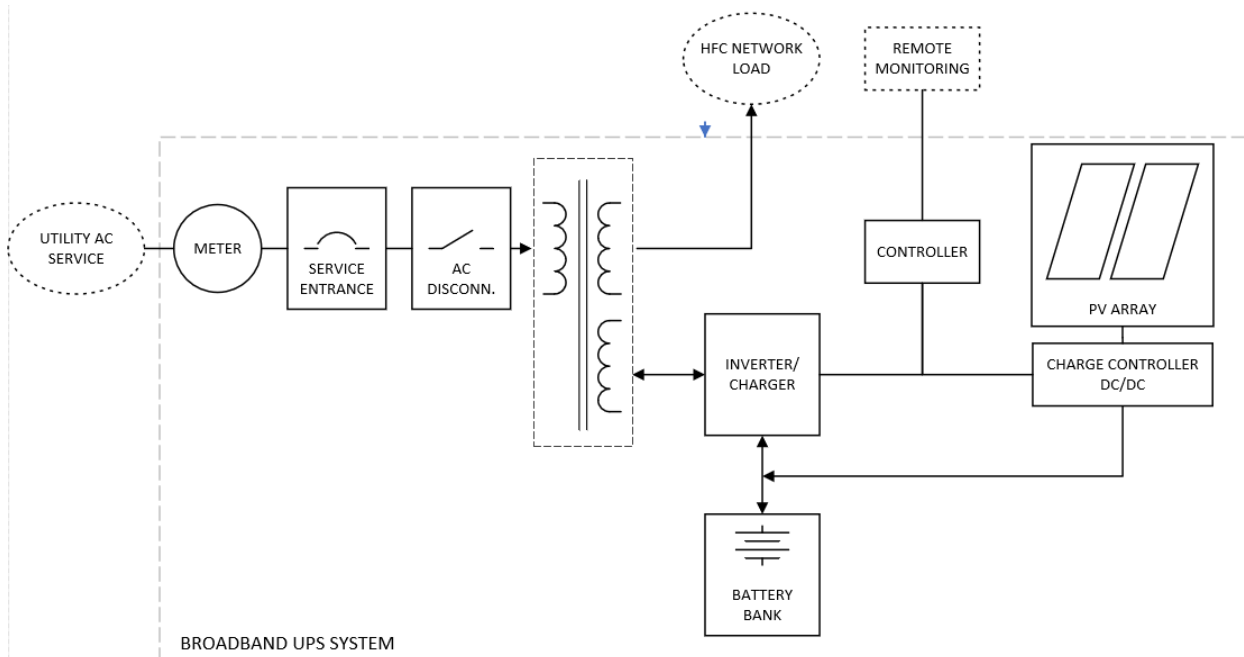

Figure 12 - Basic diagram of a cable power supply augmented by solar

5.2. Time-of-use mitigation

Large scale generation of energy is not inherently scalable, especially with cleaner sources of energy like solar and wind. When customer demand increases past a certain point, utility companies pay premiums to turn up secondary “Peaker Plants” to meet demand. Many large utility companies have rate structures that increase the price of energy during defined peak hours to encourage customers to reduce energy use during these times. This creates another interesting opportunity for reduction of operational energy cost as most OSP installations already have energy storage on site for emergency backup.

Business

Business Time Periods and Delivery Rates

	Peak	Off-Peak
Hours	8 a.m. to 10 p.m.	10 p.m. to 8 a.m. and all day on weekends
TIME-OF-USE DELIVERY RATES		
June 1 to Sept 30	29.38 cents/kWh	1.08 cents/kWh
All other months	14.47 cents/kWh	1.08 cents/kWh

Figure 13 - Example utility time-of-use rate structure

By slightly oversizing the battery array and deploying a battery with the capability for frequent cycling, batteries can be used to power the plant during hours with more expensive rates and recharged later with lower cost energy. For example, using the rates above a power supply drawing 700W from the utility would about \$3 a day to power in the summer. By using batteries to remove it from the grid during peak rates for 4 hours and recharging later in the day when energy is inexpensive you could reduce your energy bill by \$1 each day in the summer.

With major utility companies deploying time of use rate structures with peak rates as high as \$0.57 per KWh this strategy should be explored further. Although, this strategy does not actually reduce total energy use, peak energy usage historically tends to be more carbon-intensive. Thus, this strategy does reduce carbon footprint, if not overall energy consumption. However, by combining time-of-use mitigation with solar augmentation and building intelligence into network power supplies to use the energy source that is most economically viable at any point of time - grid, solar, or batteries – This strategy can yield significant savings in power usage and operational energy spend.

6. Conclusion

As we progress along the path to 10G and beyond it is imperative that we continually seek out new solutions to reduce energy consumption of the network. There is significant opportunity to improve the way we power the access network and specifically reduce the inefficiencies in the plant. The possibility of leveraging renewable energy to reduce grid dependency of the OSP is becoming more economically viable. There is opportunity in front of us, however there is much work to be done.

The power map that we have created in this paper and the mathematical model used to analyze it are an early step to realizing energy savings. The opportunities identified above must each be investigated in depth and economically viable solutions developed to address them. More efficient power conversion, reduced transmission losses, and renewable energy augmentations all can have huge impact on energy usage. Even smaller changes like ensuring minimal resistive impact from network passives and reducing the need to float charge backup batteries can have a cumulative impact that can save millions of dollars and megawatt hours of energy. With significant network upgrades on the horizon to facilitate the path to 10G and beyond, the time is now to understand everything that can be done to reduce power consumption in the access network and ensure that near-future network is as energy efficient as it is fast.

Abbreviations

AC	alternating current
AGM	absorbent glass mat
AN	aggregation node
DAA	distributed access architecture
DC	direct current
HFC	hybrid fiber coax
MDU	multi-dwelling Unit
MSO	multiple-system operator
OLT	optical line terminal
OSP	outside plant
P2P	peer-to-peer
PON	passive optical network

RDOF	Rural Digital Opportunity Fund
UPS	uninterruptible power supply
VRLA	valve regulated lead acid
kWh Google	kilowatt hour

1. Introduction

1.1. Zero Trust Architecture

Zero Trust Architecture (ZTA) is an information security model that de-emphasizes computer networks as trust factors, focusing instead on strong user & device authentication and contextual, risk-based authorization. In this paper, we:

- Review the background and history of ZTA (Section 2).
- Summarize the history of our organization's Zero Trust journey (Section 3).
- Discuss highlights of our organization's ZTA program, including its guiding principles, security focus areas, and governance (Sections 4 – 6).
- Reflect on lessons learned (Section 7).
- Consider future directions for our ZTA program (Section 8).
- Evaluate ZTA as it relates to service providers (Section 9).

2. Background

2.1. History of Zero Trust

Zero Trust Architecture is an information security model based on the principle of **Never Trust, Always Verify**. The term “zero trust” can be traced to a 1994 doctoral dissertation by Stephen Paul Marsh of the University of Stirling, and the concept was later popularized in a 2010 whitepaper by John Kindervag of Forrester Research. ZTA argues that the traditional perimeter network security model is obsolete, and that modern security programs should instead focus on authentication of security principals, security policy compliance, and continuous risk assessment.

ZTA assumes that all computer networks are untrusted by default, and that enterprise networks are no different – and hence no more secure – than non-enterprise or public networks. Viewed in this light, Never Trust, Always Verify requires:

- Strongly authenticating, authorizing, and auditing all access to resources and services.
- Measuring user and device compliance against organizational security policy.
- Continuously assessing the security posture of all principals (users, devices, resources).

2.2. Elements of ZTA

2.2.1. Foundational

The foundational elements of a ZTA are:

- **Users.** Users are human actors and include the organization's employees, contractors, business partners, and other third parties.
- **Devices.** A device is a physical computing resource designed to be used interactively by a user. Desktop computers, laptop computers, smartphones and tablets are all examples of user devices.

- **Resources.** Resources are repositories of organizational data, and as such, primary targets of attack. They include both physical and virtual machines, as well as the server operating systems, containers, services, and applications running on such machines.

At the most basic level, Users use Devices to access Resources. All three elements are security principals, in that they have identities and can attempt to perform actions. A ZTA authenticates identities and authorizes actions as required.

Figure 1 – Users, Devices & Resources

Additional dimensions to each element must be considered as well:

- For any given Resource, User audiences might vary (employee, business partner, guest, etc.). Additionally, the Users may be local to one of the organization's offices, or they may be remote.
- Resources might be owned and administered organizationally at one or more premises locations. Alternatively, the Resources might be hosted by a service provider (e.g., **Cloud** services).
- Devices might be owned and administered organizationally. Alternatively, Devices might be owned and administered by a third party, or personally owned by their Users.

2.2.2. Security Support Structure

The Security Support Structure (SSS) is an all-encompassing term used to describe the set of services that enable ZTA. To varying degrees, the foundational elements depend on each of these services. Common SSS components include:

- Application Access Frameworks – on-premise, off-premise
- Configuration Management Databases (CMDB)
- Directory Services (LDAP)
- Endpoint Detection & Response (EDR)
- Identity & Access Management (IAM) & Identity Providers (IdP)
- Multi-Factor Authentication (MFA)
- Mobile Device Management (MDM)
- Public Key Infrastructure (PKI)
- Security Information and Event Management (SIEM)
- User Behavior Analytics (UBA)

Collectively, the SSS bolsters the Zero Trust posture of Users, Devices, and Resources. An example SSS can be depicted as follows (significant integrations illustrated):

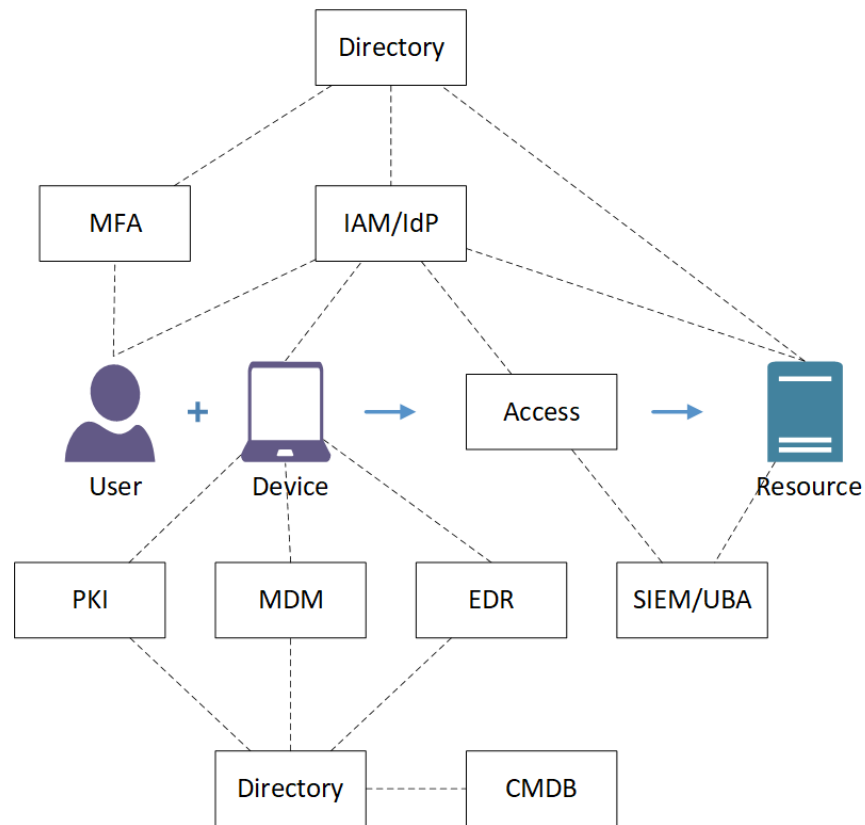

Figure 2 – Security Support Structure

2.3. ZTA Fundamentals

All Users and Devices begin a work session in a state of Zero Trust. That is, absolutely no security relevant attributes are assumed or inferred about a User or a Device. Examples:

- Assertions of Identity
 - “I’m Alice!”
 - “I’m Bob’s computer!”
- Assertions of Network Location
 - “I’m on the Internal network!”
- Assertions of Compliance
 - “I’m fully patched!”
 - “My storage is encrypted!”

Users and Devices must therefore establish trust before obtaining access to Resources. Trust is established in three primary ways:

- **Authentication.** User and Device identities must be confirmed with high confidence. This typically requires strong authentication, which can be defined as:
 - Multi Factor Authentication (MFA) for interactive User access. Examples include knowledge factors (passwords, PINs) combined with physical or logical possession-based factors (time- or event-based One-Time Password (OTP) generators, digital certificates, challenge/response mechanisms, FIDO 2 tokens).
 - Cryptographically sound authentication for Device-level, non-interactive access. Examples include shared symmetric keys, asymmetric key pairs, digital certificates, refresh tokens, and so forth.

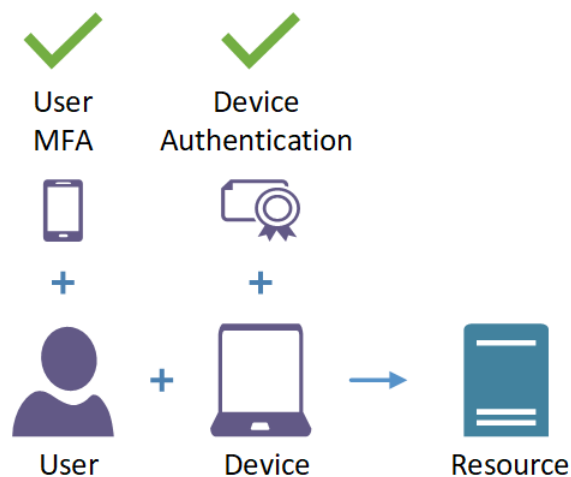

Figure 3 – Establishment of Trust Via Authentication

- **Security Policy Compliance.** Users and Devices must be assessed for compliance with organizational security policy. This could include factors such as:
 - User Authorization Checks
 - There are many possible criteria for user authorization, including directory group memberships and/or other directory attributes, requested Resource, work schedule (time of day, day of week, etc.) and so forth.
 - Device Authorization Checks
 - Determination that device properties and configuration are acceptable (e.g., idle UI timeouts are enabled, storage media is encrypted)
 - Verification that all expected security tooling is installed and operational
 - Confirmation that OS and/or security tool patch levels are suitably recent

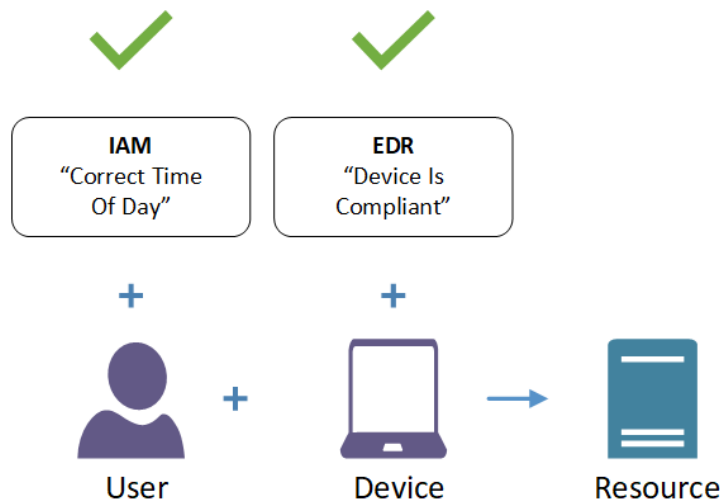

Figure 4 – Establishment of Trust Via Risk & Compliance Assessment

- **Continuous Risk Assessment (Context).** Risk is not a static property to be evaluated only once, at session initiation. Rather, risk is a dynamic property, and the level of risk posed by a User or Device can change mid-session. For example, a Device could move from a trusted state to an untrusted state (e.g., EDR detects a malware infection, or Device IP address reputation changes from benign to malicious). For this reason, User and Device risk should be continuously assessed throughout the duration of a work session. This continuous risk assessment is referred to as Context.

Once a sufficient level of trust in a User and a Device has been established, access may be granted to one of more Resources as specified by policy.

2.4. ZTA Frameworks

The descriptions above provide a generic, high-level understanding of basic ZTA principles. In practice, however, ZTA cuts across many different policy and technology domains, and implementing a full ZTA program can require considerable effort and attention to detail.

Industry, academia, and standards bodies have responded to this challenge by producing several reference frameworks for ZTA, to guide organizations in their approach to Zero Trust. Here, we review a few examples.

2.4.1. Google – BeyondCorp

Starting in 2014, Google published a series of influential whitepapers documenting their own multi-year Zero Trust implementation. Collectively referred to as “BeyondCorp,” the six whitepapers propose Google’s vision of a ZTA, with special emphasis on migrating to a network architecture without traditional perimeter controls.

Google's ZTA features five design objectives:

1. Securely Identifying the Device
2. Securely Identifying the User
3. Removing Trust from the Network
4. Externalizing Applications and Workflows
5. Implementing Inventory-Based Access Control

In general, BeyondCorp shifts access controls from network edges and perimeters to individual User and Device identity, embracing the oft-repeated maxim that “identity is the new perimeter.” This focus allows an organization's employees, contractors, and business partners to work more securely and remotely from any location without the need for a traditional remote access technologies like Virtual Private Networks (VPN). Key to this architecture is a next-generation access model for resources, an Internet-Facing Access Proxy (alternatively called an “Identity-Aware Proxy” or simply an “Access Proxy”). The Access Proxy enforces the security requirements of traditional VPN – strong authentication, strong encryption, etc. – in a centralized manner, without the protocol overhead of IPSec and similar tunnelling approaches.

2.4.2. NIST – Special Publication 800-207

In 2020, National Institute of Standards and Technology (NIST) developed its own framework for ZTA (NIST Special Publication 800-207). The standard does not propose a definitive architecture for Zero Trust; instead, it proposes several architectural variations, emphasizing the advantages and disadvantages of each. Each of these variations, however, reflect a common set of design goals (or “tenets” as they are described in the standard). They are as follows:

1. All data sources and computing services are considered resources.
2. All communication is secured regardless of network location.
3. Access to individual enterprise resources is granted on a per-session basis.
4. Access to resources is determined by dynamic policy—including the observable state of client identity, application/service, and the requesting asset—and may include other behavioral and environmental attributes.
5. The enterprise monitors and measures the integrity and security posture of all owned and associated assets.
6. All resource authentication and authorization are dynamic and strictly enforced before access is allowed.
7. The enterprise collects as much information as possible about the current state of assets, network infrastructure and communications and uses it to improve its security posture.

2.4.3. Other Frameworks

Other Zero Trust frameworks of note:

- Although not exclusively billed as a “Zero Trust” architecture, Gartner's Continuous Adaptive Risk and Trust Assessment (CARTA) framework embodies many basic ZTA principles, such as continuous risk assessment.

- The US Cybersecurity and Infrastructure Security Agency (CISA) has published a “Zero Trust Maturity Model,” intended primarily for consumption by federal agencies. CISA framework focuses on five domains, each with maturity levels ranging from “traditional” to “optimal.”
- The United Kingdom’s National Cyber Security Centre (NCSC) outlines a six-pronged Zero Trust network architecture in its broader published guidance for device security.

2.4.4. Using the ZTA Frameworks

There is no uniform, “one size fits all” approach to ZTA. Organizations will have to evaluate their current IT strengths, capability gaps, and the overall threat landscape to develop their own unique approach to ZTA. To the extent that ZTA frameworks (such as those mentioned above) can guide and assist with this effort, so much the better.

2.5. Scope of ZTA

It should be noted that the scope of a ZTA typically applies to:

- An organization’s enterprise Users, Devices, and Resources.
- Third parties (contractors, business partners, vendors, etc.) performing enterprise duties on behalf of the organization.

Although the same fundamental concepts apply, information security management of an organization’s customers or subscribers should be treated separately from its enterprise needs.

2.6. Embarking on ZTA

It is often stated that Zero Trust is not a specific product or technology. Rather, it is an assemblage of multiple components, all operating in concert, to realize a specific security posture. As such, any approach to ZTA is most fundamentally an effort in systems integration. In terms of project management, organizations would be well advised to approach ZTA from this perspective.

It is also often stated that Zero Trust is not a specific project deliverable or operational practice, but rather a “journey.” This choice of language reflects the reality that – for all but the smallest of organizations – migrating to a Zero Trust posture will require sustained effort over a significant period of time. For example:

- In a 2022 executive memorandum from the US Office of Management and Budget titled “Moving the U.S. Government Toward Zero Trust Cybersecurity Principles,” OMB noted that “Transitioning to a zero trust architecture will not be a quick or easy task for an enterprise as complex and technologically diverse as the Federal Government.” The memo further requires that specific Zero Trust goals be met within a three-year timeframe (end of Fiscal Year 2024).

Accordingly, claims of “overnight” transformations from legacy networks to Zero Trust should be regarded with skepticism. The Zero Trust journey is one of incremental successes – it is a marathon, not a sprint.

3. Brief History of ZTA at Comcast

3.1. 2019 – The Start of Our ZTA Program

Comcast has been on its ZTA journey since 2019. The journey began as most large initiatives do – by building the business case for Zero Trust and why it was important to the organization.

At the time, the need to consider new security strategies was self-evident – the rate of publicly disclosed security incidents was increasing dramatically. To cite just one example of many, in the third quarter of 2019, the RiskBased Data Breach QuickView Report noted that there had been 5,183 breaches during the year, exposing 7.9 billion records. Compared to the 2018 Q3 report, the total number of breaches had increased 33% year over year, and the total number of records exposed had increased 112%.

Zero Trust was quickly identified as the security strategy most worth pursuing. In terms of socializing this new approach to information security, the “Castle and Moat” metaphor really helped paint the picture whenever we needed to explain the concept of Zero Trust to internal stakeholders. For example, a traditional medieval castle may feature high walls made of brick or stone, perhaps further protected by a moat and a drawbridge-style gate. The walls and moat form the “perimeter” by which the residents of the castle are protected from external threats. Entry and egress to the protected castle is governed by the gate. However, if an intruder can get past the gate, they have unfettered access to what is inside the castle. There may be some impedance once past the walls and moat, but the reality is that access can be quite open.

Figure 5 – Classic Physical Perimeter Defense Architecture

Replace “castle” with “internal and/or enterprise network” and “gate” with “firewall” and one arrives at the traditional network security perimeter model, which was developed in the late 1980s and served the Internet community well for the better part of two decades.

In our new reality, however, with the rise of business partner integrations, public cloud services, and application deployment at network’s edge, it is not enough to rely on the traditional network perimeter model. We need to verify every User, every Device, and every attempt to access Resources (systems, applications and information), every time.

The “Castle and Moat” analogy served to ground technical and non-technical professionals and executives, which in turn was important to gain their support. A tremendous amount of stakeholder engagement was required on how we were approaching Zero Trust because it required ongoing partnership across the organization, with entities including our network engineering team, information technology, and our geographic divisions. Another important partner in this endeavor was Comcast’s Cybersecurity Guild. With over 200 members, the Cybersecurity Guild is a rich and interactive community of employees who are cyber-minded or have day-to-day responsibilities for cybersecurity in their business units.

Although developing the business case involved significant effort, it found a receptive audience, as our executive leadership has long regarded cybersecurity as a critical partner to the business. We didn’t have to convince everyone that it was important to embark on the Zero Trust journey – everyone knew that we just had to do this. The challenge was figuring out how we were going to do this and devising a strategy in a relatively short period of time.

We soon began developing the overall structure of our Zero Trust program. Some of the earliest influences included the BeyondCorp framework (discussed in Section 2.4.1) and Microsoft, which was underway with enterprise solutions and SSS to enable Zero Trust at scale.

Our leadership, architects, engineers, and other stakeholders eventually coalesced around a three-pronged program structure, consisting of:

- **Guiding Principles**
- **Security Domains**
- **Program Governance**

We discuss these in more detail in Sections 4, 5, and 6, respectively.

3.2. 2020 – COVID-19

In early 2020, the COVID-19 pandemic emerged as a worldwide health concern. The pandemic created a seismic shift in how our employees and business partners worked, and everyone was living with the reality of remote work and further diminished network perimeters. Companies like ours could no longer rely on the safeguards that we took for granted before the pandemic – working together, in common facilities, on an enterprise network that provided a basic degree of assurance. Our new way of working made it much more clear why Zero Trust is so important.

Arguably, because of the COVID-19 pandemic, Zero Trust is even more relevant today than it was in 2019.

The threat landscape also changed significantly during COVID-19. The Harvard Business Review highlighted the challenge that with the migration to remote work during COVID-19, cyberattacks increased exponentially. Businesses saw more attacks of every kind, but the headline for 2020 was ransomware attacks, which increased 150% over the previous year. Equally worrisome, the amount of money paid by victims of these attacks increased more than 300% in 2020.

COVID-19, however, did not deter our ZTA efforts. Quite to the contrary, COVID-19 accelerated them. Moving a significant portion of our workforce to remote work re-emphasized the need to move beyond the traditional perimeter security model.

3.3. 2021 to Present – Acceleration

Recently (and particularly within the last one to two years) there has been more industrial awareness of security as a business enabler. Conversations have shifted, with business clients increasingly asking about their service provider's adherence to Zero Trust practices.

In May 2021, we saw the issuance of the White House's "Executive Order on Improving the Nation's Cybersecurity." The order states (emphasis added):

The United States faces persistent and increasingly sophisticated malicious cyber campaigns that threaten the public sector, the private sector, and ultimately the American people's security and privacy. The Federal Government must improve its efforts to identify, deter, protect against, detect, and respond to these actions and actors. The Federal Government must also carefully examine what occurred during any major cyber incident and apply lessons learned. But cybersecurity requires more than government action. Protecting our Nation from malicious cyber actors requires the Federal Government to partner with the private sector. ***The private sector must adapt to the continuously changing threat environment, ensure its products are built and operate securely, and partner with the Federal Government to foster a more secure cyberspace.***

4. Guiding Principles

As previously discussed, the Zero Trust model assumes that every security principal (every User and every Device) is a potential threat until verification. This assumption holds regardless of whether those principals' network location appears to be internal or external to the organization.

We also assume that despite our best efforts to adopt sound information security practices and secure our enterprise, incidents can and will occur. Many factors give rise to this reality, most notably Zero-Day exploits (exploits directed at previously unknown and/or undisclosed vulnerabilities).

These assumptions give rise to the two guiding principles of our ZTA:

1. **Never Trust, Always Verify.** Users and Devices must establish trust before obtaining access to Resources.
2. **Prepare To Be Breached.** Our networks, systems, and applications must be designed to limit the impact of incidents.

Principle #1 was discussed at length in Section 2 but bears repeating. Users/Devices begin a work session in a state of Zero Trust, and Users/Devices must therefore establish trust before obtaining access to Resources. Trust is established through authentication, policy compliance, and risk assessment. Importantly, Trust must *not* be established by the perceived physical or logical network location of a User or Device.

Principle #2 asserts that if incidents cannot be prevented with certainty, the next best strategy is to plan for their eventuality. The goal is to minimize the degree to which Resources are affected by incidents in the broader technical environment. This is often referred to as minimizing the “blast radius” of an incident, preventing spillover effects and lateral network movement.

These two guiding principles informed our work across our entire ZTA program. For every significant architectural decision, we would ask the same two questions:

1. How does this decision improve the trustworthiness of Users and/or Devices?
 - a. Or conversely, how does this decision further reduce our reliance on networks as trust factors?
2. How does this decision help mitigate the effects of an incident?

5. Security Domains

Next, we applied the guiding principles across three broad security domains:

- **Security Hygiene.** Hygiene concerns the security posture of our main ZTA principals – Users, Devices, and Resources.
- **Network Microsegmentation.** Microsegmentation focuses on partitioning our network environments into smaller, workload-specific enclaves.
- **Application Access.** Access governs how our Resources are exposed to Users and Devices, regardless of their physical or logical network locations.

Each of these domains is discussed in turn.

5.1. Security Hygiene

Like many large companies, Comcast has a complex IT environment that was built through years of product and platform growth and acquisitions. There was some foundational work that needed to be addressed to ensure that as a company, we were ready for our Zero Trust journey. This foundational work was called **Security Hygiene** (or simply “Hygiene”), defined as a focus on the security posture of our security principals: User, Devices, and Resources.

We defined the scope of this work across several parallel workstreams, termed **Pillars**. For each Pillar, we defined the problem space that we needed to resolve, and definitions of what success looked like. We also aligned on quantified targets for success wherever possible.

The Pillars were defined as follows:

- 1. User Identity & Access Management**
- 2. Resource Identity & Access Management**
- 3. Asset Ownership**
- 4. Device Identity & Management**
- 5. Visibility & Hardening**

5.1.1. User Identity & Access Management

Section 2.3 notes that strong authentication for Users plays a pivotal role in ZTA. This more broadly requires an examination of how an organization performs Identity & Access Management (IAM) for its Users. IAM refers to an entire suite of tools and services for provisioning, managing, and deprovisioning User identities. IAM is also used to manage User privileges and entitlements, as determined by a User's title, position, and/or organizational roles.

A core component of IAM is the Identity Provider (IdP). The IdP's primary responsibilities are:

- **Authenticating Users.** This can be accomplished using one or more of the mechanisms described in Section 2.3.
- **Asserting User Identities to Resources.** This can be accomplished using protocols such as Kerberos, Security Assertion Markup Language (SAML), and Open Authorization & OpenID Connect (OAuth, OIDC). Proprietary protocols also exist.

Ideally, an organization should implement one, centralized IAM platform with as few IdPs as possible (again, ideally one).

The alternative is multiple IAM platforms with competing/duplicative identity stores that complicates:

- User provisioning and deprovisioning
- Assignment of user authorizations and entitlements
- Compliance
- Reporting
- Far from least important, the User experience (e.g., access to some systems works whereas access to other systems does not, confusion over which credentials or MFA/SSO mechanisms to use for a given system, and so forth).

5.1.2. Resource Identity & Access Management

Resource IAM is essentially the complement to User IAM. If ZTA requires Users to produce strongly authenticated assertions of identity, it becomes necessary for Resources to consume those assertions. Otherwise, the identity assertions serve no purpose.

This generally requires Resources to align with:

- The same Identity Provider (IdP) employed for Users
- The same authentication protocols (SAML, OAuth/OIDC) supported by the IdP

The amount of effort required to integrate a Resource with a modern IdP varies considerably. It can range from the trivial (e.g., simple changes to a configuration file) to the substantial (e.g., installation and integration of third-party authentication libraries, custom code, and extensive testing). The latter is often the case with older, “legacy” Resources, for which modern protocols like SAML/OIDC did not exist at the time they were deployed.

5.1.3. Asset Ownership

Information systems cannot be protected if they are unknown to the organization. This requires an accurate inventory of:

- Devices
- Resources
- The organizational owners of such Devices and Resources

In most organizations, this requires the creation and maintenance of a CMDB or similar inventory/asset management system. As with user identities, the ideal is a single CMDB that provides complete coverage for all Devices and Resources in the organization. Multiple, competing CMDBs exhibit many of the same challenges experienced with multiple, competing IAM platforms – inconsistent views of asset ownership, impaired ability to protect unregistered assets, and so forth.

5.1.4. Device Identity & Management

As with User identity, Device identity is extremely important for purposes of ZTA. It allows organizations to assign specific roles and entitlements to the Device (for example, an administrative workstation, compared to workstations intended for normal workforce use), establish unique accountability for Device activity, and so forth.

Device identity should be established through cryptographically strong mechanisms. Examples include digital certificates, public key pairs (independent of certificates), bearer tokens such as OAuth refresh tokens, and so forth. These credentials are typically created at the time a Device is activated or joined to an administrative framework (such as an Active Directory domain, a Kerberos realm, and so forth).

Device management is equally important as establishment of identity. A Device is said to be “managed” if an organization has administrative control of the Device and can apply security policy to it; otherwise, the Device is considered unmanaged. An insufficiently managed or unmanaged Device poses risk to a ZTA. The device may lack appropriate security tooling like EDR, or may not be configured to require commonplace security controls, such as idle UI session timeouts.

A subset of device management, Mobile Device Management (MDM) refers to the administration of mobile devices, such as laptops, smartphones and tablets. MDM caters to the unique characteristics of mobile devices, in that such devices are typically more limited in their capabilities than server, desktop or workstation computers. Mobile devices are also more easily lost or stolen than their desktop counterparts; as such, MDM is frequently used to enforce confidentiality-preserving security requirements, such as storage encryption.

5.1.5. Visibility & Hardening

Visibility (often also called Telemetry) refers to the monitoring of systems and networks in real time.

Resource Visibility refers to the degree to which system-level properties and activity can be observed on a Resource. Examples include:

- Resource utilization (CPU, memory, storage, network & other input/output)
- Process and thread activity
- File- or filesystem-level artifacts (existence of absence of specific files, etc.)
- (Windows) Existence and/or values of specific registry settings
- Collection and/or examination of system logs

Depending on the level of visibility required, some management frameworks (such as membership in an administrative domain or MDM) may provide sufficient data. In other cases, the deployment and management of specialized agent software may be required.

Resource Visibility also assists with maintaining accurate asset management (Pillar 3).

By contrast, **Network Visibility** refers to the monitoring of network communications in real time. Ideally, such monitoring can be summarized into data flows, or sequences of network packets from sources to destinations.

Communications may be monitored:

- Via the capabilities of standard network infrastructure (both physical and virtual), such as routers and switches.
- Via specialized, media-specific collection devices, often referred to as network taps.

The purpose of network visibility is to detect signals that possibly indicate:

- Lateral movement within an organization
- Data exfiltration

Hardening applies to Devices, Resources, and network infrastructure (collectively, “nodes”) and primarily consists of:

- The disablement of all unnecessary network services on a network-attached node.
- Enabling all practical security controls on the node’s remaining network services.

The main objective is to reduce the **attack surface** of network-attached nodes.

In security taxonomy, “attack surface” is the set of all possible entry points into a Device, a Resource or other information system. A system with a large amount of attack surface is thought to be more vulnerable than a system with less attack surface. The rationale is simple – every entry point represents a potential avenue of attack, either in terms of vulnerability, incorrect configuration, or both. As such, the more entry points an attacker has to work with, the greater the likelihood that one of them can be successfully exploited (and lead to system compromise).

Fortunately, attack surface can be reduced through appropriate system hardening. However, hardening does have its practical limits. Some services must inevitably remain operational for a Resource to perform its intended function – a web server must respond to requests for HTTP content, for example, and a DNS server must respond to name service queries. Other services might need to remain for purposes of monitoring or management, such as SNMP or SSH.

5.2. Microsegmentation

5.2.1. Definition

Even with proper hardening, the overall attack surface of many environments continues to increase, in many cases simply due to the sheer number of Resources and other nodes that are internetworked. The inevitable result is:

- More humans interacting with machines.
- More machines interacting with machines.

In terms of ZTA, one way to address this challenge is through the adoption of **segmented** network architectures. A network is said to be segmented if it is physically or logically separated into smaller, isolated subnetworks. The goals of this approach are twofold:

1. Separate public-facing components from private (e.g., non-public-facing) components.
2. Separate unrelated components from each other.

Taken to its logical end state, this approach results in **microsegmentation**, or the subdivision of networks down to the level of discrete, application-specific workloads. In a microsegmented environment, each distinct application receives its own dedicated, logically independent subnetwork.

Many technologies exist to facilitate microsegmentation. Virtual Local Area Networks (VLANs) are a classic example, and variations of this approach (e.g., Private VLANs) exist as well. More contemporary approaches include:

- Software Defined Networks, which use a centralized component to make forwarding decisions for individual packets. OpenFlow is a classic implementation of SDN.
- Overlay networks (e.g., VxLAN), which are networks layered on top of other networks.
- Hypervisors, which can enforce network isolation between guest virtual machines.
- Host-based firewalls, in some cases complemented with agent-based implementations to facilitate firewall rule management.

It is important to consider the various different approaches to microsegmentation when building and deploying new applications and application components.

5.2.2. Example

A good motivation for microsegmentation comes from the shipbuilding industry. The watertight body of a maritime ship is referred to as the hull. Modern shipbuilding techniques separate the hull into “compartments,” or individual watertight subdivisions. The rationale for this design is that damage to any portion of the hull can (hopefully) be limited to a specific compartment, instead of flooding the entire hull and sinking the ship.

An example of compartmentalization is depicted in Figure 6. Here, one shipboard compartment has sustained damage and subsequently floods with water. Adjacent compartments, however, are sufficiently isolated from the damaged compartment, and hence do not flood. In effect, the severity and extent of the incident has been minimized.

Figure 6 – Shipboard Compartmentalization

This design can be extended into the worlds of computer networks and distributed systems. For example, consider Figure 7:

Figure 7 – An Unsegmented Network and a Microsegmented Network

Here we have an example of an unsegmented network (left). In typical “Castle and Moat” architecture, it has a substantial exterior perimeter but no interior perimeters. Should an adversary make it past the perimeter firewall and compromise a Resource, they can leverage that access as a foothold to further move laterally within the network. In the depicted example, an attacker manages to compromise one system (lower left), then uses that system to launch additional attack against other reachable systems in the same network (lower right, upper right).

Compare this to the microsegmented network depicted on the right, where each system occupies its own individual subnetwork. Each of these “micro” subnetworks is isolated from one another, and each features its own individual perimeter. Breaching the perimeter of one subnetwork (and the systems contained within) does not gain an attacker access to other, unrelated subnetworks. In this manner, and as with the example of the shipboard compartment, breaches and incidents can be isolated to the fewest possible number of systems. Not only does this architecture reduce the “blast radius” of an incident, but it also gives organizations more time to detect the incident and mount a response, before too much additional damage is done.

5.3. Application Access

Before delving into our ZTA access model for application Resources, it would be helpful to review the traditional access model that has accompanied “Castle and Moat” perimeter architectures.

In the traditional model, organizations deploy applications to their internal, trusted enterprise networks. Users access these applications from the safety of those internal, trusted networks, shielded from external abuse and attack by firewalls and other perimeter controls.

Now consider the use case where the Users are remote – other organizational locations, business partner locations, or perhaps the Users’ residences – and hence in untrusted network locations. In such cases, technologies like VPNs are often employed to provide secure connectivity over public networks, like the Internet. In the traditional model, VPNs provide paths to trusted networks over untrusted networks.

However, ZTA asserts that computer networks should be regarded as untrusted. Viewed this way, VPNs provide paths to untrusted networks over *other untrusted* networks, which is nonsensical. ZTA essentially puts all users into a perpetual remote access security posture, but traditional remote access mechanisms (like VPN) are not philosophically aligned with ZTA.

This situation gives rise to the Identity-Aware Proxy/Access Proxy models discussed in Section 2.4. Comcast decided to pursue deployment of Access Proxy infrastructure as the third domain of its broader Zero Trust program.

5.3.1. Architecture

With ZTA, the Access Proxy becomes the primary model by which Resources are exposed to Users and Devices.

Figure 8 – Access Proxy Arbiting Access to Resources

We decided to decompose the Access Proxy into three functional components:

- Policy Enforcement Point (PEP)
- Policy Decision Point (PDP)
- Enterprise Risk Engine (ERE)

This was done primarily so that we could:

- Develop each component independently, on its own release schedule.
- Scale each component horizontally within a given datacenter environment.
- Geographically load balance the components across our enterprise footprint.
- Facilitate an active/active configuration for high availability and redundancy.

An exploded view of these components and their integration can be depicted as follows:

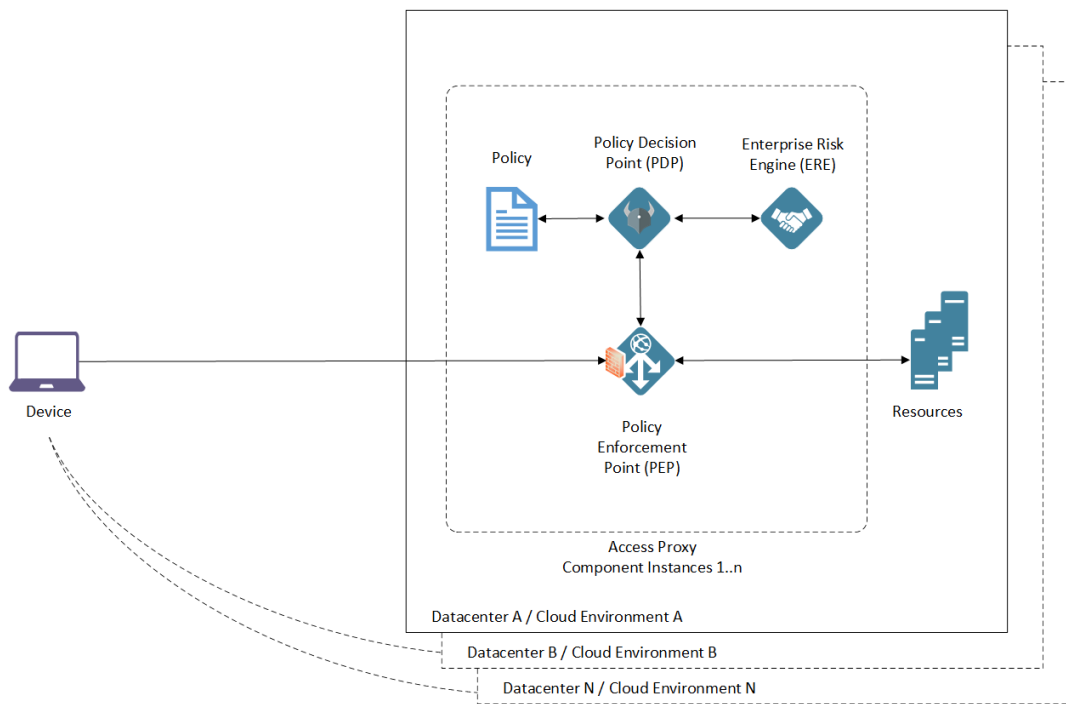

Figure 9 – Exploded View of Access Proxy Components

5.3.2. Policy Enforcement Point

The PEP is essentially an identity-aware reverse proxy. It is responsible for directly mediating connectivity between security principals (Users and Devices) and enterprise Resources. The PEP serves as the ZTA boundary between Resources and their microsegmented networks (which are managed by Resource owners) and all other networks.

5.3.3. Policy Decision Point

The PDP is primarily responsible for authorizing access to enterprise Resources. The PDP uses a combination of static policy (in the form of predefined security rules) and context (in the form of dynamic, near-real-time risk data and other signaling) when making access control decisions. Access control decisions are then enforced by PEPs as necessary.

5.3.4. Enterprise Risk Engine

The ERE is the primary aggregator and provider of context, primarily in the form of risk signals. A risk signal is any kind of data or metadata that provides contextual insight into the security posture of a User, a Device, or a Resource the User/Device is attempting to access. Examples of risk signals include geolocation, velocity, IP address reputation, and Device compliance.

The ERE continuously receives risk signals from sources of truth, including MDM, EDR and IP Reputation. It can then evaluate and share the risk levels of Users and Devices across the security ecosystem.

At of this writing, the PDP is the primary consumer of ERE services, which in turn considers risk signals provided by the ERE when making access control decisions. The ERE is essentially an adjunct used by the PDP to make context-aware access control decisions.

6. Program Governance

We believe that success is tied to how you engage with your enterprise partners. Any effort as large as a ZTA journey requires significant governance and project management. To this end:

- Our ZTA program was championed by our Executive Vice President, who is also our Chief Information Security and Product Privacy Officer.
- Product, Program and Architecture leaders were nominated to guide the overall effort.
- A team was defined to support the overall ZTA program. Each hygiene Pillar was assigned an Executive Leader, a Product Lead and a Program Lead. In most cases, this team was comprised by cybersecurity professionals; in other cases, it included partners from other departments within our organization (IT, Reliability Engineering).
- An Executive Committee was established to provide guidance on a quarterly basis that included leaders from our organization, our business units, Human Resources, Procurement, Legal, Compliance and Finance. We work for a very financially disciplined company. The meetings are a force and function to regularly remind us of the goals that we set, our progress, what's next and whether we need to shift course.
- A Steering Committee was established to provide stakeholder direction between the various organizations contributing development, engineering, and support resources to the program. This committee meets twice a quarter.

We engaged our Executive and Steering Committee members directly very early on in the program to ensure we were properly framing our strategy. They in turn connected us with the critical influencers in our organization who were very supportive and conveyed their commitment to our ZTA journey.

As ZTA started to gain traction, we expanded the formal means of communication to include:

- Cybersecurity Stakeholders – This includes engagement with our Business Information Security Officers (BISOs), Portfolio Leads and Cybersecurity Leads across the company.
- Employee Resource Groups – We closely partnered with technology resource groups to promote, inform and engage partners in our ZTA program:
 - Cybersecurity Guild – Our primary partner is our Cybersecurity Guild with hundreds of members. The Guild hosts a ZTA-themed event at least every quarter that is open to all of our Comcast technical resource groups.
 - We partner with other technical resource groups where they can provide necessary subject matter expertise. For example, we presented our architectural strategy as early concepts to Comcast's Software Ambassador's Guild, and we gained invaluable feedback that influenced our onboarding approach and commitment to automation wherever possible.
- Our ZTA scope is included in annual and quarterly roadmap planning across our technology and business units.

- We are very intentional about how we approach wider employee communications. We have a very tech-savvy workforce and recognized that ZTA would have an impact on how we work. We design our employee experiences and workforce communications around the north star of making it easy for our employees to do the right thing to protect our organization. We partner with our Communications Team to produce campaigns that make the concepts relatable. Cybersecurity Awareness Month is always observed in October, during which time we socialize important security trends. Last year, we introduced ZTA in a game called “Cyber Splash,” a popular smartphone application that is available to all our employees. Our “Trust Titan Superhero” made his big debut in October 2021.

As our ZTA program gained further traction, our BISOs soon became critical partners. The BISOs facilitate a streamlined engagement model for delivering security services to our business units. The BISOs worked with the leaders across Comcast to manage ongoing priority setting for ZTA programs and to continually assess feedback on how those programs were going. The feedback wasn’t always easy to hear. There are times when we had to address technical issues, process issues, and team issues. In addition, our technical and business partners also felt the strain of the convergence of several compliance programs. We view feedback as a gift and used the opportunity to improve our approach and for corporate leadership to stay better aligned.

7. Lessons Learned

7.1. Engagement

It is crucially important to get key stakeholders involved early. An organization’s IT function is the most obvious candidate for collaboration, and our security organization spent much time meeting with IT and aligning efforts. Other key partners included our Office of the CIO, Network Engineering, Procurement, Finance, Human Resources, and Corporate Communications. The governance framework described above ensured ongoing executive engagement and alignment with our key stakeholders.

7.2. Cloud First

Applying elements of ZTA to existing systems and infrastructure – particularly microsegmentation – can be a challenge. Early experimentation and prototypes confirmed this reality. As such, we initiated our ZTA journey with a priority on our new cloud deployments. We focused on enabling microsegmentation and other controls through automated policy. Over the course of one year, we trained our development teams in a “cabin crew” structure that allowed for imbedded expertise within each development organization. Later, we expanded the focus to our legacy applications that require a more hands on, consultative approach.

7.1. Buy vs. Build

In one sense, ZTA is like any other information technology initiative, in that solutions can be realized in many ways, each with its advantages and disadvantages:

- Purchase commercial solutions (licenses, subscriptions, etc.)
- Leverage open-source solutions
- Develop in-house, proprietary solutions

This is often referred to as the “Buy vs. Build” scenario.

More often than anticipated, we had to make buy vs. build decisions throughout our program. These buy/build decisions were driven by our requirements and speed. We had to say “no” to some prototype development efforts in the beginning of our journey, and that’s hard to do when you have talented architecture and engineering resources at your disposal. Like any strategic initiative, ZTA needed to deliver value for the company. In some cases, we built our own ZTA components and SSS; in others, we purchased commercial solutions and services. In the latter case, vendor partnerships and strategic integrations have helped us get to where we need to be.

In our experience, the key to successful ZTA is exploring and finding the optimal mix of all three approaches (commercial off-the-shelf offerings, open-source, custom development) and spending the time and effort to integrate these solutions.

7.2. Application Owner Collaboration

For Application Access, we developed an onboarding process to identify strategic applications and register them for access via our Access Proxy infrastructure. Our initial approach entailed identifying the application owners for such applications. We soon discovered that our CMDBs used for identifying and cataloging application and asset information can become outdated over time. To accommodate this, we employed an intensive “white glove” engagement strategy to help identify application owners. This impeded our initial progress, but we learned and adapted the application ownership step as part of the onboarding process if necessary.

The next step in the onboarding process was to identify application authentication mechanisms and determine if they met the minimum thresholds established by our IAM program. In our case, that minimum threshold was based on the OpenID Connect standard (built on top of the OAuth 2.0 protocol). This proved to be a challenge for some application owners, for two reasons:

1. The longer an application has been in existence, the higher the probability that its organizational ownership has changed, possibly multiple times; and
2. When these transitions occur, knowledge transfer for the application’s business logic often overshadows IAM knowledge transfer, due to time constraints and other factors.

The result is that the basic application security knowledge is sometimes lost. In such cases, the ZTA team works collaboratively with application owners to understand their authentication frameworks.

And finally, it goes without saying that implementing a comprehensive ZTA often requires application owners to undertake multiple security workstreams, sometimes in parallel. For example, an application team may be asked to simultaneously:

1. Modernize their authentication mechanisms
2. Migrate to a microsegmented network architecture
3. Onboard their application for Access Proxy integration

This can be a tall order for even the most well-resourced application owners. Multiply this single example by the total number of candidate applications in the environment, and one can see that this can seem like an overwhelming set of asks for an organization's application community.

It is imperative that the ZTA team convey and communicate to application owners "security is a team sport" and that everyone is in the ZTA journey together. Defining ZTA priorities at a program level will help build trust between the security and application teams and prevent the perception that ZTA is a series of individual asks, but rather a set of unified strategies to improve the overall security posture of the enterprise.

7.3. Business Partner Collaboration

We spent considerable time defining the quantitative goals for ZTA and the impacts across our internal business units. We had big goals (e.g., "harden X thousand Resources by Q4") and we had to define the intermediate milestones to get to those goals. The challenge was that we didn't always know exactly how we were going to get there. We persistently took stock of what we needed to address and defined risk-based priorities (e.g., "harden Internet-exposed Resources first"). Our business partners appreciated that we put so much thought into the strategy.

Still, this required a high degree of collaboration between Cybersecurity and our business and technical partners. Successful ZTA requires partnership across an organization, not competition. It was important to us that the collaboration meant that the outcomes were better because of teams working together. There were a lot of synergies across the Pillars and meeting security needs also addressed other needs for our business.

At the core of a team is solving those unsolved problems and making the most of our ecosystem. We had to become a provider not just of standards but of solutions for our enterprise. Our business units expect us to look out for them and to anticipate the needs to secure the business.

8. Future Work

In this section, we briefly examine opportunities for enhancement and improvement to our ZTA.

All estimates of this nature are subject to change due to the ever-dynamic needs of our business, as well as unforeseeable events and trends in the information security landscape. As the entire Internet community learned with the Log4j vulnerability of 2021, even the best plans can be upended by a single ill-timed Zero-Day.

8.1. The Multi-Year Journey

In Section 2.5, we noted that for all but the smallest organizations, ZTA is a multi-year endeavor. Overall, Comcast is making good progress on its ZTA journey.

We expect much (if not all) work in the Security Hygiene domain to be complete by the end of 2022. We have also been microsegmenting in cloud/virtual environments for the past three years, and our Access Proxy infrastructure entered production in 2021. These were all big mountains to climb. We are lucky to be a part of an organization where our employees appreciate leaning into a challenge.

Continued expansion of microsegmentation and Access Proxy infrastructure will be primary focus areas of 2023 and beyond. Most net-new deployments already align with our ZTA; it is the uplift of existing and/or legacy Resources that will command most of the effort.

8.2. Centralized and Continuous Risk Evaluation

One of the key tenets of the 2022 OMB memorandum (Section 2.6) is the need for a Continuous Diagnostic and Mitigation (CDM) process. A CDM process ensures that continuous policy evaluation and risk assessment can be conducted on Users and Devices during their active sessions. The memorandum further states that:

A necessary foundation for any enterprise-wide zero trust architecture is a complete understanding of the devices, users, and systems interacting within an organization.

The generally accepted practice in introducing and incorporating an enterprise wide CDM system into a company's security ecosystem is to:

1. Enable risk signal collection for all Users, Devices and Resources
2. Evaluate the signals in a policy driven manner
3. Gradually and incrementally enable and enforce the policies to improve the overall enterprise security posture.

Comcast has developed its ERE component, currently part of the Access Proxy infrastructure. This essentially serves as a CDM engine. Our future plans are to enhance the ERE with more risk signaling from more risk sources, ultimately including Resources and other end-user applications. The latter possibility is especially intriguing, as it would allow for suspicious application-level activity (e.g., Mallory transferring unusually large amounts of money in a finance application) to serve as a source of risk signals.

8.3. Microsegmentation

Our initial forays into microsegmentation have largely centered around cloud deployments (both on-premise cloud environments as well as hosted/public cloud environments). It is generally easier to microsegment in a virtual environment, as individual application workloads can be allocated their own virtual microperimeter environments (virtual switches, virtual networks, virtual firewalls, etc.)

In 2022 and beyond, we seek to retrofit the microsegmentation concept into “bare metal” and other non-virtualized environments. Several strategies have been considered (see Section 5.2 for examples) and our ultimate strategy may yet employ multiple approaches.

8.4. Converged Application Access

As an organization with a significant mobile/remote workforce (made even further mobile/remote due to COVID-19) we deployed our Access Proxy model initially to support remote access use cases, as an alternative to VPN. Over the long term, however, we wish to route all application access through Access Proxies, both on-premises as well as off-premises.

Figure 10 – Converged Access Proxy Architecture

Depicted in this figure are two network paths – one from an organization premises network, the other from an untrusted network such as the Internet. Ultimately, both paths converge on an Access Proxy – one network path is not favored or preferred over another. This is the ultimate end-state architecture for application access in ZTA.

9. Service Provider Considerations

In many ways, ZTA for Multi-System Operators (MSOs) and Internet Service Providers (ISPs) is not fundamentally different than other organizations.

9.1. Infrastructure Hardening

For many years, it has been common practice for operators to harden their access networks to Zero Trust security standards, long before the term “Zero Trust” even entered commonplace use. The Data-Over-Cable Service Interface Specifications (DOCSIS) 3.0 Security Specification, which dates to 2006, states its goals as follows:

1. To provide cable modem (CM) users with data privacy across the cable network;
2. To prevent unauthorized users from gaining access to the network’s RF MAC services.

These goals align neatly with ZTA, in that:

1. Assume that the network provides no assurances of privacy. If privacy is desired, it must be established by higher-layer communications protocols.
2. No assumptions are made regarding the identity or authenticity of devices (CMs) on the network. Devices must establish identity through strong authentication before services are provisioned.

DOCSIS then specifies solutions that achieve these goals:

1. For privacy, the Baseline Privacy Interface (BPI) protocol.
2. For authentication, X.509 digital certificates.

Similarly, providers have long hardened the network infrastructure – routers, switches, Cable Modem Termination Systems (CMTSes), etc. – that are used to provision DOCSIS services. Examples include:

- Centralized Authentication, Authorization & Accounting (AAA) frameworks, such as RADIUS, Diameter, TACACS+, LDAP, Kerberos, etc.
- Strong administrative authentication (OTP, public key, etc.)
- Role-based authorization (read only, read/write, CLI command authorization, etc.)
- Encrypted administrative interfaces (HTTPS, SSH, etc.)
- Access Control Lists (ACLs)

In general:

- Service providers should begin regarding their enterprise networks as akin to their access networks, in terms of default trust levels and security guarantees.
- Service providers can and should use their experience hardening access network infrastructure to similarly secure enterprise infrastructure to the same degree.

9.2. Network Visibility

Service providers often deploy significant network monitoring infrastructures, to as to monitor their access networks for performance, faults, and other useful diagnostic information. Simple Network Management Protocol (SNMP) – now in its third version and with significant security enhancements – is the most well-known monitoring protocol.

Existing investments in access network monitoring can and should be deployed to monitor enterprise networks as well, for the reasons discussed in Section 5.1.5.

10. Conclusions

ZTA represents a fundamental shift away from traditional approaches to information and network security. In the past, “internal” networks were safe places, walled off from external threats by “the firewall” and other perimeter controls. Now, however, we are in a state of constant vigilance, where networks do not provide the security assurance they once did.

ZTA recognizes this reality and proposes an alternative approach, one where Users and Devices must establish trust before gaining access to Resources. Trust must be established with confidence (e.g., strong authentication) and network location is not to be used as an authenticator or a credential.

Finally, ZTA is not an experiment – it is a practical, pragmatic approach to security that can be realized with modern IT support structure. If not already on their journey, organizations should strongly consider the merits of ZTA and act accordingly.

Abbreviations

AAA	Authentication, Authorization & Accounting
ACL	Access Control List
BISO	Business Information Security Officer
BPI	Baseline Privacy Interface
CARTA	Continuous Adaptive Risk and Trust Assessment
CDM	Continuous Diagnostic and Mitigation
CISA	Cybersecurity and Infrastructure Security Agency
CM	Cable Modem
CMDB	Configuration Management Database
CMTS	Cable Modem Termination System
DOCSIS	Data-Over-Cable Service Interface Specifications
DNS	Domain Name System
EDR	Endpoint Detection & Response
ERE	Enterprise Risk Engine
FIDO	Fast IDentity Online
IAM	Identity & Access Management
IdP	Identity Provider
ISP	Internet Service Provider
MDM	Mobile Device Management
MFA	Multi-Factor Authentication
MSO	Multi-System Operators
NCSC	National Cyber Security Centre
NIST	National Institute of Standards and Technology
OAuth	Open Authorization
OIDC	OpenID Connect
OMB	Office of Management and Budget
OTP	One-Time Password
PDP	Policy Decision Point
PEP	Policy Enforcement Point
PKI	Public Key Infrastructure
RADIUS	Remote Authentication Dial-In User Service
SAML	Security Assertion Markup Language
SCTE	Society of Cable Telecommunications Engineers
SIEM	Security Information and Event Management
SNMP	Simple Network Management Protocol
SSS	Security Support Structure
TACACS	Terminal Access Controller Access-Control System
UBA	User Behavior Analytics
VPN	Virtual Private Network
ZTA	Zero Trust Architecture
