1. Introduction

In proactive network maintenance (PNM), a goal of downstream spectrum analysis is to identify customer devices with impairments in RF (Radio Frequency) spectrum. Identifying the type of impairment is useful in determining the general causation, which is leveraged to infer the geolocation of the impairment's origin in the network. This paper describes the implementation of an automated, end-to-end solution that analyzes millions of sets of spectra and delivers PNM opportunities for the organization.

Utilizing wideband RF frequency response data from full-band captures (FBC), spectral impairments in the downstream are detected using a signature matching algorithm implemented as a 1-D convolutional neural network (CNN). The signature matching algorithm evaluates the set of spectrum data for customer devices on the cable plant. Certain impairments that originate in the cable plant, such as resonant peaks that can occur at an amplifier, impact the RF signal for multiple customers further downstream of the impacted component. One of the goals is to identify when multiple customers are experiencing the same signature, pointing to an issue in the network that can be resolved without individual visits to affected customers.

The impacted modems feed into a root cause analysis (RCA) algorithm that overlays the impaired devices onto a graph representation of the network topology. Through methods rooted in graph theory, the RCA algorithm narrows down the geolocation and system component(s) for the probable network device(s) where the issue originates. The impact of this workflow is an automated capability to identify not only customer-impacting issues, but also opportunities to proactively resolve issues before they become impacting across the entire network.

2. Background

2.1. Proactive Network Maintenance (PNM)

Utilizing full band capture data for the purpose of PNM initiatives to detect impairments in the downstream frequency response has been discussed in significant detail in multiple preceding works. Those contributions have directly influenced this automated system, by serving as a general roadmap for the planning, design, and implementation. The scope of this document starts with these works as the base knowledge and describes an automated system to enrich PNM opportunities [1-10].

2.2. FBC Data Characteristics

The basic unit of data for this system is the FBC of RF spectrum for customer devices where each spectrum sample consists of 8,704 values spanning 6 MHz to 1026 MHz. Spectrum features important to this work include downstream SC-QAM channels, guard bands, vacant spectrum, and pilots. Figure 1 illustrates a sample of a normal frequency response from a modem that maintains consistent power for occupied spectrum at the appropriate levels (approx. -17.1 dBmv).

Figure 1 – An Example of a Normal Frequency Response

Downstream SC-QAM channels are defined as 6 MHz wide spans separated by guard bands. Along with pilots, guard band power values are not particularly useful in detecting impairments in many cases. Vacant spectrum represents a span where no services occupy one or more channels and can be identified programmatically by the power values and channelizing the spectrum. By reducing the spectrum only to occupied channel signal power, the signatures become more amenable to machine learning techniques that detect anomalous spectra.

2.3. Downstream Wave Impairments

Certain impairments in downstream SC-QAM channels can be identified in the FBC. For the scope of this implementation, the focus is on four impairments – standing waves (amplitude ripples), water in the cable, resonant peaks, and suck-outs. These patterns will be referred to as the ‘wave’ patterns. Figure 2 shows examples of each type of wave impairment. Within each plot, the solid green line at -17.1 dBmV and solid red line (bottom line) at -33 dBmV represent an appropriate range for frequency response values of occupied spectrum.

Standing waves, caused by impedance mismatches, are periodic in nature and generally extend across the entire downstream spectrum (Fox, et al., 2021). When water is introduced to the cable, an aperiodic wave is produced due to random attenuation and may also be associated with a negative tilt (Fox, et al., 2021). Resonant peaks are significant, narrow spikes in the spectrum caused by any number of reasons (i.e., cold solder joints or loose modules) on network devices (Cable Television Laboratories, Inc., 2016). A suck-out is represented as “a concave notch with sinusoidal boundaries with attenuation in amplitude/power caused by impedance mismatches evenly distributed through the network” (Cable Television Laboratories, Inc., 2016).

Figure 2 – Examples of Wave Impairment Frequency Responses

2.4. Network Topology as a Graph

A convenient way to analyze network topology is through graph theory. Comcast has mapped the “access network from the CMTS to the customer premise equipment (CPE)” into a graph structure “while incorporating all of the physical and logical elements that form part of the network” (Harb, Subramanya, Narayanaswamy, Walavalkar, & Rice, 2021). The graph facilitates the application of algorithms, such as lowest common ancestor (LCA), to network elements and their attributes. For example, clustering RF impairments on the graph gives the organization comprehensive knowledge about the network elements involved and a view of the common experiences amongst multiple customers. In turn, this knowledge is leveraged to deploy the correct resources to a specific physical location for resolution. In combination with network monitoring tools, an opportunity arises to automate the workflow from the current manual process.

3. Model Architecture

The adopted neural network for classifying RF impairments is a four-layer CNN that makes binary classifications for each of the wave patterns. Figure 3 represents the architecture diagram for building the pattern detection data model. Each of the 1-D convolutional layers uses a kernel size of five and a rectified linear unit (ReLU) activation. The convolutional layers are followed by a down sampling operation via max pooling. The max pooling operation calculates the maximum value in each section of the feature maps, pointing to the most present features. The increasing number of filters, as the CNN grows in depth, is attributed to the larger number of pattern combinations in each subsequent layer and using an increased number of filters allows the capture of more abstractions from the signal data.

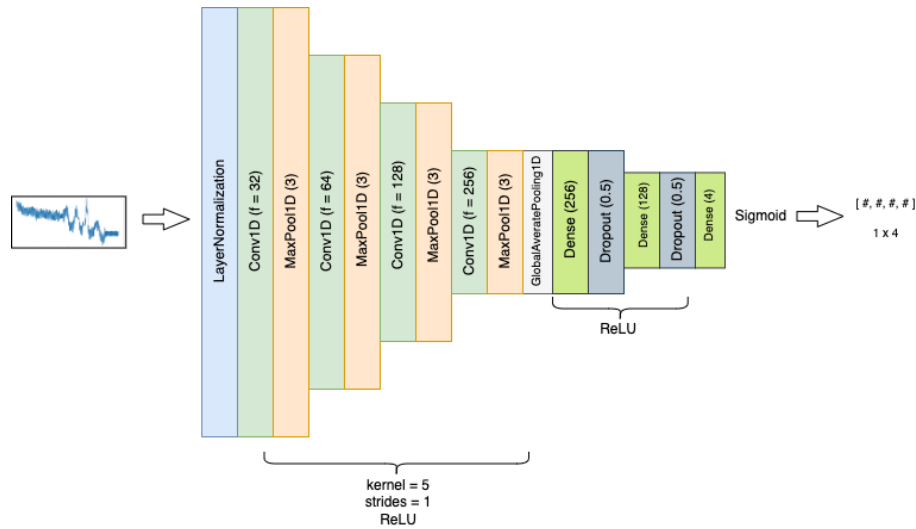

Figure 3 – The Neural Network Architecture

Multiple impairments may manifest on a single capture of spectrum. For example, for water to get into the cable, it needs an access point, such as a nick/chew in the cable, which would commonly cause standing waves (Fox, et al., 2021). Therefore, in certain cases it is difficult to differentiate among them, and their classification may impact the type of maintenance that would be referred to resolve the issue. It is more common to observe water in the drop cable or tap near the home; however, it may be observed in components for a larger group of customers and thus may be an issue that requires a network technician (Fox, et al., 2021). Being able to differentiate the impairments guides downstream decision-making processes.

Instead of structuring the model to calculate a single classification per spectra, the model predicts a probability for each type of wave. Taking this approach gives additional opportunities for analyzing the signatures of wave types within any given group and gives insights that improve the root cause analysis. Table 1 demonstrates possible classifications of multiple impairments.

Table 1 - Example Binary Classification

Sample Identifier	Water	Standing Wave	Resonant Peak	Suck-out
A	T	F	F	F
B	T	T	F	F
C	F	F	F	T
D	F	F	T	T

4. Model Training

The training dataset consists of 3,170 samples of labeled spectra from a population of 10,000 sets of spectra. The validation dataset consists of 500 hold-out samples. The labels were manually entered by a group of subject matter experts over the course of four weeks. The full collection of impaired and non-impaired spectra was acquired from an existing threshold-based detection algorithm that served as the basis for addressing this problem with machine learning methods.

Due partly to the limited training dataset and available resources, applying transformations on the data to reduce the noisy data points allows the CNN to learn appropriate classifications under the constraints. A downside of the transformations is the extended processing time for the feature extraction portion of the pipeline, processing millions of spectra for each iteration in production. As part of the model re-training cycle and growing the training dataset from validated classifications, we are optimistic that the preprocessing steps will be reduced in the future.

4.1. Labeling

To derive accurately labeled data, SMEs were presented with a random selection of both impaired and non-impaired sets of spectra via a user-interface (UI) adapted from a CableLabs initiative. Each spectra sample could be assigned any number of 13 labels. Figure 4 is a screenshot of the UI with a sample containing a standing wave. The two horizontal lines at -17.1 dBmv and -33 dBmv serve as visual indicators of the tolerable range in DOCSIS protocol to facilitate user interpretation.

At least two different users would be presented the same frequency response, with the usable training data samples meeting the criteria that more than one user assigned the same label. While this approach expedites much of the label validation effort, the overall number of samples is reduced because of requiring multiple labels from different users. Based on initial modeling experimentation, it was discovered that high-quality labels would be more useful than a few thousand additional labels whose quality was not checked as stringently. A follow-on experiment determined that by adding samples with a single label degraded the model's classification capability.

Figure 4 – The Labeling User Interface for Assigning Impairments

4.2. Transformations

The transformations applied to the raw data fall into one of two categories – data reductions and signal smoothing. Reduction logic reduces the number of data points per spectrum, while signal smoothing methods reduce the noisy parts of the spectrum's signal including guard bands, pilot signals, and vacant spectrum.

4.2.1. Full Spectrum Smoothing

An initial smoothing algorithm is applied to the spectrum based on the channelization of power values. The static nature of downstream SC-QAM channel characteristics enables a smoothing algorithm that considers the signal between guard bands but leaves the guard bands intact. Since the data source for the smoothed channel data is from a visual tool, it maintained spectral characteristics for presentation in a UI.

Figure 5 – Full Spectrum Smoothing

4.2.2. Truncate

The impairments under investigation all primarily reside in the downstream portion of spectrum. As a standardized transformation for all spectra, the usable spectrum for model training is defined as the span from 113 MHz to 748 MHz and may include OFDM spectrum values. As this applies to all spectra straightforwardly, any downstream services above 748 MHz are not considered for the wider bandwidth devices. Each sample in the transformed dataset now contains 5,420 values of smoothed spectrum.

Figure 6 – Spectrum Truncated to Downstream

4.2.3. Binning

As a further reduction of data volume, the samples of 5,420 values each are placed into 2,000 evenly spaced bins. For each bin, the mean of the values inside becomes the updated spectrum values. This not only reduces volume, but also irons out excess data points that ultimately can be supplanted without degradation to the primary patterns in the spectrum.

Figure 7 – Preprocessed Spectrum Binned to 2,000 Values

4.2.4. Guard Band and Pilot Removal

In early modeling experiments with labeled data, the data model would misinterpret guard band and pilot artifacts as characteristics of impairment types in many cases. Since this created a significant number of false positive results, it became necessary to smooth the values at these locations along the spectrum.

To remove the artifacts, the values are replaced with averaged values of the power immediately around the artifact – essentially creating a short linear regression line. A second approach to this for guard bands specifically would be using the channelized characteristics to replace the spectrum values. Both have proven to work well, and both achieve the desired transformational outcomes.

Figure 8 – Preprocessed Spectrum with Guard Bands and Pilots Removed

4.2.5. Vacancy Removal

The final transformation removes the spans within spectrum considered to be vacant – meaning there are no services in that span for any number of reasons. Vacancies are programmatically detected using thresholding techniques with the spectrum values being updated similarly to guard band and pilot artifacts. A linear regression is calculated between where the vacancy starts and ends; this matches the general trend of the spectrum at that location.

Figure 9 – Preprocessed Spectrum with Vacancies Removed

For very wide vacant spectrum, this approach may introduce a signature that resembles characteristics of one or more impairments. While the false positive rate is very low for these situations, discovering improved vacancy removal algorithms remains an important task. Again, the channelized spectrum data provides another strategy to identify vacant spectrum with high confidence and is the next step in this evolution.

4.2.6. Final Data Form

The final data form consists of 2,000 values, with noise removed for the model while retaining the signature's primary characteristics. From a scaling perspective, the transformations facilitate faster model training and inference operations, but at the expense of requiring more processing resources prior to involving the model.

The training data was lastly augmented by simply reversing the order of each sample, doubling the number of samples that retain the same pattern signatures but in different locations. Prior to training on the CNN, the data were passed through a normalization operation to improve consistency.

5. Model Performance

With a limited set of data to train the model, a 5-fold cross-validation architecture is implemented for estimating its generalization capabilities. The top performing cross-validation model is selected based on validation and training loss results, and then re-trained on the complete set of training data.

The model's ROC-AUC curve is 90% or greater for both the test data and for the hold-out validation dataset. The most confident classifications are the resonant peak and water signatures. Standing waves are the most difficult impairments to classify as certain signatures are similar to water or resonant peak signatures in some cases. Suck-out misclassification occurs primarily when artifacts remain from the vacancy removal process in which the leading or trailing edge was not properly cleared.

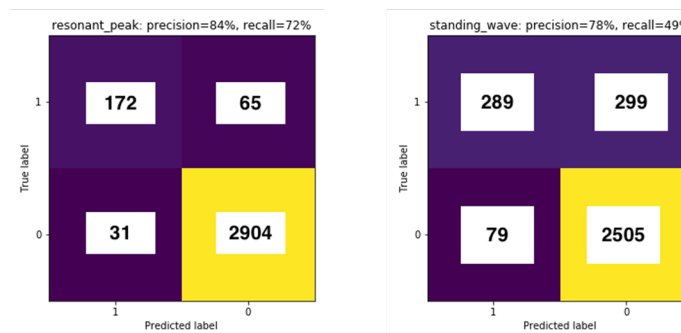

Figure 10 – Confusion Matrix for Resonant Peaks and Standing Waves

To calculate model lift, a dummy model (all samples labeled as no impairment) was evaluated in which the accuracy ranged from 81% for standing waves to 93% for resonant peaks. The impairment detection model outperformed the dummy model and created significant lift for each impairment in consideration.

Table 2 – Model Performance Metrics

Impairment	Training / Test AUC	F1 Score	Dummy Model Acc	Lift	Validation AUC
Resonant Peak	98%	0.78	93%	12.1	98%
Standing Wave	90%	0.60	81%	4.1	91%
Water	97%	0.74	89%	7.6	97%
Suck-out	94%	0.70	87%	6.7	91%

5.1. Model Predictions

Figure 11 highlights an example from each impairment with a correct prediction (TP), a false positive prediction (FP), and a missed prediction (FN) – reading column-wise. The red text in the middle row indicates the label applied to the sample during the labeling process described above.

The model performs exceptionally when the impairment type is straight-forward and mostly follows the definitions of the impairment. The model is less-confident when a frequency response indicates the presence of complex waves – that is, when multiple impairments or other conditions show characteristics of multiple anomalies. An example is the FP sample for standing waves shown in Figure 11. The frequency response has strong characteristics of a standing wave and weaker characteristics of a water wave, giving rise to a complex wave type. Since water waves are akin to standing waves, an assessment of this spectra is that there is moisture present in a standing wave, but not enough to induce drastic random attenuation. This determination impacts the root cause analysis algorithm, explained later in this document.

Another factor influencing model behavior is the volume of data and the quality of labels. The limited dataset lacks signature diversity, making it difficult for the model to interpret frequency responses that are considered complex. The labeled data also contains contradictory labels for similar-looking samples, demonstrating that interpretations of spectra can differ among individuals.

Figure 11 – Classification Examples (True Positives, False Positive, False Negatives)

5.2. Model Improvement

To obtain a larger training dataset for model recalibration moving forward, a system was established that collects random samples of predictions from each pipeline iteration, feeds them into a UI where a user validates the prediction, and the sample gets added to the training data. Figure 12 represents the workflow for retraining the model with additional samples.

The diversity in the initial training dataset was limited due to the low volume of available samples. To correct the model for any shortcomings related to this, obtaining validated predictions is critical for growing the training data. Additionally, the validation system can be filtered to a particular impairment so that any imbalances in the training data may be addressed by validating more quality samples of specific impairments.

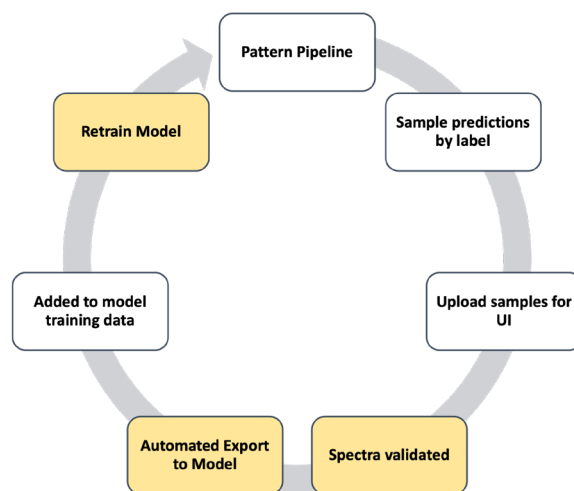

Figure 12 – Model Recalibration Cycle

In the validation process, a user can observe the original frequency response in addition to the data passed through the model. This has been helpful in catching edge cases with the preprocessing in which unwanted artifacts remained under certain conditions. In the vast preponderance of cases with an unexpected prediction, the artifact had a direct impact on the visual representation of the sample as it passed through the model.

6. Root Cause Analysis

An RCA algorithm was developed that leverages the graph representation of the network topology. Conceptually, the RCA examines a group of impaired modems within the context of seeking common network elements in the topology and calculates probabilities that each common network element may be the origin of the impairment. The algorithm surfaces results of the RCA to network monitoring tools, so that as PNM opportunities arise, the appropriate action can be taken to improve network conditions and reliability.

6.1. Methodology

The inputs into the algorithm consist of the following primary elements:

1. Type of impairment;
2. Impaired device list; and
3. Total device list in the grouping that reported frequency responses (a fiber node, for these purposes).

The graph of the topology for the node is extracted and a lowest common ancestor (LCA) search is performed for the impacted devices. The LCA makes different determinations on network elements depending on the type of impairment. Only amplifiers are considered when evaluating resonant peaks. For water in the cable, only customer drops are aggregated – meaning each LCA will point to a specific customer location and not a network element. Standing waves and suck-outs do not restrict which network elements are considered.

Standard F1 scores are calculated for each of the network components available in the topology as shown in Figure 13.

$$Precision = \frac{\# \text{ impaired devices on network element}}{\# \text{ devices reporting spectra}}$$

$$Recall = \frac{\# \text{ impaired devices on network element}}{\text{total } \# \text{ impaired devices}}$$

$$F1 \text{ Score} = \frac{(2 * Precision * Recall)}{(Precision + Recall)}$$

Figure 13 – Standard F1 Score Calculation for Network Elements

The LCA scores are ranked in descending order, with the possibility that multiple vertices (network elements) have the same score. This occurs in situations in which a sequence of vertices has the same number of impaired devices and the same population of devices that reported spectra – i.e., when multiple networks elements are connected with no additional modems in between them. To break the tie, the element with the longest path back to the CMTS is selected, as that element is the one closest to the impacted devices.

6.2. Annotating the Plot

When plotting the data for visual inspection, both physical and logical network elements are represented using the color scheme shown in Figure 14 (left). The figure also describes the highlighting scheme that represents the status of individual customer devices.

Vertex Class		Highlighting	
●	clamshellRx (Node)	a	Impaired Spectrum (Resonant Peak)
●	RfActivePort (Bus-leg)	a	Missing Spectrum
●	RfActive (Actives – i.e., Amplifier)	a	Normal Spectrum
●	RfPassive (Passives – i.e., Splitter)	a	Root Cause
●	RfTap (Taps)		
●	device (Modems, STBs)		

Figure 14 – Color Scheme Legend for RCA Graph Plots

The device highlighting provides visual clarification for where the impairments exist within the larger collection of devices available in the topology. Not all devices report spectrum, and since the LCA scores consider only the reporting devices, identifying them on the plot assists in validating the RCA results. High scoring vertices will contain few instances of normal spectrum and have more devices that are impaired or did not report spectra. The lowest common ancestor (highest scoring vertex) is highlighted in a unique color and has an annotation attached that describe the type of network element and the unique identifier.

6.3. RCA Results per Impairment

The initial problem statement for developing the RCA algorithm using the network topology was an issue commonly seen in amplifiers that causes resonant peaks to present in FBC data. For this reason, the RCA algorithm only calculates the score for each of the amplifiers found in the node's topology. In Figure 15, the modems impacted by resonant peaks are clustered on the left side of the graph (highlighted in pink), with no modem in the cluster reporting having normal spectrum. Therefore, the amplifier highlighted in the figure has an RCA score equal to the maximum possible.

Figure 15 – Resonant Peak RCA Graph Plot

Standing waves are a result of impedance mismatches caused by damaged cables, breached cable jackets, improper connections, and animal chews, to name a few. Standing waves may be manifested either in the plant or in a customer's home. The RCA algorithm considered only the standing wave events that likely originate in the plant or at a multiple dwelling unit (MDU) by considering a minimum number of impacted devices. In Figure 16, the highest scoring vertex was a passive network device under which the preponderance of modems showed impairments alongside only a few with normal frequency responses.

The topology edge data includes properties about cable lengths between vertices. While not yet implemented in this system, the capability exists to calculate the length to the voltage reflection in the cable from a starting point. With the known length, it is then possible to further refine the LCA calculation by considering only common network elements with a minimum cable length of the known distance to the reflection in the line.

Figure 16 – Standing Wave RCA Graph Plot

Suck-outs are commonly caused by “mechanical or grounding issues in active or passive network elements such as seizures, connectors, lids, or fittings” (Cable Television Laboratories, Inc., 2022). Similar to the diagnosis of standing waves and resonant peaks, a minimum number of impacted modems were required to pass through the RCA. The identified vertex in Figure 17 was a tap under which some modems had normal frequency responses, and some showed the suck-out impairment.

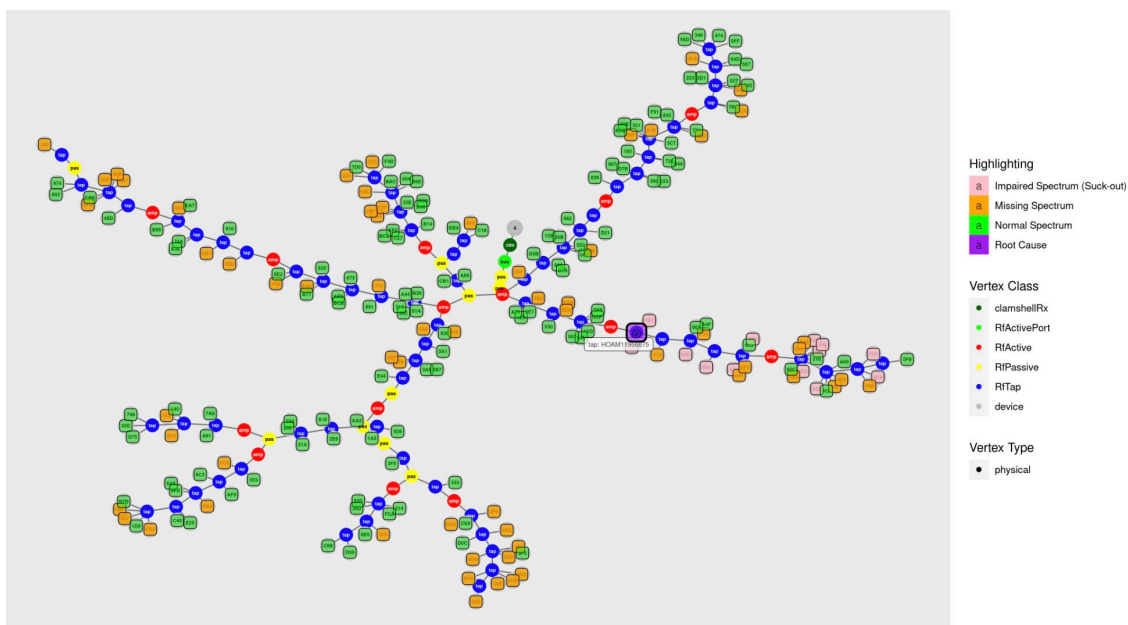

Figure 17 – Suck-out RCA Graph Plot

Water waves are most identified in customer drop cables and taps (Fox, et al., 2021). The RCA algorithm here only considers the drop locations to group the devices in the home/MDU into a single event. This was an intentional implementation decision while the clustering algorithms for water waves remained under development and will be used in future iterations.

7. Conclusion

Frequency responses from FBC data have been used extensively to identify certain impairments that impact network reliability. Additionally, multiple initiatives have surfaced deep learning models designed to automate detection of signal impairments in different types of signals. This implementation takes an additional step by automating the triangulation amongst network elements to narrow down the origin of the impairment through a network topology graph representation.

The deep learning model described here is but one form the model can take. In the development of this system, multiple models that produced quality results were evaluated. This detection model is an improvement over currently known threshold-based algorithms, often finding anomalous frequency responses where threshold-based algorithms miss them. The advantage to the previous algorithm is that it reliably finds moderate to severe cases; however, it is unable to differentiate among some wave types so they are categorized under one label. This impairment detection model not only differentiates the waves, but also has demonstrated the capability to detect both obvious and subtle impairment signatures.

By leveraging network topology as a graph, more advanced analytics are possible to understand the scope and impact of impairments on collections of modems. The lowest common ancestor algorithm is one of several forms of analysis that can be done. Through an understanding of RF impairments and their causes, a root cause analysis performed on network topology generates confident assessments of where within the plant the issue originates. The impact is better visibility into network conditions and improved support for the technicians that deploy to resolve issues in the network and at customer's homes.

Abbreviations

CNN	convolutional neural network
CPE	customer premise equipment
dBmv	decibels relative to one millivolt
FBC	full-band capture
FN	false negative
FP	false positive
LCA	lowest common ancestor
MDU	multiple dwelling unit
OFDM	orthogonal frequency-division multiplexing
PNM	proactive network maintenance
RCA	root cause analysis
ReLU	rectified linear unit
ROC-AUC	receiver operator characteristic – area under curve
RF	radio frequency
SC-QAM	single-carrier quadrature amplitude modulation
SME	subject matter expert
TP	true positive
UI	user interface

Appendix

Network Topology

Network topology can be accurately described as a directed acyclic graph or DAG. This allows for easier and more efficient algorithms to be used without the need to cycle check. A DAG is a special type of graph that allows traversal in one direction without the chance for a connection to “backtrack” to a previous vertex. The reason for this is plant topology does not loop back on itself and upstream edges will always direct to the devices closer to the CMTS in the plant.

The two primary plant topologies revolve around having an analogue CMTS doing all the work vs having a distributed access architecture where the load is balanced across the node. These two topologies do pose a challenge when creating the topology map as different devices have similar functionality yet different naming schemes. Nodes with vCMTS (virtual Cable Modem Termination Stations) have no amplifiers and scale incredibly well leading to easier changes in the plant.

Creating the graph that this work depends on took many teams a lot of effort in order to overcome the challenges required. In order to flesh out the graph, multiple data sources needed to be pulled from and synced. To achieve this the team used a property-graph architecture as well as Apache Tinker pop to perform the aggregation queries, look-ups ext. The graph database ROCI is still not fully mature but has proven extremely valuable in many projects including our own.

1. Introduction

Content is comprised of video, audio, and text or auxiliary information(e.g., closed captioning). An absence of any media component can lead to an incomplete media experience. A non-synchronized playout of the media components can lead to an incomprehensible media experience. Yet each media component has a separate creation, production, distribution encode and client decode path in its workflow chain with each step traditionally requiring all media components to be received together before processing such that complete and synchronized media playout is ensured.

The speed of each step is dependent on the processing of the slowest media component of the content. Processes can be both automated and manual with creative processes being usually slower than automated processes. Automated processes can still add latency to the workflow, dependent on the amount of compute power needed for operational processes or scene analysis and scaled to match expected quality output. And yet, with the introduction of cloud processing, this can be adjusted.

How can we create evolutionary changes to these workflows? It may be through adapting media workflows to be more like data workflows and taking advantage of better bandwidth and adjustable compute power. Through IP interfaces, increased network capacity, and volume-efficient cloud server processing, media workflows can be more efficient, and deliver better quality along with additional media experiences. But these improvements require us to separate (demuxed) media components to be handled with better optimizations in today's technology environment. Demuxing content allows for better handling of processing demands but reassembly is also important and should add additional information for resynchronization of media components in order to make the playout of the content feasible.

This paper will provide an overview of these processes in the context of traditional media workflows, what can be done today with present technologies, and what could be done in the future with newer technologies like over-the-top (OTT) delivery and cloud processing.

2. Production Media Workflows

Content origination starts with production and distribution workflows (see Fig 1) from capture to editing to distribution by service providers. This can be in the form of scripted content (e.g. movies and TV shows) or live events (e.g. a football game televised live). Some operations that happen are more automated such as chroma subsampling (4:4:4/4:2:2 to 4:2:0), bit depth reductions (16/12 to 10 bits), audio formatting, or lookup table (LUT) conversions for high dynamic range (HDR)/standard dynamic range (SDR) conversions. But there are a lot of creative operations happening here as well, such as editing, shading, translations, and subtitling, all of which can take longer but could also be parallelizable. Ultimately this is received by the service provider in the form of contribution linear feeds (e.g. see SCTE 277) or mezzanine assets. Multiple feeds or files may result from this process.

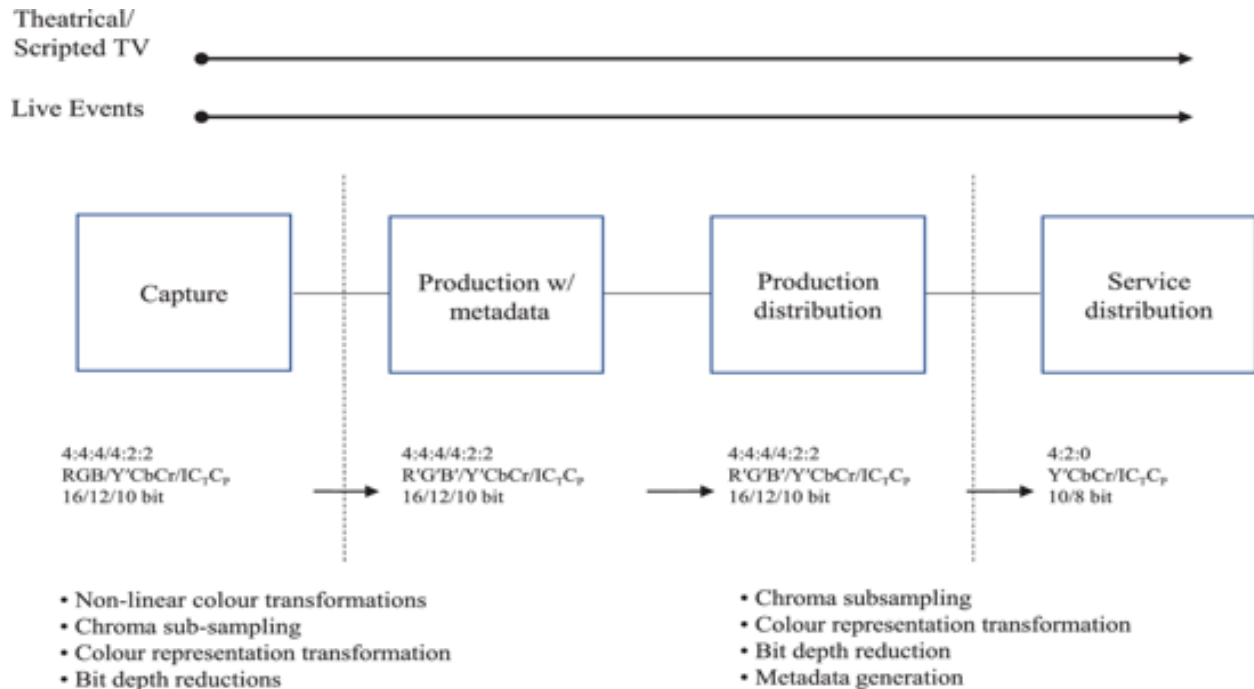

Figure 1 – Production Workflow¹

In terms of moving assets or feeds around in this domain, SDI (Serial Digital Interface) (see Fig 2) is widely used (e.g. SDI, HD-SDI, 3G-SDI, 12G-SDI) providing a baseband interface to allow for frame editable content to be distributed within a local area. An SDI frame allows for a timing frame to encapsulate video, audio (16 channels), closed captioning, and timecode within a serial stream.

Figure 2 – SDI Frame

The limitations in this type of setups are that content is only locally moveable and that the cabling infrastructure is designed specifically for moving SDI signals around to production and post-production sites. With the developments from ST 2022-6, which encapsulates SDI over IP, it facilitated production workflows to begin to move beyond the local plant.

3. Carriage of Media in Distribution Service Workflows

Once the studio passes content to the service delivery workflow, the content is mostly formed and it is more of a question of delivering the content in the right format for the client player for playout. The

¹ From ITU-T H. Supp 19/ISO 23091-4

workflow still follows the live and file-based workflows that are then encoded for distribution to create a decodable bitstream in which compression of content to utilize bandwidth efficiently is essential to operate within the capacity and scalability limitations of the distribution network. Most of the media operations are done on a single device on which the content is unwrapped, the components are processed, and finally the components are reassembled back into an integrated content format again to be carried on the network for device distribution.

Figure 3 – MPEG-2 TS Service Distribution

Figure 4 – MPEG-2 TS Muxplex Composition²

For traditional one to many broadcast QAM delivery over MVPD networks, an MPEG-2 transport stream is used to carry content (see Fig 3). The transport stream packetizes each media component into elementary streams, which are grouped together as a program stream. The MPEG-2 packetization allows for the media component packets of the same timeframe to be interspersed in the data stream (see Fig 4), such that a decoder with coded picture buffer can receive the packets and output a time-continuous stream while taking advantage of temporal compression strategies to reduce the bandwidth demands of delivering the content.

Figure 5 – Adaptive Streaming HTTP Service Distribution³

² From SCTE 223 – Adaptive Transport Stream

³ From IEEE ICIP Tutorial Ali Begen/Yuri Reznick Sept 19th, 2021

With recent adaptive streaming technologies that are used in OTT delivery, service functionality moved from a single encoding device to distributed functions (see Fig 5). Because OTT services deliver content over the internet using unicast internet protocols, the operations of encoding, packaging, placement, and delivery were spread across the network; additionally, media components did not have to be packaged together for delivery, but ultimately delivery still was constrained by the same decoder buffer restrictions on outputting a continuous stream of frames.

4. Real-Time Considerations in Media Workflows

Video is a series of frames displayed to the eye at a certain rate (see Fig 6), allowing a simulation of the what the brain would perceive in the real world. The rate to achieve this is known as frame rate (frames-per-second [fps]) and can vary from approximately 24fps for feature film content to 60fps for live production and most video sources. There are also some sources at 30 fps and new high frame rate video formats at 120 fps that are better at reproducing fast action.⁴ For real-time processes, frames need to be created, edited, produced, delivered, encoded, packaged, distributed, buffered, and then decoded before the next frame is outputted. Causes that will add time to the workflow would be compute time for media processing at different points in the chain, or network bandwidth needed to deliver bits across to different points in the workflow, or simply any creative handling of the content.

Figure 6 – Stream of Frames

At a constant frame rate 60 fps mode, successive frames need to be outputted every 16.7 ms (1/fps). This means that for a glass-to-glass delivery, all processes need to be completed within this time. Traditional mechanisms to achieve this are to introduce startup delay such that the player buffer could be filled before an initial frame would be outputted, then the duration of the buffer could extend the time that the next frame would need to be sent to the buffer to keep it filled. This adds latency to the video, but through approaches like this, continuous video can be achieved at a manageable bandwidth for the network.

Other ways to address real-time demands would be to reduce temporal compression by creating a simplified group of pictures (GOP) structure such as all I-frames or forward predicted pictures (FPP). Another way would be to increase the network bandwidth such that created content packets could be delivered faster than real-time; this would work more for file-based workflows and less for live feeds.

⁴ Typical framerates in use also includes fractional framerates such as 23.97, 59.94, or 119.89 which can add some complexities to timing and synchronization factors, but conceptually remains the same. For this paper, integer number frame rates examples will be used for simplicity while discussing concepts.

Figure 7 – Quality-Latency-Bandwidth Tradeoffs

But real-time processes are not the only factors to consider when delivering video. Depending on the service, the video delivered also must be of acceptable quality and of acceptable bandwidth for network distribution (see Fig 7). Increasing quality or bandwidth may result in increased delay and designing workflows must consider and balance all three of these factors in delivering content (see Fig 8).

Figure 8 – Factors in Playback⁵

To avoid stalls, the decode buffer must have new frames coming in at regular intervals. To have fewer resolution switching factors, managed bandwidth network connections or smaller bandwidth requirements must be maintained while handling more bits to deal with higher bandwidth or color space demands. The need to reduce latency factors also brings into play reduced player buffer capacity, which puts increased pressure on real-time computation demands.

5. Adapting to Newer Technologies: IP Interfaces/ Cloud Processing

Carriage of Media workflows as data across IP interfaces bring many advantages, and the content production ecosystem is gradually adopting new IP based approaches. For instance, in production workflows, the same source point can be sent to multiple end points in a local network so that editorial or

⁵ From IEEE ICIP Tutorial Ali Begen/Yuri Reznick Sept 19th, 2021

production tasks do not always have to be serially performed but could be performed in parallel (see Fig 9). Through SMPTE ST 2022-6, SDI video can now be encapsulated and carried through an IP distribution. A benefit of this is the reutilization of existing production equipment with only an SDI interface while using IP to carry the signals and IP routers to switch and distribute them. With SMPTE ST 2110, the IP carriage takes a further step to natively carry the video, audio, and data as independent essences that are sent separately, thus allowing for individual points to deal with specific media components without sending the entire content. With moving to a demuxed delivery of media components, a timing synchronization is now required to reassemble the media components into the complete content. In SMPTE 2110, this is achieved through using a Precision Time Protocol (PTP) timing mechanism.

Figure 9 – IP Encapsulated SDI

In adaptive streaming delivery, a similar evolution occurred from what initially was IP carriage of MPEG-2 TS streams (e.g. HLS and DASH). This evolved to utilizing an ISO base media file format (ISOBMFF) delivery that allowed each media component (independent essence) to be requested from a set of options (adaptationSets) and delivered separately using segment timelines as the method to synchronize media components (see Fig 10). Further refinements with CMAF allow segments to be broken up and delivered separately as chunks; this assists in providing lower latency delivery.

Figure 10 – Adaptive Streaming using HTTP

Cloud processing is now becoming utilized in many places for high performance computing, AI/ML analysis, or on-premise offloading. The modes of service in the cloud can be infrastructure as a service (IAAS), platform as a service (PAAS), software as a service (SAAS), or serverless. For content media workflows, cloud processing can operate in several areas for real-time captioning services, basic SDR/HDR conversion processes, scene detection for more efficient guided encoding, third party processing, or manifest manipulation. For better integration of cloud processing into content media

workflows, it requires more efficiencies in bandwidth workflows to handle even editable workflows and IP addressing to multiple source delivery points (see Fig 11). To make it more practical, compute latency, storage latency, and network latency need to be reduced. For compute latency, more pipelining and parallelization strategies as well as more powerful processors need to be available, depending on the processing task. For storage latency, better caching and reading/writing strategies already exist but need to significantly improve to reduce latency. Lastly, network latency needs to be improved through the analysis and adoption of new strategies in regard to compute placement (e.g. edge compute).

Figure 11 – Roles of Cloud in Media Workflows

6. Content Processing and Content Experiences

In content media workflows, processes can be categorized as automatic or manual (see Fig 12). Automatic processes typically can be done without manual work; examples in production are up/down sampling, tone mapping, and some speech recognition/captioning; while examples in distribution include such functions as transcoding and packaging. Manual processes require more hands-on work and can describe functions like editing, shading, audio description, or third person signing. With cloud processing and artificial intelligence (AI)/machine learning (ML), some of the manual tasks can be done or accelerated with assistance by trained AI/ML approaches. With post-production, developing a format that allows for IP distribution while allowing for frame accurate editing is needed to reduce the bandwidth demands and compute demands to allow for this. Through developments in I-Frame HEVC/VVC or JPEG-XS or J2K, future image/video coding techniques may address these needs in the future.

Figure 12 – Content Processing and Content Experience Processing

Another type of category is processing of existing content or adding to experiences of the content asset (see Fig 12 again). Processing of content type of operations does not change the version of the content but may change format, or appearance of the content. These can include adding more subtitle language tracks, or new dubbed languages in audio, or simply adding audio description tracks to the content. Most of these types of processes are more automated tasks rather than manual tasks. Content experience processing usually alters the version of the content and provides additional personalization of the content such as additional languages, alternate versions of content, adding announcers to sporting events, or adding audio descriptions to events. Many of these added experiences are manual processes but with new types of cloud processing, IP carriage, and bandwidth efficiencies, some of these tasks can reduce latency through assistance using these new technologies. An example of this that is now seen frequently is the real-time creation of subtitles from the audio track.

7. Demuxing Content for Improved Workflows

Demuxing content into separate media components can benefit media workflows in both production and distribution by reducing the amount of content that needs to be wrapped, transported, unwrapped, processed and re-wrapped many times in the overall media workflow. For production, demuxing can help with real-time operational processing demands such as real-time generation of closed captioning through implementation of an audio track or in translation an existing closed caption track. With third party signing, it may require generating a video proxy linear stream to send with the audio track. Content processing transformations (see Figure 12) can also be done offsite but requires some sort of frame accessible video format that is protected and is transportable across IP networks instead of the local network. In addition to processing content, information can also be gathered for scenes that can be beneficial for distribution transcoders to do higher quality encodes. Lastly, some additional experience tracks can be generated during this production process.

Using separate media components for processing provides some step up advantages to that triangle of quality, latency, and bandwidth considerations (see Fig 7). For bandwidth, there are fewer bits to be sent across IP networks to process media through the production and distribution workflows. For latency, the ability to send information in a parallel fashion earlier in the media workflow and the ability for the cloud to assign elastic processing power to what the task demands are strong advantages. Additionally, developing AI/ML techniques that may be continually refined would be helpful to get better quality

distribution encodes (including pre-processing techniques) at lower bit rates. Lastly, third party contributions to content assets and feeds for such content enhancements as home/away announcers, third party signing, or real-time indexing for more searchable content could be done across IP networks as well.

8. What Further Work is Required?

Some additional development that will be required – some of which already is happening – to better handle demuxed workflows falls into five categories:

- Automation in production and distribution workflows;
- Synchronization across media components;
- Integration of third party created media components;
- Placement of new content experiences across adaptationSets in manifests; and
- Playability of content assets and linear feeds in an OTT system.

To pull off media components of the content for separate processing, metadata is needed to automate job processes. This metadata, which can include metadata generated by AI and ML processes, can aid in other future processes in the workflow such as enhanced quality encodes. This information when generated or provided needs to be stored in a format that may originate in production but may be needed upon distribution. A format needs to be developed that can provide this time sensitive information in both the production and distribution domains and may need to be stored as a metadata track retrievable in the manifest.

For automation in production, an editable format of the media component needs to be created that can span across IP networks rather than be limited to a local LAN, at a reasonable bandwidth. Some formats being looked at are JPEG-XS, I-frame only AVC/HEVC/ VVC, or J2K. Audio Formats may not need to be compressed since audio file and feeds are smaller but may require video proxies to be sent along with them, but there is also a need also to carry some of the distribution signalling metadata for audio back to baseband carriage. For third party components such as signing, audio description, or subtitling, these type of files or feeds may need to be fed into the distribution workflow rather than returned to the production workflow.

Synchronization between media components is also a factor that needs development. In one area it is more conforming additional tracks to the content asset or file; this basically means each media component should have an aligned timeline that can be used to generate synced timelines on newly created assets. In the production domain and with the SMPTE 2110 format, the PTP timing format is used. In the distribution area, however, time is more aligned with segment timelines and alignment between both approaches needs to be realized. Another area is synchronization between audio and video; in OTT the video segment determines the edit point but there are instances in which the audio segment that goes along with the video may naturally be slightly lagging the video; in those cases that slight lag needs to be maintained.

To integrate third party media assets and linear feeds to the content, IDs need to be created and matched such that manifests can add these new adaptationSets and authentication systems can validate that content. URLs involving the retrieval of content need to consider content distribution network (CDN) design and whether one or more CDNs are involved. There also needs to be a way to identify tracks that are being processed versus tracks that are finished and retrievable by the client player. Gaps in timelines of media components need to be considered and handled as well so mechanisms such as content failover can be considered. Additionally, player behavior needs to be redefined such that new content experiences can be added to an existing media layout which may be added as the manifest is updated. Even when the

concept of a linear feed or a content file being complete no longer exists, the playability of the asset needs to be known.

9. Conclusion

Content is nowadays not a static asset or channel. It is evolving according to the expectations of the viewer and can involve multiple parties creating the overall content experience. More formats, better quality, multiple types of playback devices, and more ways to experience content is an expectation. The platform for media workflows is also evolving to incorporate faster and intelligent processing not limited to all work being done in a specific location. Media workflows for production and service workflows have traditionally been linear, but with the advents of higher bandwidth, IP interfaces for both uncompressed and compressed workflows, and access to cloud processing, linear workflows can evolve. Production efforts can be outputted directly into OTT feeds and into CDNs to be ingested by OTT players as they become aware of what new options they have to experience the content, and authorized third party contributors can also provide new experiences to the content without delaying the workflow. Cloud processing can accelerate the workflows by just adapting processor power to the job demand or by pre-processing analysis to aid in encoding of the content. But these evolutionary efforts do require some adaptation of the current system to make it easier to conform and synchronize separate media assets to the content and to create adaptationSets, IDs and URLs to incorporate these workflows and to make players aware of new choices in the manifest.

SCTE has a number of working groups that are already involved in these areas. In the Digital Video Services committee, there are two related working groups that are involved in these areas. Working Group 1 (Video/Audio) just recently published SCTE 277 (Linear Contribution Encoding Specification) which defines ingestion of signals that originate from production/post-production services. Additionally, WG1 also defines the Video and Audio codec streaming constraints for consumer distribution including recent modifications for adaptive streaming to consumers. On the consumer distribution side, WG7 (adaptive streaming /DASH) works on the suite of SCTE 214 specification which define manifest and segment constraints for HTTP IP delivery of content through MVPD networks.

Abstract

More than a decade ago we began introducing analytics, machine learning, and finally artificial intelligence to our networks and services. Evolving our work teams from a data-driven culture to AI-driven. It was not an easy task, it involved great challenges and cultural changes, it really is an accelerated transformation process during this pandemic, and it continues.

In this technical paper, we go through the path we are transitioning in Telecom Argentina from data analysis and AI/ML perspective to achieve operational excellence. We present the challenges we went through along, difficulties, learned lessons, success stories and next steps.

Content

1. Introduction

In our networks and services, the Artificial Intelligence (AI) has the potential to change, the way we operate, and to become the foundation of the transformation that leads to the fourth industrial revolution. But this requires hard work, a long-term commitment, and a deep cultural change. That is why we present here our journey that we started to make our operations AI-driven.

In the industry, Analytics, AI, and Automation are often differentiated. Let us remember that in [5], we define:

- Data Analytics: monitoring data to look for patterns and anomalies (without applying intelligence) and applying those patterns towards effective decision making.
- Artificial Intelligence: the development of computer systems capable of performing tasks that normally require human intelligence; this includes visual perception, speech recognition, decision-making, and translation between languages.

In a survey regarding enterprise networks, automation was enquired. The poll results indicates that more than 65 percent of enterprise networking tasks are carried out manually (often referred to as "ClickOps"), indicating that own network automation underlies on servers' automation. Ansible, customized "DIY" scripts (usually based on Python), and single-vendor, network infrastructure-focused packages are among the most widely used network automation tools. It is worth noting that these scripts are totally deterministic, that is, they only perform repetitive tasks. AIOps is the term used when a decision-making process is automated using an AI algorithm.

In next sections, we introduce in more detail what we understand by AIOps, we may state:

$$\text{AIOps} = \text{Analytics} + \text{AI} + \text{Automation}$$

AIOps is part of the 5G ecosystem, since from its conception the knowledge plane has been included. That is, a layer within the architecture oriented to the operation and orchestration of networks and services [7]. Figure 1 shows the percentage of network activities that are automated according to Gartner.

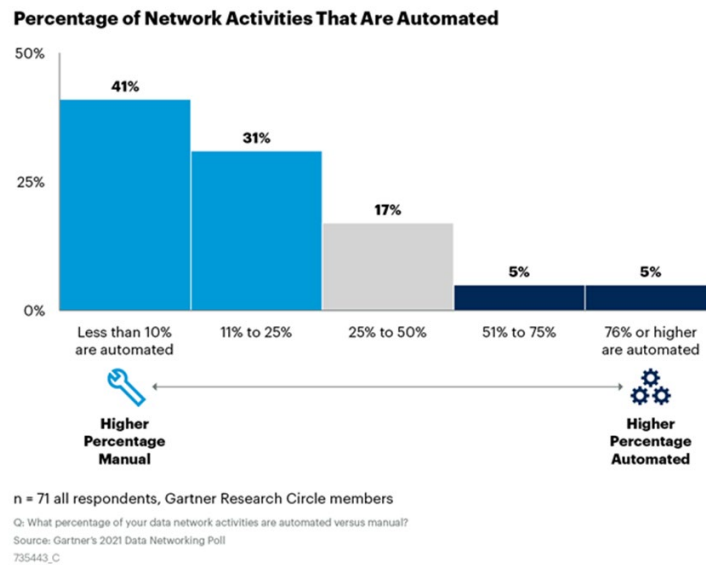

Figure 1 – Percentages of Network Activities that are automated, 2021.

Source: gartner.com

In this technical paper, we outline the path we've taken toward converting our AI-driven networks and services, along with a few use cases. The use cases development provided us with many lessons learned.

This document is organized as follows. After this section, we introduce Telecom Argentina and Financial impact of Analytics, AI, and Automation. At section 2, we expose AI-driven Operation. In section 3 we present the concept of the knowledge plane and our reference architecture. In section 4, we introduce the first use cases we did using AI and Big Data. On section 5 we present the AIOps use cases in Telecom Argentina and the state of the art in the evolution towards autonomous networks. In section 6 we outline the key lessons learned along this journey and lastly, at section 7 we describe the next steps we are considering.

1.1. About Telecom

Telecom Argentina is a company in constant evolution, which offers connectivity and entertainment experiences and technological solutions throughout the country. We boost the digital life of our over 30 million customers, with a flexible and dynamic service, in all their devices, through highspeed mobile and fixed access, and a live and on demand content platform that combines series, movies, gaming, music, and TV programs.

Our trademarks Telecom, Personal and Flow consolidate an ecosystem of platforms, and new businesses, a comprehensive and convergent experience for individuals, companies, and institutions across the country. We are present in Paraguay with mobile services, and in Uruguay, with cable television services.

Telecom Argentina has become a company that thrives in the digital world. It evolved from a traditional telecommunications company to consolidate itself as an ecosystem of apps and platforms that are based on connectivity as a differential quality value.

With the vision of going beyond connectivity, we are developing new 100% digital businesses, based on IoT, 5G, Fintech, entertainment, and Smart Home solutions, among others. With the most innovative

technology, in alliance with world class technology partners, and an investment which over the last five years reached USD 5 Bn, the company focuses on enhancing its infrastructure and systems and providing more and better services.

Our fixed-mobile network is the most extensive of the country. With more than 75,000 kilometers of FTTH, HFC and ADSL technologies, we are present in 18 provinces with over 60% of coverage of households in the country. Our 4G+ mobile network is the fastest in the country, and it is available in 100% of our infrastructure. We reach more than 1,900 locations and have a coverage of 95% of the population. In 2021 we inaugurated the first 5G network in Argentina, with 20 sites in the City of Buenos Aires, Rosario, and Costa Atlántica. We also bring connectivity to numerous towns with less than 500 inhabitants in different provinces, and in many cases, we are the only link they have with the rest of the country and the world.

The convergent and comprehensive operation of the network is one of the key challenges of the evolution of Telecom Argentina. Automation, analytics, and artificial intelligence, among other innovative technologies, will undoubtedly mark the path of our completely transformation from a Communication Service Providers (CSPs) to a Digital Service Providers (DSPs), Figure 2.

Figure 2 – From CSP to DSP.

1.2. AI-driven

Adoption of cloud computing, network function virtualization (NFV), and the development of software-defined networking (SDN) have all advanced considerably in recent years.

These developments have made it possible to create infrastructure that is more adaptable and to make storage and computing power more plentiful than before. We are compelled to use both artificial intelligence and machine learning techniques because of this progress and the growing requirement to enhance the management and administration of networks and services.

On the other hand, the next generation of 6G communications is already being investigated, where the devices, antennas and infrastructures are embedded with artificial intelligence software. Today networks cannot survive without artificial intelligence [1].

We are confident that these technologies will assist us in resolving and enhancing the current challenges with network efficiency so that our more than 30 million consumers have a better digital experience. Additionally, it will free up our specialized labor to work on more difficult tasks connected to emerging digital services and businesses.

These technologies will help us to:

- Reduce time to market for new products and services
- Predict and mitigate network and equipment service issues before they happen

Operating, managing, and provisioning future services with automation processes becomes essential to increase efficiency.

- Future Challenges: We are starting down the path towards the automation of our network operations. Using AI to efficiently manage the exponential traffic growth and the complexity and variety of new services that 5G will enable.

2. What it means to be AI-driven operation

When working on AI-driven initiatives, it is crucial to establish the minimum level of understanding inside our organization regarding the scope and restrictions of AI technology as it relates to the functioning of our networks and services.

There is no single definition for all AI technologies or framework. When we refer to technologies such as DOCSIS or 5G, there are no ambiguities since they are very mature in their standardization process.

AI-driven operations refer to the use of AI for the operation, planning and decision making in networks and services. To convert the operation of networks and services into an AI-driven operation, it is necessary to go through three stages:

Stage 1: Use of artificial intelligence techniques to develop applications and use cases.

Stage 2: Using AI to improve services, processes, or products.

Stage 3: Use of AI to help decision making.

In Figure 3 we present the Hype Cycle for artificial intelligence according to Gartner.

Figure 3 – Hype Cycle for Artificial Intelligence, 2022.

Source: [gartner.com](https://www.gartner.com) (July 2022)

3. Our first steps without AI using math, statistics and small data

In this section we present some data-driven decision-making use cases we performed as our first steps in this AI-driven operation journey.

3.1. Dimensioning of our VoD system

By the end of year 2012, Telecom Argentina launched its Video on Demand service. Due to certain recommendations from other operators, the original coverage was 900 HD set-top boxes (STBs) per service area (SA). However, when the service was launched it was not possible to achieve this (because of CAPEX restrictions), and many service areas were oversized up to 2,500 STBs. Hence, our customers experienced VoD service outages.

For the above, it was necessary to propose a statistical model that enables the resizing the SAs, establishing a balance between the system capacity, the number of customers and the *blocking probability* [2].

After studying and analyzing various models, we proposed a model based on the Queuing Theory applied to VoD traffic, the Erlang B formula, already used in telephony traffic [2]. In particular, the Erlang B formula allows us to relate three fundamental variables: the offered traffic, the number of available streams and the blocking probability, resulting in the appropriate number of STBs that the SAs must contain given a certain blocking probability that is considered acceptable.

Traffic definition is based on empirical assumptions, including peak service period, penetration per SA, average content duration, and average number of first-attempt requests. These last two depending on the quality of the content (SD or HD).

The data analysis was not only critical for the design of the model but, also contributed to establish an acceptable blocking probability for the service and to determine the phenomena that influence the performance of the service and their affectation degree.

3.1.1. Erlang B statistical model

The objective is to calculate the number of STBs per SA to obtain an acceptable blocking probability for our system.

For its formulation, certain empirical assumptions were considered after the characterization of the service. Such as, peak period, peak period duration, average duration per quality (SD/HD), average number of requests and penetration rate. We didn't consider blocked orders to be retried.

The traffic calculation is then formulated as follows:

$$A = \frac{h \cdot (\lambda_{SD} \cdot t_{SD} + \lambda_{HD} \cdot t_{HD}) \cdot p}{T}$$

Being,

- h : n° of STB per SA.
- λ_q : average number of first attempt requests, per STB and per period ($q = \text{SD or HD}$).
- t_q : average time spent on the system per period (min) ($q = \text{SD or HD}$).

- p : VoD service penetration per period.
- T : peak period duration (min).

Since we analyze the number of STBs needed for each SA, the goal is precisely h . It is obtained, using the Erlang B formula, based on the blocking probability (P_B) and the available streams during the peak period (N). They are dynamic depending on the bitrate of the content, which varies between 1.875 and 15 Mbps (depending on SD/HD quality and encoding).

The application of the formula is possible since the system satisfies the hypotheses of the model.

$$P_B = \frac{\frac{A^N}{N!}}{\sum_{i=0}^N \frac{A^i}{i!}}$$

Figure 4 shows graphically this formulation evaluate on different scenarios.

We sat a blocking probability (P_B) value of 3%, based on our observations and conditions of acceptance for quality of service. Then, from the model, for a MPEG2 content with a ratio of SD/HD of 70/30, our recommendation was 700 STBs per SA.

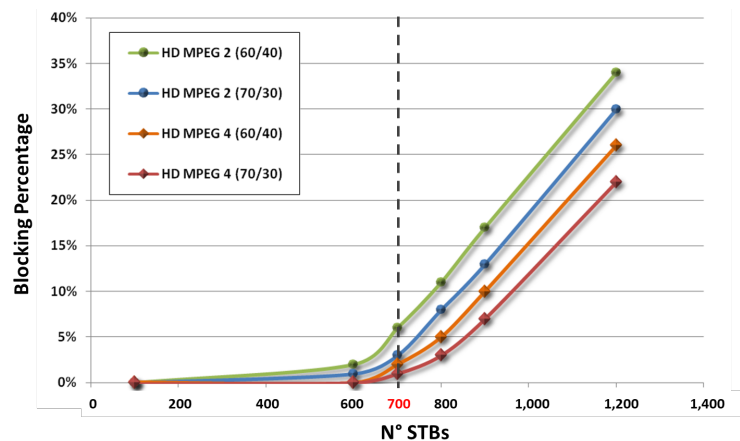

Figure 4 – Relationship between n° STB and Blocking (%) for different scenarios according streaming codification and quality.

The variables that most affect the model were also studied, these are:

- Very high rating content (peak time)
- Free content
- SD/HD service ratio
- HD Encoding (MPEG 2, MPEG 4)
- Holidays

Given the success of the model, we extended its use to assess the impact, in terms of probability of blocking, of different modifications to the service, such as: conversion to HD of CatchUp content, the addition of new services related to the 2014 World Cup, among others.

3.2. Characterization and impact of user behavior of OTT services

One of our major tasks was the study of applications' traffic. OTT video services represents more than 50% of our total downstream traffic. In terms of downstream traffic and client consumption, Netflix was the service with the highest utilization, especially during peak hours.

We found evidence that the link between subscriber count and traffic volume fits sub-exponential distributions. These long-tailed distributions can conveniently describe high variability. Historically, some long tail distributions have an origin in the income distribution, for example, Pareto and Log-Normal. The latter is one of the least understood and most widely used functions.

In Argentina, broadband users access streaming video content, mostly located in the USA. Thus, the impact of Round-Trip Time (RTT) in service performance is very important. A typical RRT in our service groups is around 120-150 msec. Therefore, CDN usage turned crucial.

Two server farms were set up in different company data centers to create a local cache of Netflix content. Each Open Connect Appliance is made up of three 12 Gbps-capable servers and were provided by Netflix. We had to connect to Netflix in Brazil via international peering since we were getting roughly 100 Gbps of Netflix traffic at its busiest each day. This allowed us to meet the demand for traffic that our CDN was unable to provide.

Since throughput is inversely related to RTT, which is smaller at shorter distances, an increase in throughput was obtained by connecting to Brazil instead of the USA. This was made possible by Netflix's adoption of the TCP-based DASH protocol.

3.2.1. *Measuring performance for decision making*

At the beginning of the Netflix CDN implementation, since it was only applied to the half of the service groups, we performed several tests where the traffic from Netflix users was compared pre- and post-implementation for each partition.

We observed the performance increase was noticeable for service groups using CDN, even more during the morning when workload was low. We have found the traffic generated by Netflix CDN users had doubled the traffic generated by those who were not using CDN.

Based on the above results we could estimate the total bandwidth traffic growth in the service groups. Assuming an increase of about 25% in traffic, since the implementation of the CDN, and maintaining the same number of active flows, the associated downstream Netflix traffic should have the same grow proportion. Let:

- N : "Previous Netflix Traffic"
- T : "Previous Total Traffic"
- N' : "Post Netflix Traffic"
- T' : "Post Total Traffic"
- Δ : "Traffic Growth"

So,

$$N' = N + \Delta N, T' = T + \Delta T \quad \text{and} \quad \Delta T = \Delta N \quad \rightarrow \quad T' = T + \Delta N$$

$$\frac{T'}{T} = 1 + \frac{\Delta N}{T} * \frac{T'}{T} = 1 + \frac{\Delta N}{N} * \frac{N}{T}$$

Thus, the percentage increase in total traffic is the product between the percentage increase in Netflix traffic and the percentage that Netflix represents of total traffic. Assuming a service group not using the CDN the relation N/T is 35% (calculated previously) and the percentage increase is 25%, we got:

$$\frac{T'}{T} = 1 + 0.23 * 0.35 = \mathbf{1.0805}$$

So, the total traffic growth of the service group will be 8.05%, supposing the number of concurrent subscribers remains invariant.

3.2.2. Forecasting subscribers and traffic

Having understood the Netflix's traffic importance on the capacity planning, we developed a time series model to forecast Netflix subscriptions, the amount of generated traffic and therefore, the impact on the access network.

We proposed a model based on time series, which provides powerful statistics. Commonly used in business and economics where data occurs in the form of successive values of a variable, in an ordered sequence in an equally spaced time interval. A stochastic model for a time series will generally reflect the fact that nearest observations in time, more closely relation than observation further apart.

Time series models allows us to:

- Understand underlying characteristics and structure that produced the observed data, through different analysis methods.
- Fit a model and forecast future values based on previously observed values for monitoring or even feedback and feedforward control.

Through statistical software, we observed that ARIMA was the best-fitting model. For Netflix users forecasting, we selected a confidence interval (CI) of 95% that, calculated from a given set of sample data, returns an estimated range of values which is likely to include an unknown population parameter. The results are shown in Figure 5.

Figure 5 - Monthly evolution and forecast of Netflix users among our subscribers.

Remarkably this model has been successfully applied to forecast the whole broadband subscribers' population and particularly for Netflix subscribers, by fitting properly ARIMA model parameters.

In following sections, we describe how these first forecast models evolved into a tool with much more features and characteristics.

3.3. IP traffic dimensioning based on patterns

In this work we presented a forecasting model for the Average Bandwidth per Subscriber parameter, as a novelty we have made clusters by Service Tier Levels and by subscriber's location.

Exploiting our DPI tool, we analyzed trends and Internet users' preferences. Through mining our data at different periods, we found common daily patterns among our subscribers. This allows us to focus on a single day to have a whole understanding of the network. Considering the different Service Tier Levels, we also found common patterns related to the most used applications. Only Video Streaming services showed a variation among the lowest tiers. Thus, increasing download access speed drives consumption much more in video applications.

The resulting statistical parameters of our subscriber's characterization are inputs for a network dimensioning tool we have developed to analyze traffic impact over the service group's QAM carriers and simulate different scenarios.

For the last years, we have been collecting and analyzing various statistical measurements including the average residential bandwidth (BW) traffic considering the access speed and we found there is a mathematical relationship between them.

Some technology vendors have different proposals to estimate bandwidth capacity. Cloonan et.al proposed in [3], a technic based on the average amount of bandwidth per subscriber during the busy hour (T_{Avg}) calculated as follows:

$$T_{Avg} = 8 \cdot \frac{B}{W * N_{sub}}$$

Where N_{sub} is the number of subscribers within a typical service group, B is the number of bytes passed into the service group within a given window of time (W) measured in seconds.

We introduce a different methodology, we collect 5 minutes of bandwidth traffic data from the whole network (global, per service and per tier) and the four service tier levels, using a DPI technology. Monthly, we take the maximum bandwidth traffic per service tier level and divide it by the total number of subscribers of each. Then, we model this data with Linear Regression algorithms.

We found at least three different applications of this methodology:

- Adjust current BW traffic values per Tier
- Estimate BW traffic values for future offered access speed
- Forecast BW traffic values for the following two years

We define

- Avg_BW_subs : Average bandwidth per subscriber per Tier.
- $Speed$: Max access speed for the Tier.
- j : Tier number.
- t : Number of months used to forecast.
- β, γ : Parameters to estimate.

To adjust and to estimate, our model takes the form:

$$Avg_BW_subs_j = \beta \cdot \sqrt{Speed_j} + \varepsilon, \quad j \in \{1, \dots, 5\}$$

To forecast:

$$Avg_BW_subs_j = \gamma_j \cdot t + \varepsilon, \quad j \in \{1, \dots, 5\}$$

Figure 6 shows the Linear Regression of the average bandwidth per subscriber. Blue line represents the adjusted and estimated current values. Green and orange lines, the forecast for the next two years.

Figure 6 - Linear Regression of the average bandwidth per subscriber. Blue line represents the adjusted and estimated current values. Green and orange lines, the forecast for the next two years.

3.3.1. Dimensioning tool based on simulations

We developed a tool that aims to obtain a set of simulations to evaluate the use of bandwidth by service group, traffic consumption, customer portfolio and its evolution over time. The tool outcomes allow us to visualize measurements, make estimates and use projected values to simulate consumption.

The traffic sizing criteria adopted suggests taking the maximum 95th percentile, within a 15-day period, to predict the estimated growth at a given time. We take these statistics as sample of the worst hour. Simulations are performed in 24x15 scheme to compare measurements and simulations using the same criteria.

Portfolio update scenario simulation entails some essential input parameters: service tier levels distribution per service group and *Avg_BW_subs* values obtained through linear regression. The latter allows us to analyze service group's load, considering the number of subscribers and their respective service tier. It also allows to estimate the impact on the network by adding new tiers to the customer base as well as a massive portfolio upgrade.

3.3.2. COVID-19 and HFC traffic growth

Since the lockdown started in 2020 because of the COVID-19 pandemic, totally disruptive changes in clients' behavior began to be observed, affecting network performance. Therefore, we began to analyze the evolution of downstream and upstream traffic on a weekly basis with the aim of finding new patterns of use, that allow the growth prediction in a completely uncertain scenario and take proactive actions in the network to alleviate the impact on the service.

We presented these changes graphically to briefly understand the suffered impact after lockdown, Figure 7; and numerically to enable the comparison between past situations and predict future ones.

Figure 7 – Change in daily HFC traffic patterns.

Traffic increases were calculated between peak of April 30th, 2020 (post-lockdown), and the peak of the reference week, Feb 29th to March 6th (pre-lockdown), for midday and peak hour. Midday is defined as 12 p.m. to 2 p.m., and peak hours are defined as 8 p.m. to 2 a.m. Peak hours remain to be when DS and US traffic peaks happen rather than midday. For US traffic, the post-lockdown midday spike outpaced the corresponding spike pre-lockdown peak-hour by 41%. Figure 8 and Figure 9, display the evolution of US and DS. SARIMA model was implemented to describe and predict the US and DS behaviors.

The Home Office, school online courses, and Internet-related recreation are the main drivers behind this transformation. The most popular categories are video meetings (Zoom, Webex, etc.), streaming (Netflix, Youtube) and gaming; file sharing also increased. The former calls for a heavy reliance on upstream, which has not been in great demand for years.

Traffic Increase April 30, 2020	DS	US
Mid-day	4%	85%
Peak Hour	28%	93%

Max Traffic Increase	DS	US
Mid-day	37%	90%
Peak Hour	48%	95%

Table 1 – Traffic increase for a particular date and maximum traffic increase registered.

Figure 8 - Evolution and forecast for Downstream traffic, 2020.

Figure 9 – Evolution and forecast for Upstream traffic, 2020.

3.4. Real-time analytics for IP video multicast

To understand the impact of multicast implementation, it was necessary to collect data on key indicators such as the number of concurrent streams, average bitrate, and average bandwidth to estimate bandwidth gain [13].

3.4.1. Multicast gain formula

We evaluated the multicast gain at service group levels as a percentage of the capacity needed under a 100% Unicast scheme, which we define as follows:

$$Capacity\ 100\%\ Unicast = \sum_{\substack{All \\ channels}} Concurrence \cdot Avg\ bitrate$$

When working with data from the Legacy system, we used the access frequency to approximate the concurrence, and we assumed that the average (Avg.) bitrate is 4 Mbps.

We examined different scenarios defined as follows: *Top "X"*, the "X" most popular channels are delivered to Multicast, and the rest remain Unicast.

The capacity needed is calculated as:

$$Capacity\ Top\ "X"\ Scenario = \sum_{\substack{Top\ "X" \\ channels}} Avg\ bitrate + \sum_{\substack{Other \\ channels}} Concurrence \cdot Avg\ bitrate$$

Finally, the multicast gain is:

$$Multicast\ gain\ for\ Top\ "X"\ Scenario = \frac{Capacity\ 100\%\ Unicast - Capacity\ Top\ "X"\ Scenario}{Capacity\ 100\%\ Unicast}$$

Gain is calculated using the overall concurrence for each channel. Additionally for service group level gain, internal service group concurrence is used.

In addition, a theoretical scenario is proposed, in which all the channels are transmitted via multicast to estimate the maximum multicast gain. This is helpful to determine whether the gain in other cases is nearly at its maximum or not.

$$Capacity\ 100\%\ Multicast = \sum_{\substack{All \\ channels}} Avg\ bitrate$$

The maximum gain is estimated as:

$$Maximum\ Multicast\ gain = \frac{Capacity\ 100\%\ Unicast - Capacity\ 100\%\ Multicast}{Capacity\ 100\%\ Unicast}$$

When there are approximately 10 channels delivered via multicast, it has been shown that the gain is approximately 50% during peak hours. The marginal gain tends to decline as more channels are multicast supplied. It was discovered that the benefit almost reaches its maximum with 25 multicast channels.

3.4.2. K-means clustering applied to the selection of multicast channels

K-means algorithm was used on ranking data to investigate the channel count that would be provided using multicast if it were an autonomous and unsupervised procedure, Figure 10. We discovered this technique categorized between 4 and 9 channels as the most popular after evaluating six months of worth data.

Figure 10 - K-means clustering applied to the access frequency per channel by day for the Legacy system. Algorithm used to classify the signals between multicast and unicast.

Real time analytics provides an efficient alternative for monitoring a policy-driven multicast strategy, due the advent of unconsidered special event which could drastically shift the ranking for a few hours.

It is proposed a continuous process, based on k-means clustering algorithm, executed every 10 minutes. The application searches for the channels with the highest viewing rates and determines if they are on the list of multicast channels. It sends an alert and reports the top list when it detects one or more channels that are being accessed massively and are not in the multicast list.

4. Evolving with AI and Big Data

Machine Learning has made significant advances in the telecommunications business, delivering numerous benefits. Given the tendency of strong virtualization, it simplifies operations.

However, we must not forget that the success of the application is dependent on the duties performed by people. In general, the tasks must be established to locate the learning models are as follows:

- Data: Split data into development and validation. Define instances, classes and attributes.
- Experimentation: Attributes selection. Performance metrics. Cross-validation.
- Model validation: Processes intended to verify that models are performing as expected, in line with their design objectives and business use case. It's the most important step in the model building sequence.

At Telecom, there are a few initiatives that we have considered within the AIOps framework. At STEM team one of our missions is to lead AIOps in our current and future networks. Our recipe is diversity, work in cells, agile mindset, and self-learning. In the following sections we present two of the initiatives we have been working on.

4.1. Network capacity and Machine Learning

We proposed the use of machine learning techniques such as Principal Components Analysis (PCA) and Artificial Neural Networks (ANN) to characterize the optical nodes that integrate our network and define the strategies the company will use to meet short and long-term demand [4].

We conducted different analysis at node level based on variables such as monthly consumption, households passed, traffic per port and downstream channels distributions, among others. We used a huge volume of data from different sources to obtain examples for the training sets used in the algorithms. Due the produced results are needed for a significant number of cases and on a regular basis, the process must be automated by applying machine learning and multivariate analysis techniques.

This analysis used traffic-data collected every Sunday during prime time, from all network's ports. One variable in the datasets contains the maximum traffic (Kbps) registered in each port. Our approach consisted in analyzing two key indicators:

- Average bandwidth traffic per residential subscriber at peak time.
- Ports usage.

The first one will provide information about the zones where there is a need for higher bandwidth, and the second will help us find the optical nodes where ports are operating at almost their full capacity, conditioning the Quality of Service (QoS) and limiting the demand.

To assess the average bandwidth traffic per subscriber at peak time, the metric was defined:

$$\text{Average BandWidth per Subscriber [Kbps]} = \frac{\text{Port Traffic}}{\# \text{Subscribers connected}} \quad (1)$$

For measuring ports usage, the maximum utilization was defined:

$$\text{Max utilization [\%]} = \frac{\text{Max Port Traffic}}{\text{Port capacity}} \quad (2)$$

To gather data about how the two key indicators relates to other variables, we also included in our analysis: the count of segments or zones connected to the port, CMTS model, optical node classification according to the region of location, investment plan status, network capacity (1GHz or other), DOCSIS version, cable modems count, HHP, network extension (in Km) and total monthly downstream consumption.

4.1.1. Principal Component Analysis (PCA)

Principal Components are the underlying structure in the data. Their interpretation is based on the weights obtained from the original variables. PCA is a way of identifying patterns in data and expressing it with fewer variables.

We made a PCA for the ports database. The variables included were:

- Maximum traffic per port for each Sunday
- Count of downstream channels in use per port (Channels_used)
- Count of areas connected to each port (Areas_port)
- Households passed (HHP)
- Residential subscribers per port (Subscribers)

- Traffic Management

We concluded there are two main PC, which can be explained as follows:

- PC1: It takes higher values for those ports that registered more traffic during the time surveyed. Channels in use, areas, amount of cable modem and HHP per port also have a positive yet lower impact.
- PC2: This component takes higher values as the number of areas, cable modems and HHP per port increase, as well as traffic management. On the other hand, it takes lower values as the number of downstream channels in use increases. This variable informs about a port's incapacity to provide a good service in highly populated areas.

PCA highlighting there are two port groups, Figure 11. One where the aggregation of more subscribers draws a substantial increment in the traffic, and another where the impact of adding subscribers is lower.

Figure 11 - PC1 vs PC2 and its relation with traffic management.

4.1.2. Artificial Neural Network (ANN)

We based our ANN on the following principles:

- Parsimony Principle: the simplest model that fits the data is also the most plausible.
- Sampling Bias Principle: if the data is sampled in a biased way, then learning will produce a similarly biased outcome.
- Data Snooping Principle: if a dataset has affected any step of the learning process, its ability to assess the outcome has been compromised.

We determine one of these four options to increase network capacity and, as a result, access speed: chassis upgrade, recombination, node segmentation, and node division

For the neural network training we first needed a sample of nodes to be classified by the expert team. Sample characterization was made by classifying nodes into three strata: the first one has the nodes in which their ports have a mean utilization below 50%; the second stratum contains nodes where mean utilization lies below or equal to 80%, the third groups the nodes with mean utilization above 80%. It is in our interest to have a faithful representation of the HHP variable in the sample.

For overfitting avoidance, sample data was split in training (60%), cross-validation (20%), and testing (20%). Training set was used to estimate the weights in the neural network. Cross-validation helped validating the model in terms of variables and optimization of the selected parameters. The testing set wasn't used in the construction of the neural network but to check whether there was overfitting or not, by measuring network classification performance with 'new observations. Quadratics terms were included to search for higher accuracy. The ANN scheme got is shown in Figure 12.

Network's first layer contains eight inputs, the four variables mentioned (represented as x) and the same variables at square (x^2). Second layer, also called hidden layer, contains eight data points too ($a^{(1)}$), and the output layer contains five classes ($a^{(2)}$), which refer to the four strategies already detailed and the fifth option 'no action needed', for the nodes where no investment was needed at the time.

The optimal weights solution in the network threw an accuracy level of 96% with the training set, and an accuracy around 90% with testing set.

Figure 12 – Our ANN scheme.

4.2. Optimizing video customer experience with Machine Learning

For video service providers it is important to evaluate the processes that affect the quality of video considering the perception of customers. The subjective evaluation of the quality of the video measuring the opinion of human users is expensive and slow, although there are public databases with standardized results. To automate the evaluation of quality of video objective models that try to approach the subjective evaluation human are used. Recently, objective models emerged using Machine Learning (ML) algorithms which are trained using databases with subjective evaluations, to combine a variety of classical metrics. Classical metrics are much simpler to implement and at a lower cost but, they produce worse results that do not always fit the human perception. On the contrary, the metrics based on ML produces results very close to the subjective opinion of the customers, but they are more complex to implement and provide development opportunities.

Within the objective metrics based on ML there is a method named Video Multimethod Assessment Fusion (VMAF), an open-source method proposed by Netflix in 2016 and is a video quality metric that combines human vision modeling with ML to provide a great viewing experience to their members.

Telecom has its own IPTV platform, called Flow, that is based on unmanaged (second screens) and on managed devices (set top boxes). It provides different types of advance video services, including Linear TV, various flavors of On Demand services (VoD, CuTV, Reverse EPG, StartOver, network DVR, Pause Live TV, and Trick Modes), using different streaming technologies, Search and Recommendations. Thus, it's very important for the Company to develop VMAF as a tool for optimizing Flow customer experience and to equalize video quality with other existing video platforms.

In order to train VMAF for optimized Flow customer experience we defined a dataset following Netflix recommendations regarding the type of content. We selected 35 videos, each 10-sec long from Flow catalog. To make the distortions, each source video was encoded with 6 resolutions up to 1080p. Video characteristics were variable, and used a selection of videos with fire, water, nature, animation, close-up, action, crowd, among others.

We ran a subjective test through 6 different focus groups. Each group of about 15 subjects. Each subject sits in a living room-like environment and was instructed to watch an unimpaired reference video, then the same video impaired and give a rating on a continuous scale from “bad” to “excellent” (ACR methodology), then we translated the scale to a range from 1 to 5 and calculated the MOS.

Then, we trained several models with different sets of parameters for the Support Vector Regressor, the ML model used to perform VMAF (Figure 13), to avoid the underfitting and the overfitting.

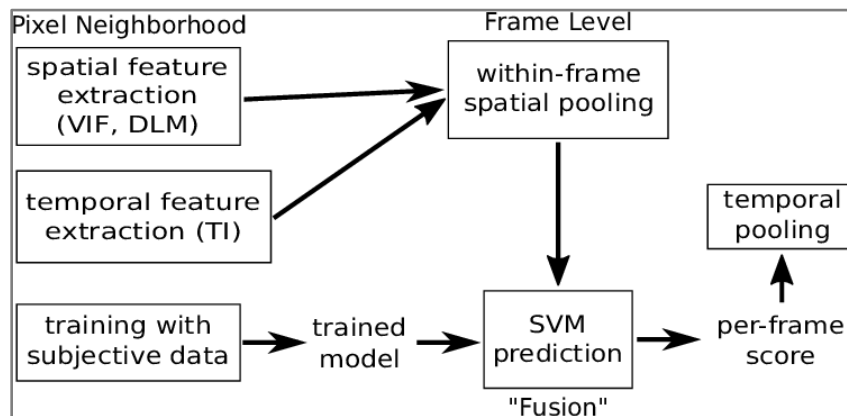

Figure 13 – VMAF Algorithm.

Once we had our model trained, we tested it with the testing dataset previously defined. After the testing, we calculated the performance metrics to measure the prediction accuracy (60%). Based on the results we obtained, we understood that we must continue improving the model with larger training and testing datasets or with other elementary metrics combination. In any case, the accuracy of machine learning models that use subjective variables does not usually exceed 70%.

5. AIOps

The term AIOps was coined by Gartner in 2016 and have pushed the concept into the marketplace. According to Gartner “AIOps combines big data and machine learning to automate IT operations processes, including event correlation, anomaly detection and causality determination”. And, according to Figure 14 has three main elements: observe, engage, and act.

Figure 14 – AIOps cycle by Gartner.

While AIOps was developed to give scalability to the management of IT systems, given their increasing complexity and framework, we can extend its applications to Telecommunications operations.

A first definition of AIOps in the telecommunications industry is the use of Artificial Intelligence for the operation of networks and services. The long-term goal is to achieve autonomous networks (AN), which in some ways, at the beginning, entails automating many of the operational procedures [5].

Automation in AIOps is understood to range from automating network capacity planning through some ML algorithm, automatically detecting anomalies in traffic flows through ARIMA time series, or even automating a process of adjusting a modulation profile in the form autonomous (closed loop) (Figure 15).

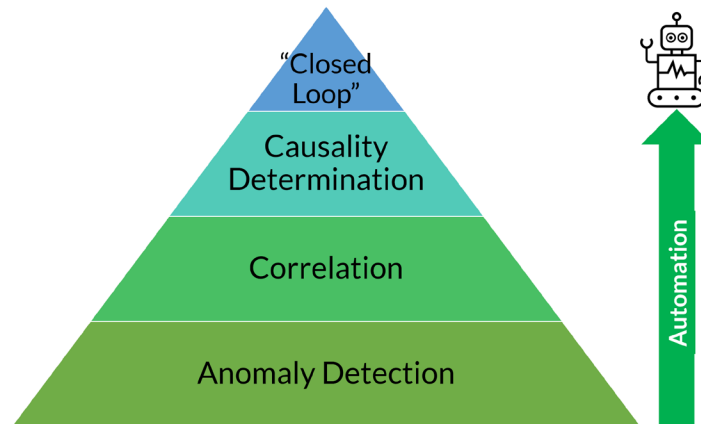

Figure 15 – AIOps automation path.

Gartner also defines four levels of Network AIOps, that we can see in Figure 16.

Four Levels of Network AIOps Functionality

Level 0	Level 1	Level 2	Level 3	Level...
				
Full Human Intervention Required. Reliance on templates, manually refreshed best-practice database, detects basic configuration errors	Substantial Human Intervention. Real-time detection and correlation of issues, limited or no automated issue remediation	Minimal Human Intervention. Detection and correlation of cross-domain issues, advanced issue remediation and real-time optimization	No Human Intervention Required. Automated topology mapping, resource orchestration, pervasive remediation and real-time optimization	Future AIOps Functionality yet to be defined

Source: Gartner
763626_C

Gartner

Figure 16 – Levels of Network AIOps functionality.

We adopt AIOps as a framework to continue our journey towards an AI-driven operation. While autonomous networking is our goal, we will only make a brief reference below.

In summary, AIOps refers to the application of AI technology to automate business processes and operations at CSPs.

5.1. Ada

At Telecom Argentina, we have been working on a network dimensioning solution since a long time ago. In 2017 we developed a tool that assisted the decision-making process for HFC network dimensioning, mentioned in a previous section. Later, we incorporate data from the radio-access network (RAN) and relaunched the project under the name Ada. The goal is to have a tool that combines machine learning and subject matter experts (SMEs) input to assess investment decisions on CAPEX and OPEX.

Historical data is collected on every HFC node, as well as for every cell on the mobile network. The concept is that for short-term decisions (two years forward), ML-based forecasts are offered, and the duty of experts is to identify priorities and act on them. Long-term decisions (5-10 years periods), on the other hand, ML-based forecasts would require a longitude of history that hasn't yet occurred. In our experience, however, it is possible to provide reasonable approximations if forecasts are supported not only by historical data but also by experts' knowledge. Hence, a ML clustering model has been added, which characterizes the nodes according to their traffic and other variables. Based on the short-term forecast, nodes characterization, and feasible tasks that can be carried out on the network (such as migration from HFC to FTTH), possible long-term scenarios are obtained.

Planning engineers used to research on potential scenarios and make a series of calculations to approximate what they thought was going to happen in the long-term, based on their knowledge of the average client and use cases. Working together, we built profiles for the operation area, so they can refine what to expect from a variety of use cases. For example, consider two cases where a household group mostly uses the service for social media and the income is low, with another group with heavy streamers and high income. We provide better information to planning teams at the beginning. An example of the Ada application is displayed on Figure 17.

We continue working on how to enable engineers to pass information to a model about what they expect the CAGR would be at different kinds of operating sectors, in the next 5-10 years. This will involve a combination of simulation and forecasting techniques. It will also require a certain level of automation that is not achievable outside a ML framework.

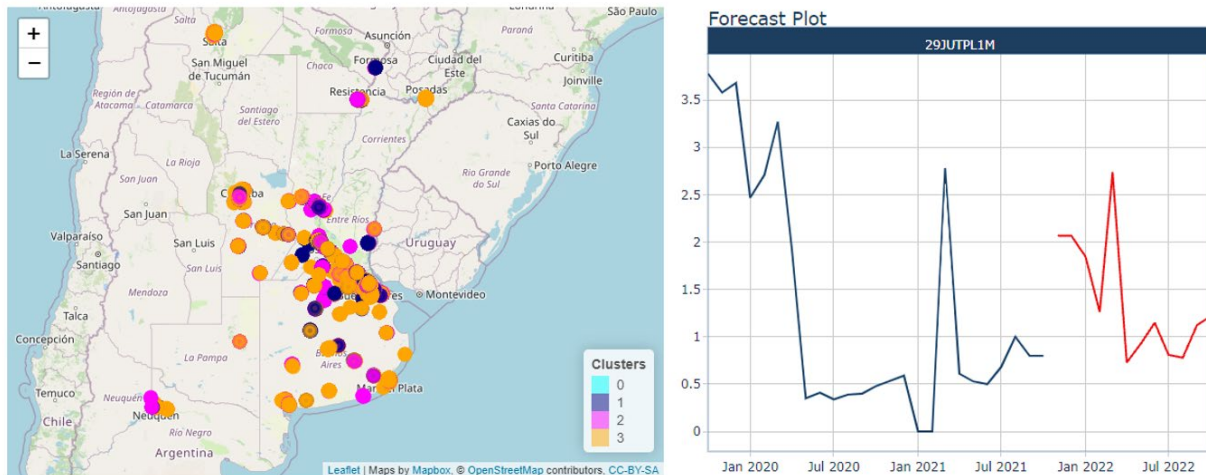

Figure 17 – Clustering and Forecast performed with Ada.

5.2. Customer claim prediction for HFC network

Within the domain of AIOps one of the most popular use cases is customer claim or tickets prediction. The main idea is to use information derived from different elements of the network, such as: CMTS, cablemodems, electronic devices, etc. to estimate the probability of a customer to generate a complaint.

Information is generally collected through OSS systems and ingested in a machine learning pipeline where preprocessing, analysis and ML model testing is performed. We are currently developing this kind of solution to ultimately increase customer satisfaction.

Using hourly collected information from over 3.5 million DOCSIS 3.0/3.1 cablemodems we are trying to anticipate customer complaints two days in advance. To handle this amount of data we have partnered with Google to develop and deploy this project using Google Cloud Platform (GCP) services. A high-level view of GCP implementation is shown in Figure 18.

Potentially relevant variables (e.g., signal to noise ratio, consumed bytes, average Rx, t3 and t4 time outs, etc.) have been identified and our Service Assurance team have been able to efficiently transfer these data, collected by our OSS systems, to GCP.

Figure 18 - High-level view of our project: inputs, outputs, outcomes and architecture.

Regarding technical challenges, two of the most difficult tasks have been dealing with an extremely unbalanced dataset and label noise. Although from a business perspective having a low proportion of customer claims is a good indicator, some ML models can struggle to learn from these kind of data sets. In our case, after filtering the target population, the positive class dropped to 0.1%, which added more complexity to the problem. To reduce the impact of this issue on model performance we applied hyperparameter tuning and a technique called SMOTE combined with an under sampling of the majority class. Both approaches led to improvements in model performance.

We have been able to overcome many challenges and finally the ML model selected was XGBoost. As a result, we obtain a daily list of customers with high probability to claim. From this list, with CX and Field Service teams, we can make proactive calls to solve customer problems remotely or to send a technician to their home if necessary. Then, we measured through surveys and NPS how was the experience of our customers and we found that this proactive action has a positive impact on their satisfaction.

Although we are going through an early stage of this project, we understand that the future result will be to increase the number of promoters of the company and consequently avoid churn. In addition, the truck roll and the costs associated with it would be reduced.

5.3. Intelligent agents and Autonomous Networks

Peter Norvig and Stuart Russell present in [6], eight definitions of AI, from which they define Intelligent Agents as “agents that receive precepts from the environment and take actions that affect the environment.” Agents’ actions change the world. Thinking (Cognition): Interpret sensory data. Then updates its environment (model of the world) and, decides on next best action. The autonomous networks that are being defined in the TM Forum and ITU are based on this definition.

Figure 19 – Intelligent agent.

**Figure 20 – Agent in AN source: Autonomous Networks Technical Architecture (IG1230).
Source: TM Forum**

There are two concepts we have been working on with our stakeholders and team in the CTO office.

- Autonomous Networks make decisions without human intervention (decisions made by Agent).
- Automation operates without human control (can be implemented without AI technology, as we have seen).

Another related idea is “intent-driven automation”. Intent-based networks enable service providers to define the behavior they expect from their network from service and business perspective. Intent was first introduced around 2015 in the context of SDN controllers. “Intent is the formal specification of all expectations including requirements, goals, and constraints given to a technical system”.

This definition is inspired by and compatible with the definition IETF has published in 2020 [10]. The definition associate's intent with goals, requirements and constraints provided in a declarative way. Intent constitutes and expresses knowledge about these concerns and enables sharing this knowledge between the originator and receiver of the intent.

“Autonomous networks are those that possess the ability to monitor, operate, recover, heal, protect, optimize, and reconfigure themselves; these are commonly known as the self-properties” [11].

The impact of autonomy on the network will be in all areas including planning, security, audit, inventory, optimization, orchestration, and quality of experience. At the same time, autonomy raises questions about accountability for non-human decisions that affect customers.

The growing virtualization and cloudification (Telco-Cloud) of our networks make possible the evolution towards AN. At Telecom, we use the AIOps framework since we know that it will lead to AN through automation [5].

6. Learned lessons

In this part, we'll highlight some of the lessons we've learnt from our experiences or those of other CSPs with whom we've collaborated on AI working groups for network and service operations. Over the years, adopting an AIOps framework and making our operations AI-driven have required significant culture change and teamwork, all in line with the company's technology strategy. The fact that AI is used in the process does not imply that we are AI-driven.

Operations + AI technology \neq AI-driven

We are training our engineers to focus on the operations-related tasks that are more challenging and where they can bring the most value rather than the less interesting and repetitive ones that can be handled by the systems. As indicated by the AIOps TM Forum framework, engineers working on AI-systems exception management and continuous optimization.

6.1. Define and communicate AI-driven operations

A lot of expectations and skepticism occur when AI is introduced because of the numerous movies that have been made over the past few decades. Because of this, it is crucial to carry out an internal communication and evangelizing work on what we mean by AI-driven operations. The various stages of the analytical component must be clearly discussed.

- Descriptive – What is happening now?
- Diagnostic – What happened and why?
- Predictive – What might happen?
- Prescriptive – What actions should be taken?

We need to plan out how we can effectively inform the various business teams about these AI-driven projects.

It's also important to mention that operations engineers view AI as a tool for augmented intelligence (AgI).

While AI builds machines that behave and function like people, AgI uses the same machines but takes a different tack to enhance human skills. AgI actually entails a collaborative effort between humans and machines that makes use of each party's advantages to boost overall commercial value. In other words, AgI's main objective is to enable people to work more effectively and smarter. [7].

Finally, it is also important to communicate what problems can we solve, and which ones cannot, their scope and limitations.

6.2. Workforce

Believing that a pair of data scientists can resolve a network operating or planning problem is one of the most frequent errors we have observed.

Teams using AI should be set up with professionals in data sciences, operations engineering, field service, customer experience and also with technicians to tackle operational challenges. We need to build internal AI teams.

Like many businesses throughout the world, our main challenge is finding experts who are knowledgeable in programming, telecommunications, and AI. We have junior and semi-senior data scientists on the STEM team because of this. Tech Scientist is the next level of seniority. The tech scientist has expertise in the technology that he uses in collaboration with the operations and field service engineers, in addition to data science and programming skills.

In several talks with colleagues from other companies, they have even raised the difficulty of recruiting data specialists. Because of this, digital training and recruitment are a priority in Telecom. Along with learning about communication technologies, our engineers at the CTO office continually train in data sciences. Our aim is to keep our work teams AI-driven learning continuously so they may continue to advance their careers and bring value to our clients.

Our recipe is diversity, work in cells (with the experts of service assurance, field service, customer experience, etc.), agile mindset, and self-learning.

To ensure that these people choose to work at Telecom despite the rising demand for these profiles in this hyperconnected world, we are creating a reskilling strategy for our employees as well as loyalty and retention programs.

Automation will also make it possible for operational departments to integrate technology to streamline procedures and improve our customers' digital experiences, which will further raise business efficiency.

To sum up, we are establishing a strategic talent plan for transforming our current teams into an AI-enabled workforce.

6.3. Models, algorithms and Explainable AI

Always keep in mind that "All models are wrong; some models are useful," and that the key is for the work team to agree on which model to adopt.

Once the useful model has been adopted to solve an operation or decision-making problem, we must somehow make the models transparent, understandable, and interpretable. Experts must comprehend how the findings were obtained and the degree of confidence that the model has before they can decide to adopt an AI tool.

The model's output shouldn't be what matters, but rather understanding why an algorithm produces a particular output. Because of this, explainable AI (XAI) is a new growing field. The goal of enabling Explainability in AI/ML, as stated "is to ensure that algorithmic decisions as well as any data driving those decisions can be explained to end-users and other stakeholders in non-technical terms" [7].

Explainability sits at the intersection of transparency (consumers have the right to have decisions affecting them explained in understandable terms), causality (it is expected of the algorithms to provide not only inferences but also explanations), bias (the absence of bias should be guaranteed), fairness (it should be verified that decisions made by AI are fair) and safety (reliability of AI systems) [8].

We know that many machine learning algorithms have been labeled "black box" models because of their inscrutable inner workings. What makes these models accurate is what makes their results difficult to interpret and understand. They are very complex. The discussion about audit AI is still open [7].

6.4. Cloud and Data/AI platforms

The democratization of data by hybrid clouds is another lesson learned. “No amount of AI algorithmic sophistication will overcome a lack of data (architecture), Data collection & preparation is the most time consuming and difficult part of AI” [12].

There is a project in our OSS systems evolution program that is solely responsible for gathering and organizing data. In complicated hybrid multi-cloud systems, we are employing platform services to tackle problems using data and AI. but before using platform services, one should give them a serious evaluation.

Platform services are increasingly being used by CSPs to accelerate the use of AI in business operations. We should take a hybrid approach to deploying platform services.

7. Next steps

Our next step is to define long-term roadmap towards Autonomous Networks. We anticipate finishing the surveys, definitions, frameworks, and scope for the strategic definition toward the autonomous networks paradigm by the end of the year. Virtualization and softwarization of networks are clearly included in this strategic framework. This ecosystem includes 5G and IoT.

In the AIOps framework, we began by identifying the claim root cause and its causality¹ using our model of customer claim prediction for the HFC network.

Conclusion

We offer the AI-driven initiatives that were significant turning points in terms of lessons learned since we started our journey. Right now, our focus is on developing within the AIOps framework.

AIOps' objective is to advance from automation to autonomous networks, but we must remember to see it from the standpoint of augmented intelligence (AgI). Together, people and robots may maximize the value of their own capabilities for the benefit of the organization.

Include operations engineers and technicians early in the use case, and keep in mind how crucial Explainability of AI models and their results are.

To reach full AN it is necessary to advance to the "Telco Cloud".

Cultural and process change is required. **"Think big, start small"**.

1. Introduction

Backup batteries are an essential part of the reliability equation for the cable outside plant architecture. When utility power fails, batteries are relied upon to power the network and helps ensure customers remain on-line. Being able to predict how long a battery can support the network is an essential planning and maintenance tool.

As one of the largest industrial Internet-of-Things (IOT) applications, Comcast has developed the unique ability to automatically test and monitor over a million installed batteries at well over a quarter of a million installations. This paper describes possible ways to use this continuous sensing of metrics from the power supplies of our outside plant network to begin developing a sophisticated diagnostic and planning tool. When finalized, this tool will use machine learning and artificial intelligence to be able to predict the expected runtime of a battery during a utility outage based on its actual load, and then to adjust this runtime prediction based on multiple key factors. The final desired result is the ability to know whether a battery is performing as expected, and to be able to track its degradation for preemptive maintenance purposes. This includes unexpected loss of battery performance from unknown factors as well as the expected losses from known factors. The status of this work is presented, showing the current predictive model, along with a brief discussion of the future work planned in this area.

2. Background

Battery systems have been used for many years to power the Cable network during a utility outage. Utilities themselves are undergoing a significant transformation, with increases in renewable generation, flexible load programs, decarbonization of commercial buildings and major capital deferrals. Throughout and sometimes due to these major strategic shifts, energy reliability and disruptions remain a significant issue that network providers must deal with. The disturbing and growing trend of electrical disturbances for the past 20 years can be clearly seen in Figures 1 and 2.

Figure 1 – Department of Energy OE417 – Annual Summary

Figure 2 – System Average Interruption Duration Index (SAIDI) – EIA-0861, Annual Report

It is relatively easy to detect an outage and to report on the duration of a battery's discharge event. However, this in-and-of itself is not sufficient to determine the health of the network. Battery manufacturers provide tables and curves for the expected discharge runtime vs. load of a new battery. Over time as the battery ages, the runtime performance of a battery will be expectedly reduced by numerous factors and conditions, while the battery remains healthy. The goal of this work was to use the existing metrics available from the power supplies to calculate the runtime of a new Outside Plant (OSP) battery, and to then adjusted the runtime based on the effects of the major, known factors. Future work will focus on identifying unhealthy batteries that have degraded faster than would be expected. This tool is expected to ultimately result in fewer truck rolls as well as enable a more effective OSP battery (see Figure 3) replacement strategy.

Figure 3 – Pad mounted Outside Plant with Batteries Shown

3. Approach

The existing set of metrics that are reported from the power supply was first examined to determine what gaps exist. This set includes the following key items.

- Power output of the power supply
- Current output of the power supply
- Individual battery voltage
- Ambient temperature
- Timestamps of all items
- Inverter status (charging, discharging, +)

Additional items known include the age of the battery, the manufacturer and the model, the number of battery strings, and the total number of batteries in the power supply. Using all of these metrics, we were able to craft a working predictive model.

The first step was to determine how the battery was expected to perform as new. Manufacturers generally provide a limited performance data set. This runtime data can be based on a constant current discharge or a constant power discharge. Using this data set, the discharge performance for each battery model in the network was plotted and curve fit to allow a calculated runtime for any load imposed on the battery. This generally follows the well-known Peukert's relationship, which is a generalized relationship between discharge load and runtime. Since the performance curve of all batteries vary based on their design, it was decided to individually curve fit the performance data for each battery model in the network. Using a standard exponential equation, a very accurate curve equation was then created for each battery model. An example of the manufacturer's data provided and the resultant curve equation for one of the battery models are shown in Figure 3.

Figure 4 - Manufacturer's Published Battery Performance Data – with curve fit equation

To use this curve equation, the actual direct current (DC) load placed on the battery is required. Unfortunately, this is not one of the measurements of the power supply. To resolve this, the efficiency of the power supply inverter was calculated using the measured alternating current (AC) voltage and current output of the power supply. By using this calculated inverter efficiency, the DC load on the battery could then be calculated. With this, we were then able to calculate a predicted battery runtime for any utility outage where the power supply transferred to battery backup.

The limitations of this preliminary equation were immediately evident. Using the performance curves from the manufacturers predicts their runtime as a brand new battery. All batteries will expectedly decline in performance over time as they naturally age. This degradation is not accounted for in the curve fit of the performance data. Additionally, temperature has a major effect on battery performance. Without accommodating for these factors, one is unable to ascertain if a battery that runs for a shorter than expected period of time is prematurely failing. A short-running battery may be defective, or it may be perfectly healthy but several years old. It could also be healthy but with a reduced runtime because it is being used in the winter in the Minneapolis area.

4. Temperature Effect

The power supply cabinets are environmentally uncontrolled, and the temperatures vary widely depending on the latitude and the season. As all students of chemistry are aware, virtually all chemical reaction rates are affected by temperature as described by Arrhenius many years ago. To complicate this temperature effect on the reaction rate, a battery's performance is the result of a two-phase reaction. The discharge reaction occurs in the liquid electrolyte phase, and then deposits onto the solid surface of the plates. Temperature will affect both rates differently depending on the battery design. The liquid electrolyte phase is further complicated due to temperature induced convective movements during extended runtimes. Finally, the surface reaction is affected by double-layer capacitive effects. For this first level model, a test program was initiated within the Comcast labs as shown in Figure 4 to experimentally quantify the total effect of temperature on the battery performance for each major battery model in the network. Using controlled environmental chambers, measured performance discharges were conducted on battery models under varying ambient temperatures.

Figure 5 – Tested Batteries for Temperature Effect

Based on these results, the Temperature Correction Factor (TCF) was determined to follow the general polynomial equation as shown in equation 1. Applying the TCF to the predicted runtime allows the overall effect of temperature for each battery model to be included in the runtime prediction.

$$\text{TCF} = A_1 * \exp(-0.05) * (\text{Temp, degrees Celsius})^2 + A_2 * (\text{Temp, degrees Celsius}) + A_3 \quad \text{Eqn. 1}$$

[A_n are experimentally derived constants]

5. Aging Effect

The second major effect on batteries is the aging effect. Industrial batteries are considered at end-of-life when their performance has degraded to 80% of their initial capacity. Beyond 80%, the change in degradation accelerates significantly, and the battery is in danger of unpredictably and sharply falling below the minimum requirements. There are two separate types of aging – calendar and cycle effects. Either of these will independently degrade the performance of a battery.

A battery has a predetermined calendar life. Even if never discharged, the internal side reactions that occur within the battery will corrode the positive grids and cause electrolyte loss. Numerous factors will affect the corrosion rate, including grid alloy, temperature, float voltage, electrolyte strength and AC ripple. These factors are generally balanced by the battery manufacturer, so that in an ideal setting, the battery will degrade to 80% capacity at the end of its published design life. Life claims vary by manufacturer, but a seven-year design life was used as an initial estimate. This is known to be a gross estimate, as the corrosion rate is known to be strongly affected by latitude/temperature. For our initial model, a straight-line estimation was used, assuming the battery loses 2.8% of its capacity each year, thus hitting its 80% end-of-life capacity at the end of 7 years.

$$\text{Calendar Aging Factor (AF)} = - (1 - 0.80) * (\text{year})/7 + 1 \quad \text{Eqn. 2}$$

The second major aging effect is due to cycling. In addition to the grid corrosion occurring during calendar aging, any discharge/recharge cycle will degrade the positive and negative plates within the battery and reduce its capacity. This is understood, but not yet implemented. The issue is that a generic model cannot be used, as the ability to cycle is dependent upon the specific design of each battery model. The types of batteries used in the network commonly are designed for approximately 200 ‘deep’ cycles, but can easily vary from 75 to 500 depending upon the internal components and method of construction. Additionally, the ability of a battery to withstand shallow vs. deep discharges varies tremendously in a non-linear manner, making it necessary to know the cycle-life curve for every battery model. This information is typically not provided by manufacturers in sufficient detail and lab testing is expected to be required. Once characterized in our labs, the number and depth of the discharge information will be collected and compiled from the field, with the intent of adding this element to a future revision of this model.

$$\text{Cycle Aging Factor} = \text{function}(\text{depth of discharge}) + \text{function}(\text{cycle quantity}) \quad \text{Eqn. 3}$$

6. Discussion/Results

The predictive model as described takes the known informational points of the power supply listed below. It calculates the predicted runtime of the power supply, based on the output load, the battery model and battery quantity. This calculation is then modified based on the temperature and the calendar age of the battery to provide a final predicted runtime.

- Battery manufacturer - recorded
- Battery model - recorded
- Number of battery strings - recorded
- Total number of batteries - recorded
- Date code - recorded
- AC voltage output - measured
- AC current output - measured
- AC power output - measured
- Temperature - measured

Actual field data was collected and compiled over a 6 week period and plotted in Figure 5. The predicted, adjusted runtimes were calculated and plotted vs. the actual runtimes. Obvious sources of error were excluded, such as missing dates, errant currents and runtime that were too short or too long to be meaningful. This is an area of ongoing work as the errors found continue to be cleaned and corrected. In an ideal world, all points would lie on a straight, 45 degree line (shown as the thin black line in Figure 5), which would indicate the model was perfectly accurate in predicting battery performance over a wide range of runtimes.

Figure 6 - Predicted Runtimes vs. Actual Runtimes

This is a very preliminary snapshot of the data, and refinements and adjustments are continuing. However, despite the substantial scatter in the data, even this preliminary snapshot is extremely encouraging. A distinct trendline shown in red in the plot shows that a correlation is evident in the runtime calculation. The deviation from the ideal 45 degree slope indicates that as the runtimes extend longer, the deviation grows from the expected. Since the model is based on the manufacturer's published data, the prediction is only as accurate as this data. One possible cause of this error shift is based on the author's experience that the published manufacturers data is often progressively more conservative for shorter runtimes. This will be verified in future planned lab testing to see if the actual performance data does indeed deviate from the published data. Another possible cause of error may be the temperature rise in the battery from ohmic heating during a discharge. During longer discharges, it is possible this internal heating could progressively improve the performance of a battery. The current model calculator neglects this effect as it corrects for only the initial temperature measurement.

In Figure 5, all points below the 45 degree line indicate batteries that ran shorter than predicted. The points very close to the horizontal axis indicate batteries that failed immediately. This could be from batteries with defects, improper connections, broken cables, etc. There currently are no predictive elements in the present calculator to identify such defects. However, from knowledge of battery failure modes, there are suspected metrics that are currently being reviewed that may identify defective batteries prior to a discharge. For instance, a large standard deviation for the batteries within a string could conceivably indicate one prematurely failing battery and could thus be a predictor of a shorter runtime. Another example is that a battery not fully charged will perform poorly. To identify batteries that are not at a full state-of-charge, it is planned to track the time and depth of previous discharges to determine the recharge efficiency. Additionally, it is expected that a battery in this condition could be identifiable by its high internal resistance, which could conceivably be seen in a low initial voltage at the onset of the outage. For this example and other suspected causes of poor performance, there are now efforts underway to use machine learning as a tool. This will allow correlation of possible groups and trends with identifiable causes.

7. Conclusion

Comcast has developed the significant ability to automatically test and monitor over a million installed batteries through its Outside Plant network. Using the data collected from this immense installed base, a runtime calculator was created to predict the runtime of outside plant batteries. This calculator is based on Peukert's law, which approximates the non-linear change in battery capacity due to changes in discharge rate. An exponential equation was fitted to each battery model's performance curve to allow an accurate prediction of the runtime of a new battery at a constant, 77 degrees F temperature. This model was then adjusted for the two major, known causes of variations in battery performance - temperature and calendar aging. With this new model, preliminary comparisons to actual field outage data shown a promising correlation between predicted and actual runtimes. Refinement of this preliminary model is continuing to identify and reduce the sources of error present. Future work will focus on additional laboratory testing of batteries to more fully characterize their performance over the range of field conditions. This includes the addition of a cycling degradation factor due to accumulated discharge events of different depths. In addition, future efforts are also planned on machine learning to associate patterns in the data with identifiable causes. (see Acknowledgements) It is optimistically expected that as this model evolves and become increasingly sophisticated and accurate, the ability to quantify and predict battery degradation will prove to be an immensely valuable tool for predictive maintenance and asset planning.

Acknowledgements

The authors would like to acknowledge our colleagues that were major contributors to the success of this effort. Matt Stehman and Chris D’Andrea were instrumental in setting up and developing the tools used in the data collection and analysis of this project. Their work has been greatly appreciated and they are expected to continue to play a major role in the machine learning efforts as this exercise continues into the future. Interested readers are encouraged to read the details of their machine learning efforts “Machine Learning and Telemetry Improves Outside Plant Power Resiliency for More Reliable Networks”, by Stephanie Ohnmacht and Matt Stehman, presented at this Expo.

1. Introduction

As the speed of access networks increases and become less of a bottleneck to providing quality service, customers turn their concerns toward reliability. But they refer to service reliability, not network reliability. Still, network reliability is a key component of a reliable service. So, what is a cable operator to do?

As the cable industry turns more attention toward reliability, we have the opportunity to lead. The reliability engineering discipline is many decades old, and has a lot of tools, knowledge, and practices that we can start from, along with our own cable industry history of successful reliability engineering. Now, service usage is different, expectations are higher, networks are built and services are provided in new and different ways, and the technology we use today is rapidly evolving. The way we assure reliability has to be different too.

This paper provides a roadmap for addressing network and service reliability for the cable industry. Instead of a complete answer, it is a roadmap for the work ahead. There are many routes to take depending on where and how far the service provider wants or needs to go. CableLabs[®] and the Society of Cable Telecommunications Engineers (SCTE) can provide the van pool for part of the journey, and there will be vendors at the rest stops to help, but the journey is for the operators to take.¹

2. Definitions

There are many sources for finding definitions of reliability and the many related terms. A few simple ones are offered here, and hopefully explain away some of the sources of confusion. Unfortunately, some of these terms have use in marketing, engineering, and non-technical contexts with different meanings. Even in an engineering use, there are often assumptions being made that make it difficult to know just what is being defined and under what context. As we apply a little focus on these definitions for our specific purpose, consider that these definitions also are the desirable properties of networks and services.

- *Reliability* as a word by itself is ambiguous, context dependent, and can mean a lot of different things depending on the situation. Consider first the perspective of the user of the word, and the context they use it under.
 - Customer – Whatever it is, it must work as I want it when I want it, without repair action on my part, so that the system is invisible to me when I use the service – this is service or use case reliability.
 - Provider – Sometimes a service provider uses this word to mean availability, suggest a lower repair rate, infer fewer customer calls, or other operational costs – this is operations reliability, or network reliability [1].
 - Academic – A more precise definition of reliability is the probability that something functions as intended up to time $t > T$ given it works at time $T = 0$. This is the reliability at time t . Note the reliability function is a decreasing function over time. Note also this says nothing about networks and services, which are repairable.

Availability is better suited for repairable items, though reliability is still relevant.

- *Availability* is the long-term percentage of time that a repairable system works. In other words, availability is the ratio of time that a service, device, or network is available for use over the total time, usually expressed as a percentage of the total time. Equally, it can be expressed as the

¹ Get it? A Roadmap for Cable Access Reliability (CAR). Did you expect a General Path Solution (GPS)?

probability that a repairable system works at some far future time. As such, availability considers the uptime, downtime, and repair time issues of the system or network as a whole. It can't tell you whether failures are frequent or infrequent, or repairs are lengthy or fast, but tells you the proportion of time that something can be counted on to work.

- *Maintainability* is the ease with which something can be maintained. Often this feature is determined by maintenance time estimates, sometimes through time and motion studies. Maintainability can include repair, but does include planned maintenance.
- *Repairability* refers to how easily and quickly a component or system can be repaired, or the property of being repairable. This term focuses on repair instead of planned maintenance, though the distinction is not always clear.
- *Survivability* is the ability of a system or network to operate under attack, and provide service in the presence of failures. Parts can fail, but the system or network still functions and provides service.
- *Resiliency* refers to failure recovery and fault tolerance, and the ability to provide service under degradation, over a broad range of demands. Degradation exists, but service functions.

Note that survivability and resiliency are related, but different in that the former refers to surviving a partial failure such as a lost link in a mesh network, while the latter refers to functioning under degradation such as ingress interference in a DOCSIS[®] network.

- *Performability* is the convolution of the performance function and the probability function of the system. It's a complicated concept, but let's think of it like this: 90% of the time, my bike works great; but 9.9% of the time, the tires are low and it is hard to pedal the bike; and the rest of the time, the bike is in the shop. If I consider that the bike with low tires performs at 50% while the fully functional bike is performing at 100%, in this simple example, the performability overall is $(0.9 * 1) + (0.099 * 0.5) + (0.001 * 0.0) = 0.9495$, which is less than 95%, even though availability is 99.9%. Think of performability as a state probability weighted performance measurement. Then realize that the probability function of the possible states, translated to the probability function of the possible performance levels, is a better measure of the experience than simple availability. If you replace the performance states with a continuous performance function, the concept still works though the math gets more complicated. But keep in mind that a single number representing performability is not as useful as the full function representing probability of performance.

Referring to the customer's definition of reliability, see that all these factors contribute to a user's perception of service or use case reliability. The unreliability of a service can be impacted by a number of performance measures as they relate to the usage or use cases associated with the service. Users are all unique, but they reveal their preferences through their product choices and willingness to pay for features; this information translates well to their perception of service friction² and thus reliability.

3. Goals for cable network and service reliability

In support of our industry's 10G Platform goals, operators have a lot of well-informed tasks to accomplish. Categorically, some of these tasks include:

² The concept of service friction in this context is new; we use it here to represent any impedance a customer experiences from using a service as intended in the desired manner.

- Assure service reliability primarily, which requires network and system reliability, availability, maintainability, and appropriate resiliency and survivability. But it also requires reliable processes, procedures, management, and more.
- Build a foundation of understanding, linking customer experience to system and network events, so operations, design, and upgrades all provide the best service possible.
- Design reliable network and service solutions, with degrees of freedom to manage service reliability, that are also reliable in executability, obtainability, etc.
- Select reliable, repairable solutions and components for given deployments.
- Create and maintain fault management that is reliable, inexpensive, and maintainable. That includes proactive network maintenance (PNM), which identifies and can be used to fix faults before customers are impacted.
- Develop operations tools that are inexpensive, reliable, understandable, and useful for proactive and reactive maintenance.
- Build intelligence to enable micro-financial decisions for preventive maintenance, technology replacement, resiliency, operations planning, etc.

3.1. Measure to Manage

Service and network reliability require well defined measures of performance that can enable management for effective results. This requires well understood service performance measures, network performance measures, and operations performance measures. When a customer experiences any service friction, that should be reflected in a key performance indicator. Aligning the measures to the customer experience is most important. It is not acceptable to answer a customer complaint with an “everything looks fine” because that suggests either you are blind to an important aspect of service, your measurements are insufficient, or your customer is wrong. The latter option is not a helpful assumption. The other two tell you improvement in your operations is needed. High levels of “no trouble found” point to the need for improvement as much as repeat trouble tickets do.

Doing all of this well requires knowledge of the failure modes, effects on networks and service, and criticality of the failure modes. A useful tool for capturing and referencing this knowledge is a failure modes, effects and criticality analysis (FMECA). Considering fault management in networks and complex systems, faults should be included with failures.

To obtain and maintain this knowledge, effective collection of components and failure modes is required. This enables analysts to determine useful corporate knowledge including what manufacturer or lot of components are not performing to specifications, what parts are wearing out, which failure modes must be addressed quickly to defend service, etc.

The most convenient example with direct application to our cable industry happens to be in this year’s Cable-Tec Expo. See [2] for this year’s Fall Technical Forum paper on applying FMECA to cable faults. Also see the Appendix of this paper for an example with explanation. This work is based on expert knowledge and is generalized for hybrid fiber/coax (HFC) networks.

But operator specific knowledge is necessary to support reliable services, so that problems specific to certain plant designs, aging or degradation, or even poorly performing components (hardware or software) can be found and addressed.

To use our cable industry’s strength of sharing knowledge and energy toward common goals, we could develop standard methods for coding repair tickets to capture failure mode and component details so

operators can fully benefit from this knowledge, and apply it to assure service. But the implementation and use of the result will still be operator specific.

The industry could also benefit by standardizing how service and network reliability are measured. Fortunately, we're well on our way in an effort through the CableLabs PNM Working Group, which is sharing the output with several SCTE Working Groups, too.

But the work is just beginning, and the industry can benefit much by continuing the effort further. We should work to specify standard ways for measuring service and network reliability including

- the measurement definitions,
- how they relate to service and network reliability,
- how to track statistics and interpret them, and
- how to set control limits, perhaps setting specification limits, too.

See the Appendix for a starting framework that could serve as the foundation. But it is only a start. As you will see in the rest of this paper, we need equivalent, supportive measurements from all aspects of network operations to fully support service reliability.

3.2. Setting Service Level Agreements

Based on existing service performance information, service level agreements (SLAs) for high end customers can be set with confidence, and even rebates can be offered at net profit. When new technology is involved, models of the resulting performance may be needed, and appropriate SLAs should be set based on the network providing the service. Fortunately, simple mathematical models are often sufficient for setting and designing services for SLAs.

SLAs should be based on customer use cases but translated to service and network measures of performance. Define the service missions and translate the measurements defined to the customer use cases. For example, consider the use case of watching a movie through video streaming, including pausing a few times, requiring several functions to work when needed for the duration; what is the resulting experience, and how does it vary by customer or network condition or resource utilization?

The SLAs must be set rationally, so that they are achievable, and demonstrable. Achievability can be validated through a model, and the model fed with field data when available. Demonstrability can be achieved through data collection and translation to the customer experience. The translation again can be achieved through a use case model. For example, the movie use case just mentioned requires high availability from the network and supporting systems, and reliable performance of the network and functions for the duration of the use. If the network availability is 99.99% (equally 0.9999), and the probability of successfully delivering the movie and needed functions for the two-hour duration is 0.99999, then the overall probability of success for that mission is approximately $0.9999 * 0.99999 = 0.99989$. If a user has this use case once a week, then the probability of not experiencing a failed attempt to watch a movie in a year is approximately $0.99989^{52} = 0.9943$; there is a good chance (0.0057) that quite a few customers (more than two in a thousand) will not be able to watch a movie at least once a year, even with these seemingly high reliability and availability targets!

3.3. Service Assurance

Low friction, high reliability service is delivered through reliable networks and systems supported by reliable, efficient operations. From a network perspective, reactive, proactive, and predictive maintenance all play a role, along with fault management.

- *Reactive*: Fast restoration first then repair, prioritized by severity of impact.
- *Proactive*: Timely repair, cost efficient, prioritized by severity and opportunity, afforded due to resiliency, with no restoration needed. Also, proactive maintenance can be thought of as fault management, as it is a mechanism to manage faults before they become failures that must be reactively addressed.
- *Predictive*: Planned maintenance to address degradation before service is impacted in any way. Predictive maintenance occurs before a fault impacts network or service performance, so it can happen ahead of proactive maintenance. For example, detecting a trend in early degradation of a particular component type can lead an operator to predictively replace those components based on useful life prediction. Prognostics and Health Management is an emerging field of research which addresses this need. But predictive maintenance can also follow from proactive maintenance, such as when additional damage is observed in the proactive repair, leading to further maintenance planning. Well planned maintenance can minimize operations costs.

Standard methods for coding repair tickets to capture failure mode and component details for service and network assurance, as mentioned previously, would help operators gain full benefit from that knowledge for superior service assurance.

Note that reliable operations can play a most important role when customer facing, because operations usually faces the customer in response to service friction. The first touch point for a customer when they experience friction is usually the call center; today that is supplemented with a software application. Behind these touch points resides all the network operations tools and back-office systems, all of which are a part of the service provided, and must reliably reduce friction for that customer. A poor experience is a failure in service, so must be addressed through rapid reactive repair. Likewise, service can be proactively and predictively repaired, too, through early detection of risk (security, privacy, fault, and failure), and continuous improvement of systems and processes.

See Figure 1 for a depiction of the various types of repair cycles which complement and assure effective operations. Note that predictive management of services includes planning and engineering, including information technology (IT), functions that engineer reliability into the solutions that deliver service, as well as predictive maintenance to replace failed systems well before they have a chance to degrade other parts or impact network functions, far ahead of impacting service. But if you wait or don't detect the problems that become faults and failures, then you can still stay ahead of service impact through proactive management, which includes fault management and PNM, plus other forms of proactivity. But if you wait further, service is impacted because the faults and failures are felt by the customer through their service experience. Reactive management requires fast, and often expensive, restoration and repair; but sometimes the repair is not as fast as everyone wants because other resources, processes and systems are reactively taxed. Spare parts supply chains may extend the restoration and repair time, as might technician availability. When service is impacted, severity should determine the restoration priorities, and repair to follow that. Note that, with proactive and predictive maintenance, restoration is not necessary. Reactive repair requires more work, higher stress, higher cost, and results in less customer happiness.

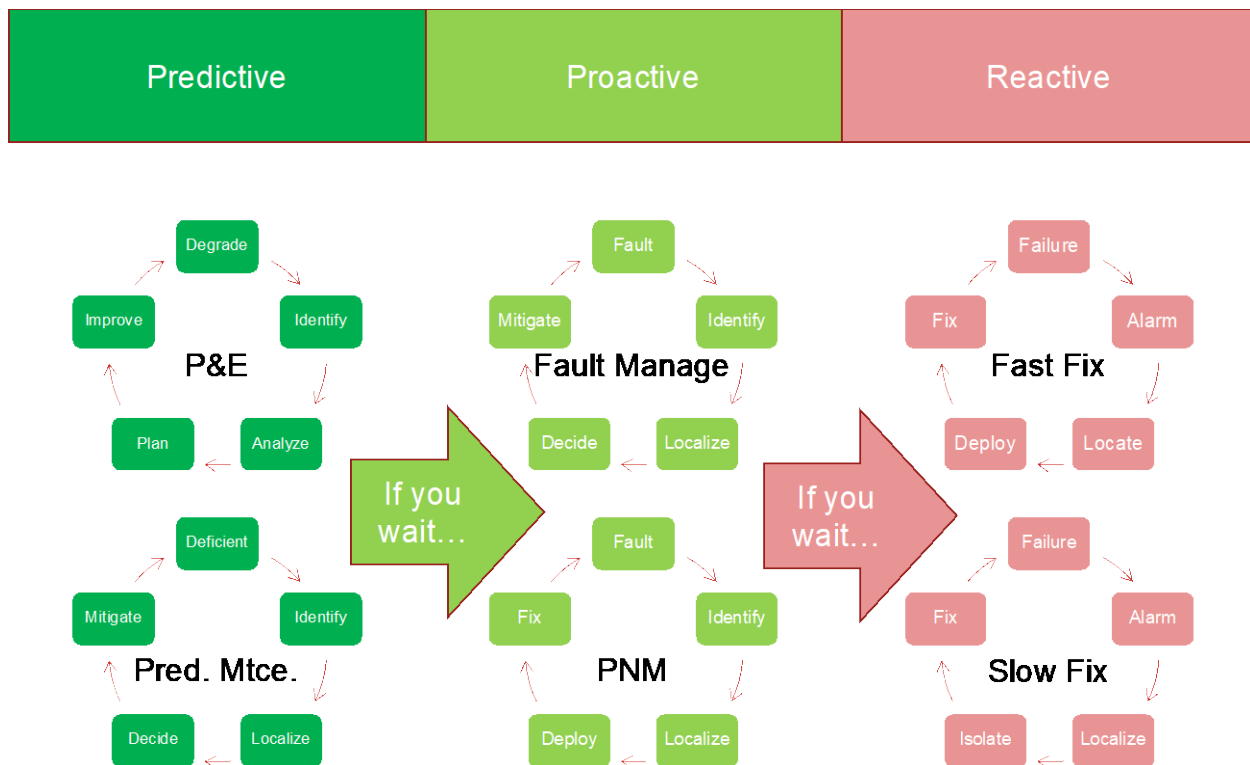

Figure 1 – Various types of repair cycles coexist in operations.

3.4. Fault Management

Knowing how a network can fail, the faults that lead to failures, and how those faults and failures are revealed in network performance can let an operator automate fault management and operate using PNM. Identifying the faults that impact service and where they come from is an important first step. How they relate to failures is important, too. An important goal in fault management is to automate as much of the fault identification, localization, and isolation as possible. And to do so reliably, which includes low false positive and very low false negative occurrences.

Based on event frequency, effect on service, and ability to test or monitor, set the policy based on established goals. Faults that are automatically mitigated can be ignored by repair technicians, but may need to be monitored by systems if they are indicators of other problems. Faults that require intervention can be handled with the appropriate repair cycle. Efficient fault management, like repair, requires an effective way to translate telemetry into action, such as the ProOps framework available from CableLabs [3], [4], [5] which provides a framework to observe (collect telemetry and information), orient (add context, assess the information, and potentially collect more information to assess), decide (translate information into faults and failures, then identify and localize faults and failures), and act (take appropriate action based on the assessment and information, with consideration of resources, priorities, schedules, etc.).

3.5. Repair and Supply Chain Optimization

With a strong handle on the priorities and planning for maintenance, operators can optimize their repair operations in many ways. Planning repairs on a longer schedule allows optimization of the travel time and distance required with maintenance, avoids unproductive technician time, and minimizes outage impact on service.

In addition, spare parts can be optimized to reduce held inventory and assure spare parts are on hand when and where needed to never adversely impact service, and never require expensive expedited shipping of parts. Critical parts necessary to correct critical failures should be readily available. Well-designed spare parts inventories can be created with lowest cost and appropriate spare parts availability. There are many applicable mathematical models available that can help operators set optimal inventory levels and policies for given targets of delivery time and probability of shortage.

3.6. Removing Degraded or Poor Quality Components

Technicians who deal with the plant all day know that some components wear out sooner than others, and some have specific faults in their design or manufacture that results in failure modes that emerge earlier or uniquely to these components. Sometimes environment has a strong influence on the early emergence of these failure modes. Temperature cycling, humidity, exposure to water, and even dry climates can impact network components differently. But even in controlled environments, poorly designed, selected, or built components can exhibit early failures which need to be addressed predictively. Early warnings from a few components can foretell the emergence of failures in the rest. As a result, tracking failure events by component type, manufacturer, age, location, and other factors can allow the operator to predict early issues and address them with predictive maintenance programs, instead of waiting for one-by-one replacement at failure. It is far cheaper to replace soon-to-fail components while doing other maintenance, to save on truck rolls and unproductive time. If such a program is required earlier than expected, a vendor management issue may need to follow, including perhaps warranty assisted replacement.

3.7. Vendor and Contract Management

Once an operator sets their goals for service, and can articulate how the network and its components translate to meeting those goals, they can align their contracts toward the goals, and even manage vendors to meet their contribution to the goals.

Component and system testing assures functionality, which reduces friction in the user experience. Testing for design and features is well established in our industry. Testing for basic features and functionality is a necessary foundation. Testing for capabilities necessary to provide specific services and features is important, too. Because long duration testing of hardware-software integrated systems is not feasible in most cases, it is important to test software well, life test hardware, and design-in system health monitoring and management capabilities for what can't be assured otherwise. Measuring early and useful life performance of components and system parts allows prediction of problems and validation of vendor performance.

3.8. Network Design

Networks should be built with performance goals in mind, and that performance should include reliability concerns as well. Doing this requires modeling of network behavior, including protection and restoration and resiliency mechanisms, for hardware, software, systems, and even people.

Network architecture will dictate allocations of service and network reliability to provide a given level of service, based on the measurements specified. How much friction-degradation and/or downtime can be allowed at, say, an optical backbone link as compared to the cable modem termination system (CMTS), cable modem (CM), or access network? Operators who are targeting service and network reliability will be collecting information and modeling to assure good decisions get made at the point of system and network design. This purposeful design enables management of network sections and knowing where to focus resources for network and service health.

Network operational cost-benefit modeling is an important component of this ability. Start with a framework for modeling the needed tradeoffs and making decisions around improvements.

This work can apply to operations design. Should a technician be sent to fix a proactive problem today, or should we wait a week in case there are more issues that can be solved with the same truck roll? If we are not sure whether a particular fault is caused by a failure mode in the home or in the yard, which technician type should be sent to keep costs lowest, and have the best chance of fixing the problem the first time?

This work can apply to decisions about the customer, too. For example, it may be worth modeling the impact of an uninterruptable power supply (UPS) in the home, or conduct a cost-benefit analysis of providing long term evolution (LTE) backup in the gateway.

But most obviously, architecture choice applies to the network decisions too. Should the operator consider media access control (MAC) manager redundancy architectures, or is a single hardware solution good enough if software and/or state are maintained redundantly? Should nodes be daisy chained in a particular deployment scenario, or is an optical ring truly necessary for the level of service we need to provide?

All these decisions need to be made with data and analysis considered, not just a gut feel, or a first-cost-driven approach. For some examples which come from our own world and are simple to use, see [6], [7].

3.9. Technology Tradeoffs and Lifecycle Management

Operators and vendors both need to benchmark the performance and reliability of existing deployed technology. This allows us all to set goals for future technology based on needed improvements or stability of reliability, availability, maintainability, survivability, and performance. Operators can model the comparison in deployed areas against the goals set by the company, and then enforce the component performance to assure goals are met as the new technology is deployed. Some high-level steps to follow:

- Benchmark existing technology
- Set goals for architectures as deployed
- Set goals and requirements for components
- Deploy and measure performance

Network components wear out. Replacing versus repairing is a decision that should consider costs, useful life, and impact to service.

At some point, an entire system or network may need to be replaced, because it has been used to the end of its useful life. This limit happens when the network or system can no longer meet its intended function in a reasonable way, or the requirements of the system or network have shifted so it can no longer meet

the current set of necessary use cases.³ See [8] for an appropriate model and treatment of the problem. Planning for wear out is important for budgeting, operations planning, supply chain management, and more.

4. History is Our Foundation

The cable access network community has given attention to reliability for decades, with considerable success. Aside from the various papers mentioned in the previous section, there are several other noteworthy works worth mention, study, and utilization.

In the late 1980s the cable industry began upgrading its networks from all-coax tree-and-branch to what is today known as HFC. Around the same time, the industry became interested in network reliability. Operators, equipment vendors, and others worked together to determine just how reliable cable networks really were and what it would take to improve their reliability. Of particular interest was whether cable networks could meet the old Bellcore “four nines” availability spec. More on that in a moment.

The topic of network reliability and availability is introduced in the context of cable networks in [10]. In chapter 20 of that book, the topics of benchmarking, definitions, calculations, redundancy, and network analysis are all discussed.

In 1992, CableLabs and several cable operators organized an Outage Reduction Task Force to “address the issues that stem from cable system outages.” The task force studied and reported on key topics relating to reliability in the cable industry [11]. CableLabs published “Outage Reduction” as a summary of the task force’s work, with chapters covering seven major topics in a large three-ring binder:

- Customer expectations, detection, and tracking
- Reliability modeling of cable TV systems
- Plant powering in cable TV systems
- Outside plant and headend protection
- Service restoration
- Cable TV system power supplies
- Power grid interconnection optimization

“Outage Reduction” was accompanied by a computer diskette with a Lotus 1-2-3 based reliability model. In addition to the published document and reliability model, CableLabs conducted half-day training workshops for member companies on the subject matter in the document’s first four chapters.⁴ Among the many recommendations in “Outage Reduction” was a critical threshold of no more than two outages in a three-month period (0.6 outages per month per subscriber) be a target for operators to achieve and maintain.

While the aforementioned guidance was considered suitable at the time for an entertainment model, any movement to telephony and data services required a higher performance threshold – hence the interest in the Bellcore four nines (99.99%) Standard Application Grade availability spec [12]. That parameter translates to no more than 53 minutes of outage time per year. Studies and analyses in the 1990s

³ Arguably, DOCSIS technology was born out of the need to meet the new set of use cases that the current network technology could not; but the network could be augmented to allow it to meet the new use cases, reusing coax.

⁴ The first four chapters of “Outage Reduction” were also published in the December 1992 through March 1993 issues of *Communications Technology* magazine.

confirmed that cable networks could meet four nines, assuming certain network architecture design criteria, device and component cascade limits, backup power and redundancy, and so forth.

While much has changed since the cable industry's earlier work in reliability and availability, some of the methods and knowledge collected form a useful foundation for today. Now that we are in a DOCSIS access network world, some of that work should be revisited.

Alberto Campos [13] in 2011 presented a paper that laid another foundation for evaluating the quality of experience (QoE). He tied performance metrics that impact QoE to the events that operators experience in the network, and the reliability of several of these features. He identified a large number of factors that contribute to the customer experience, and highlighted the importance of key elements by proposing a service availability metric. This proposed approach gathered in one place the many factors that influence service reliability and quality, plus it provided a convenient way to pull it all together into a single quantity for management. With some updating, a useful standard or operational practice could be created; with additional tailoring, operators can have a strong foundation of measurements to manage with.

Thankfully, SCTE has a new working group on Network and Service Reliability which should be the right place to tackle the new challenges, building on the foundations noted in this paper, and the papers and resources referenced by these works.

5. Conclusion

If you are an operator, you probably have been thinking while reading this paper that you already are doing all these things. You may have even participated in some of the noted foundational work. But there are at least two questions each of us should ask:

- Are we designing and executing these activities toward improved service and reliable networks and services? and
- Are we maintaining our reliability management and knowledge with changes to service, customer demand, technology changes, competition, and factors outside our control?

Operations survive by being cost focused. But that focus should be a long-term focus. And when it is, designing your operations and services toward appropriate reliability goals is your friend, and serves as the lenses for you to keep your eye on that long-term focus of managing cost as well as revenue and the drivers of both.

Once you can answer the two previous questions, you are ready to join us at SCTE's Network Operations Subcommittee Working Group 8 (NOS WG8): the Network and Service Reliability working group. See you there!

6. Acknowledgements

The authors wish to thank the numerous people who have contributed to the development of this work, especially including the hard working operator and vendor members participating in the FMECA work.

7. Appendix

7.1. Failure Modes, Effects, and Criticality

FMECA is a proven methodology for analyzing a system, process, or network for ways it can fail, determining the effects of failure, and assessing the criticality of each failure modes. The applications of this method are broad, but generally allow for appropriate design of technology to meet the requirements. An existing deployed solution is often a source of information when conducting an FMECA, either for augmenting the existing solution with improved operations, telemetry, fault management, etc.; or for designing the next generation solution for optimal performance.

A sub-team from the PNM Working Group at CableLabs has been working for many months on an FMECA that focuses on physical layer failures from the headend out to the customer, the access network. A sample of that is provided in Figure 2.

FMECA				Layer 1 - PNM first, make the layer cable later									
System	Subsystem	Component	Failure Mode	Sub-effect									
				Network Eff. Service Effect									
				Probability									
				Detection method									
Cable Access	Back office	ONT server PGP server TRIP server Config server Config files TRIP proxy											OS Spectrum Analysis

		Headend Combiner	Adjacent Channel Power Alignment incorrect filters, attenuators, etc. failed slope control - in line eq failed bad solder joints misconnected Cross talk - isolation										
		Headend Combiner - connector	bent mis-thread loose corroded crimp, poor fittings mechanical failure wrong type, model, poor fit poor EMC - poor connection quality weatherproofing failure or missing incorrect slope length										
		Headend Combiner - Amp	bent mis-thread loose corroded crimp, poor fittings mechanical failure wrong type, model, poor fit poor EMC - poor connection quality weatherproofing failure or missing										
		Optoelectronics											
		Local TV											
		Satellite	Source problem (satellite, uplink, programmer, etc.)										

Figure 2 – A sample of the draft FMECA currently being built.

In the figure, see hardline, connector, and part of the adapter failure modes; these components are part of the outside plant subsystem of the cable access system. Component and subsystem effects are described under the sub-effect heading, where we include several degradation causes and detectable impairment types. Under the heading of network effect, we indicate the effect each failure mode can have on the network from accelerating degradation, through signal impedance and capacity loss, to network separation. The service impact is indicated under service effect, and depicted in greater detail in Figure 3.

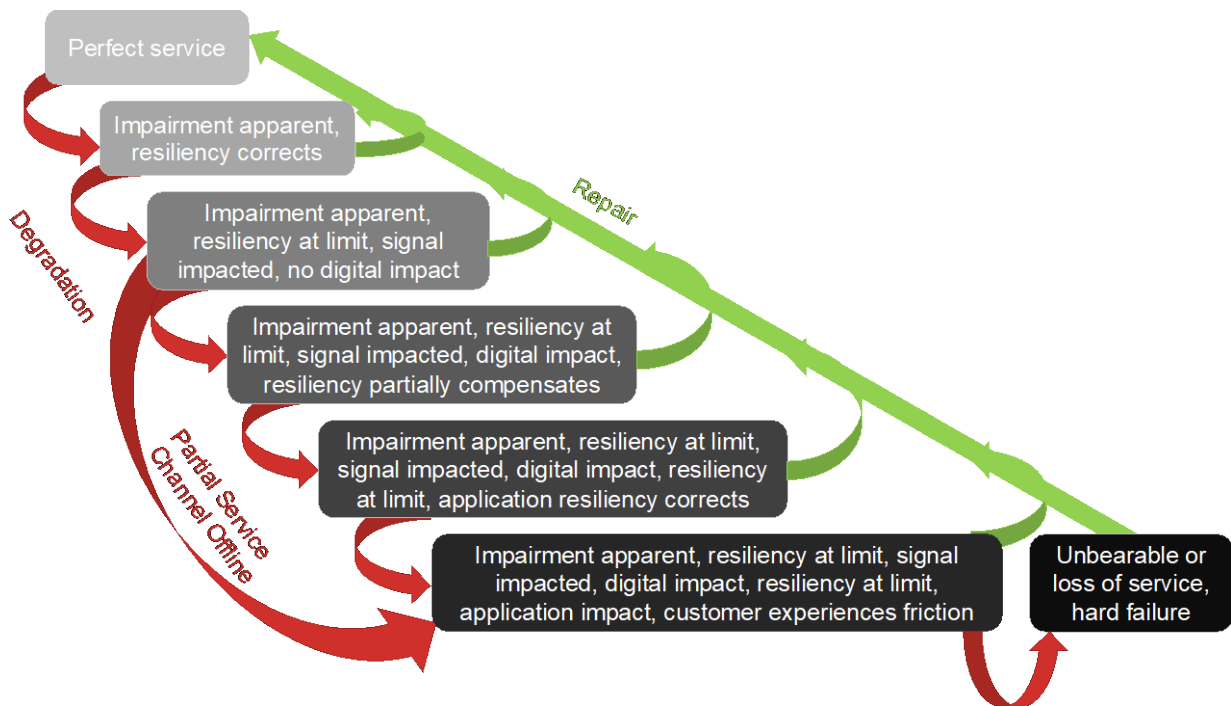

Figure 3 – A depiction of how network performance states relate, from perfect function to intolerable or failed service.

The FMECA here is focused on the physical network as it supports the mission of customer service. But some failure modes can be detected early, and some may accelerate degradation which eventually impacts service.

Because some of the failure modes can have no immediate effect on service, the FMECA documents some effects that impact the network and its components as well. PNM has identified and cataloged several signal impairments that when not too severe do not impact service, but can impact network RF bandwidth or at least foretell of future service issues.

As this work continues, we should be able to show how the repair actions relate to the failure modes, and thereby find new opportunities for improving fault management (identification, localization, and removal) in the access network.

7.2. Service Reliability

7.2.1. Reliability of a service is availability

Reliability is the probability that a system or component is working at a future time when needed. Replace component or system with product, and the intent is close but not accurate.

A service can experience downtime or degradation, but is repairable. Reliability is a non-increasing function which does not describe a repairable thing like a service. What we really want to consider then is availability, which is the probability of a service being in a functional state at some future time. And usually that future time is not defined, so we usually mean a long-term steady state of the system.

Put another way, managing service reliability requires an availability measure of the service.

7.2.2. Reliability of a service is really performance

But a service is a complicated mix of use cases and capabilities, any one or more of which could be available at different times. The service is not a single thing necessarily, and depending on how a customer wants to use it, may or may not work as intended. And if not as intended, is there value in it working in an alternate way or a degraded way? Think in terms of an email that does not go through right away, or a streaming video that takes a few seconds to buffer; does the customer notice or care, or not?

To address this issue, the concept of performability was developed many decades ago. It is a functional convolution of the performance probability distribution function with the value achieved at each performance level possible. While complicated, it does deliver a single measure of performance.

Put another way, service availability actually needs to be a performance measure of the service that includes each possible degraded performance level including complete failure, and the utility that a customer gets from the given performance level. Network reliability and performance both contribute to service availability, but they do not represent it.

7.2.3. Customers are a mystery

Note, however, that each customer is different, and the impact to their perception of performance levels varies by their situation, tolerance, emotions, and the value they put on aspects of the service. A CEO trying to close an important deal might value video conferencing much more than a student doing homework. Further, tolerance for a degraded condition might depend on the person's tolerance to previous outages, expectations of the overall quality of service, and other factors.

Put another way, the impact of service performance on individuals is highly variable and complex. The utility they get, and their overall tolerance of the experience being poor, are not easy to quantify. All an operator can do is provide the best level of service they can for the use cases known, at the price point customers are willing to pay for it.

7.2.4. Service performance

Because simple is an important goal when developing measurement systems, and recognizing that all services are a three-legged stool of cost, performance, and reliability, with cost being understood by the customer, our measure should be centered around performance and reliability, which as just described is really the aspects of performance that are delivered in each available state.

In other words, we can quantify the probability of the service delivering given levels of performance, which is what we can manage. We can seek to understand the customer, what they care about, what they are willing to pay for, and how they see competitive options. But first we must measure what we are providing in terms of service: the performance of that service as a probability space, not just an average, not an average and standard deviation, but as a probability function.

7.2.5. Measuring service performance

The task here is to identify the features of a service that describe the utility of the service to a customer. If latency is not important to, say, a webpage load, then latency measures are less important. But if the service is also being used for video conferences or video games, then latency matters, and a solid latency measurement is important to service reliability.

Examining the use cases and types of service we offer in our industry, a few basic performance measures are obvious.

1. *Goodput* – bits per second, throughput of the useful service-delivering bits on the network, assuming digital data delivery (not analog video, for example).
2. *Latency* – how long it takes to deliver each bit of data.
3. *Jitter* – packet delay variation, or how stable is the latency, and to a certain extent the goodput of the service.
4. *Packet Loss* – data that does not reach its destination.
5. *Availability State* – what is the state of performance of the service in terms of its capability?

Note that, at a packet or bit level, packet loss may be a considered measurement for either availability or as a factor for goodput or latency.

While necessary for measuring service reliability, these measures are not sufficiently described yet, and are not the end of the task for providing service.

Each performance measure statistic must be based on sufficiently detailed measurements to assure sufficient resolution of the differences in service performance levels, and measure all aspects of the performance measure. For example, measuring performance once a day at the same time every day is neither sufficient resolution nor unbiased. Measuring from the CM to the node is not an end-to-end measurement so does not represent the service experience. For understanding service reliability in sufficient depth, service providers have to design the measurement system thoughtfully, to meet their goals of continuous improvement and maintain a focus on service assurance.

But also knowing there is a problem is only the beginning; it takes more information to know the cause, locate it, and remove it from impacting service. That is the work of network operations, or network reliability, which is a key part of service assurance.

7.3. A proposed measurement framework for cable

Each service should have requirements in terms of required goodput, latency, jitter, packet loss for performance, and availability, if at all possible. Lacking a complete set of requirements, it is still incumbent on the provider to measure the service delivered. This section proposes a service availability measure based on telemetry that can be collected from the cable network.

Many of the measurements suggested here are a part of the proposed FCC 22.7, which was announced in late January of 2022. That proposal makes addressing this issue an urgent one, but also supports much of what is addressed in this document, the first draft of which formed in late 2021, with this version acknowledging what is known about the FCC proposal.

First, we need to consider several aspects of the service from a measurement feature point of view. Then we can treat each measurement in that framework.

7.3.1. Features

Several features of service reliability measurements were suggested earlier.

- Use of the measures – Depending on the various uses of the measure, the remaining features must be sufficient to address all needs.
- Bias in the measures – Because service usage varies by time of day, day of week, etc., any point measurement must be taken over a sufficiently large amount of time, with sufficient frequency, and of a sufficient sample size of the traffic to be measured.
- Resolution of the measures – The frequency of sampling must be sufficient to provide proper resolution. For example, an estimate of availability found by sampling daily will not provide good resolution for a highly available service for quite some time.
- Service level – The applications should provide the estimates when and where possible. But that is not always possible. So, service specific measures of performance at the end devices are close and sufficient for many uses. And because the operators do not manage the applications in many cases, but only the service classes as defined in DOCSIS, we should rely on these service classes first, and augment with application specific measurements when possible.
- Actual or surrogate – In some cases, we use special measurement packets to estimate actual service performance. But this method is known to be highly inaccurate and relies on a translation model that is not ideal. It is best to avoid this approach, and favor measurements on the actual traffic.

Each of these features need to be applied to each measurement. The measurements in the set are complimentary, so a complete set is needed.

7.3.2. Goodput

Throughput in terms of end user useful data is goodput. If a goodput measurement is not possible, then a throughput measurement by service type is a useful approximation because goodput can be estimated from this throughput by modeling for overhead.

When the data rate needed exceeds the capacity of the link, interface, or other component, packet queueing and congestion happen, unless discard is the only option. When the purchased data rate is not supported in the grants given by the CMTS to the CM, then applications experience latency. These understandings lead to secondary measurements for throughput.

In many cases, this measurement is used to guard against network congestion. In the access network, a simple network utilization may be sufficient. But when considering that there are customers who may be impacted by impairments and low signal-to-noise ratio (SNR), or high performing customers who also are high bandwidth users, individual CM-level throughput is important to estimate.

Recommendation: One measurement of network utilization, one measurement of bandwidth requests made and granted requests by CM, and one measurement of utilization by profile by CM. All separate for upstream and downstream.

7.3.3. Latency

DOCSIS has defined a latency measurement to support low latency DOCSIS (LLD). This measurement is taken at the CM supporting DOCSIS measurement, which is a subset of the actual experience, but a useful one nonetheless. Using this measurement for all service traffic is an excellent starting point.

Recommendation: Use the LLD latency measurement already defined for DOCSIS, and apply it to all service classes. Report by CM and service class. Augment with application-level sampling of packet delay when possible.

7.3.4. Jitter

Jitter, or packet delay variation, is the variation in the arrival of data. Some applications handle this factor through buffering, but not all applications can be made insensitive to jitter. A measurement of jitter for service types sensitive to it would be important to define. Jitter is strictly defined already, but there are alternatives that we could develop that would meet the needs for our industry.

The time between the arrival of packets would provide useful data for estimating a jitter-like measurement. A mechanism that provides the packet delay variation directly is useful if it is well defined, testable, and validate-able.

Recommendation: Use packet-level jitter measurements already defined in specifications. Augment with application-level sampling when possible.

7.3.5. Packet Loss

While packet loss is not permanent in reliable transmission protocols, thus would be reflected in terms of latency and jitter and goodput at the application layers, it is included here as it is a proposed measure in FCC 22.7.

Applications that rely on unreliable transmission protocols will not experience packet retransmission, so packet loss is an important problem and should be measured.

Applications that are latency-impacted may discard packets that are late, resulting in the same impact as packet loss. Therefore, some application consideration is important for packet loss measurement.

Forward error correction (FEC) statistics are included in DOCSIS and would be an important supportive measurement to include here, and for a DOCSIS reporting point of view would surely be more than sufficient as a measurement which can generate appropriate statistics.

However, we may need to report FEC statistics by service class or application to provide a useful measure of service reliability-availability.

Recommendation: Rely first on FEC statistics, particularly uncorrectable codeword errors. Each of these represents lost packets or data which require either application layer or protocol layer retransmission or re-requests. For reliable protocols, measure discarded packets and retransmissions. For unreliable protocols, measure lost packets. Augment with application-level sampling of packet loss when possible.

7.3.6. Availability

The overall availability of the network is an obvious, important component of service reliability. Network availability should consider cases where the user wants to use the service, but it is not available. Estimates can be obtained through polling logs from the CM, or polling state from the CMTS, or through ping-response approaches, or likely a combination.

Timeout statistics would be a useful contributor here, but there are known issues with timeouts being inaccurate as estimates of availability due to various contributing factors. However, it may serve as a

surrogate measure that could be translated into an availability estimate through a translation model, or as a contributor toward an estimate that incorporates logs and other traffic data.

Recommendation: Provide timeout statistics, augmented with logs from the CMTS and CM to estimate network availability. More detailed assessment is needed to develop the models here. Augment with application-level or device specific sampling when possible.

Overall recommendation: Measure or estimate the service experience; when insufficient, drill down toward the cause, and address the fault.

Abbreviations

CEO	chief executive officer

1. Abstract

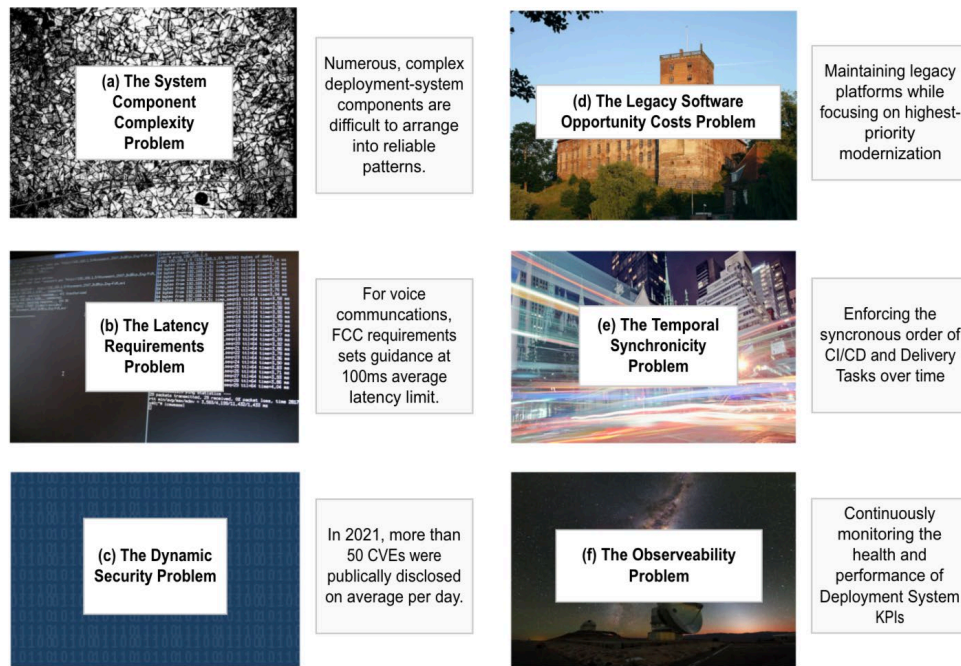

The telecom industry has moved toward a hybrid of cloud-native and virtualization technologies without a single, unified deployment approach for a variety of DevOps needs. While containerization and virtualization have both been used to solve a wide set of technical challenges in our industry, it is estimated that at least 30% of workloads worldwide still leverage virtualization technologies such as OpenStack [1]. For instance, while containerization might be advantageous for certain Layer 7 Workloads, it may be non-performant for Session Initiation Protocol (SIP) and Real-time Transport Protocol (RTP) processing needs. This trend will continue due to long-term investments to sustain both current operations and embrace more modernized ways of operating with new types of applications and infrastructure. This difference in needs across telecom organizations has led to the use of a diverse and complicated set of continuous integration and continuous delivery/deployment (CI/CD) tools and infrastructure arrangements. Unfortunately, the tendency of increasing technical-tool diversity is reflected by an increased division of organizations by technical expertise, which in turn can often-times prevent widespread adoption of modern CI/CD technologies among these organizations [2].

In this paper, we propose an approach and a framework to expand GitOps-based deployment orchestration automation into the virtualization stack, by leveraging customized Kubernetes Operators, ArgoCD, and Argo Workflows, Open Container Initiative (OCI) Containers, and Packer [3-7]. We demonstrate the feasibility and practicality of this approach on OpenStack with the help of an open source, full-stack voice over internet protocol (VoIP) implementation and Traefik HTTP Load Balancer [8]. The combination of these technologies enables several advanced deployment capabilities for OpenStack such as canary deployments and scaled rollouts. This solution has the potential to converge our industry toward a unified and modern CI/CD approach for DevOps teams and smoothen the transition towards cloud-native platforms, while helping to prevent the disorganized “tool-sprawl” [9] required to sustain both legacy and modern tech-stacks.

2. Introduction

While open-source software is “eating the world” [10] by increasing the capability of technology organizations to improve their product-competitiveness, some estimates put the proportion of costs attributed to software maintenance and sustainment at a whopping 60% of overall software project expenditures [11]. From the first monolithic inventions of a burgeoning telecommunication industry to today’s highly digital approach to scaling by means of distributed services, the burden of managing increasing levels of complexity as a result of fast-changing technologies and needs continues to be a significant cost-driver for telecom organizations [12].

DevOps professionals across our industry continue to struggle with a diverse set of organizational and technical challenges in sustaining existing operations while also looking toward future development platforms. This constant struggle to balance the two priorities can cause organizations to lose track of the core issues that are initially involved in software delivery lifecycles (SDLCs) and to get distracted by day-to-day problems. Thus, we have found that it is helpful to reframe the causes of this phenomena as a narrow set of key challenges facing modern DevOps teams:

[13]-[21]

Figure 1 - Six Key Challenges Facing Software/Systems Delivery Teams

These kinds of challenges have been denoted by organizational academics as “technical strategic bottlenecks”, which drive increased reliance on a particular cross-section of expertise within a company to solve [22]. While these bottlenecks can often be viewed as both opportunities and challenges within organizations, there are certain problems that are inherently more difficult to solve than others, such as Fig. 1(a) and Fig. 1(d). A common tactic in mitigating these issues for deployment teams is to outsource these problems into separate systems, tools, and SMEs within an organization – all of which take a non-trivial amount of productive engineering time [23]. It is thus our view that the goal of every DevOps team should ideally be to manage the widest possible problem-set with the least and simplest possible tools.

Unfortunately, some analysts estimate that software-delivery teams interact with somewhere between 20-50 different tools daily [24], which often causes the all-too-familiar “too many tabs” issue for everyday engineers. The brain-drain of having to organize individuals or teams to manage this deployment tooling complexity can cost organizations a significant amount of focus in order to silo teams by expertise and can further hamper innovation due to lack of shared understanding of deployment platforms [25].

Multiple deployment platform availability can be a blessing in disguise -- Surveys of IT leaders demonstrate that organizations tend to shy away from using multiple deployment systems due to increased costs related to learning curves and lack of expertise. As of 2020, the percentage of organizations leveraging multi-cloud technologies was nearly half of those that chose to stick with on-premises solutions [26]. Even from a CI/CD software standpoint, most workloads as of 2020 run on older, more proven tools such as Jenkins [27] and TravisCI [28], with a minority of organizations choosing newer and more powerful open-source technologies [29].

As a strategic approach to the challenge of multi-platform management and the key challenges listed in Fig. 1, this technical paper proposes a proof-of-concept system built upon OpenStack and a Kubernetes

Administrative Cluster (KADC). The central goal of our approach is to share a helpful set of solutions with engineering teams in our industry that are tasked with ubiquitously deploying, testing, and validating changes across disparate, complex systems.

Using common industry use-cases, we demonstrate both web-scale workload and VoIP workload deployments on the OpenStack platform using Git as a declarative information store. We also leverage custom Kubernetes Operators as service abstractions of core and auxiliary deployment logic. By providing a framework for how engineers might abstract deployment details in two key telecom use-cases, we demonstrate a possible solution for managing both legacy and newer forms of workloads using a single set of tools.

Such a solution is even more important today considering the tremendous amount of investment going toward infrastructure management in the telecom industry in tandem with decreased margins of traditional telecom products [30]. In response to increased technological innovation from both entrenched and burgeoning competitors, process automation is being touted as the top factor of cost effectiveness in our industry because it drives increased organizational agility and responsiveness to telecommunication customer needs [31]. With our proposed approach, we hope that we may help engineering teams deploy software more quickly and reliably, which will in turn contribute to increased resource efficiency and increased value within our larger industry.

3. A High-Level Deployment Architecture for Multiple Infrastructure Platforms

While there are many CI/CD methodologies in the open-source community that could accomplish the goals we have outlined in our introduction, the option we chose is the GitOps methodology [32]. As a self-contained approach to infrastructure management, the GitOps methodology seeks to provide high observability and re-useability of deployed state. The key initial considerations for choosing this approach were its simplicity, popularity among the industry, and ability to tie into many different deployment platforms.

3.1. GitOps Architecture

GitOps is an opinionated deployment framework with numerous valid setups used throughout our industry, however there are a few key attributes that most GitOps implementations have in common. These attributes are more clearly defined than a traditional DevOps setup that can result in a wide variety of unintended side effects and outcomes for operations teams:

Table 1 - Traditional DevOps vs GitOps Key Attributes

Deployment Question	Traditional DevOps Setup	GitOps Setup
Where is Deployment State Stored?	State is stored in databases and procedural deployment scripts.	State is implemented and stored in a declarative fashion in Git.
How is Deployment State Stored?	State may or may not be stored with its version history depending on the implementation.	State is stored in a way that supports immutable versioning and retains a complete history of changes.
How Often do Deployment State Processes Trigger?	A variety of custom-created, procedural deployment systems are typically leveraged only once to perform deployment process updates.	Software agents continuously compare a system's actual state to its desired state in order to enforce eventual consistency.
Who interacts with the Deployment State?	DevOps Engineers will typically be the primary Operators of a deployment system due to its complexity.	Developers and Code Reviewers interact with a Git interface (the "Git" in GitOps) through pull requests as a security measure to approve and commit final deployment state.

Based on our analysis, the benefits of using GitOps as opposed to traditional DevOps methods are threefold:

1. *Unification of Deployment State into a Single Location*

Compared to many of the attributes of a traditional DevOps scheme, GitOps provides a much more streamlined and unified store of application and infrastructure state. The benefits of using the Git platform as opposed to others for this purpose is perhaps the most impactful reason why the methodology is becoming increasingly popular today, with an estimated 84% of developers considering themselves as active contributors to open-source tools [33] and 92% preferring Git as their primary source control software [34]. As a single data-store of infrastructure state, the open-source Git platform also serves the principal goal in this paper of reducing excessive DevOps tooling management.

2. *Declarative Deployment State*

In addition to its unifying characteristics, GitOps also aids with separating minor, unimportant procedural details from state using the framework's declarative design. In contrast with traditional DevOps methods, specifying a group of declarative file manifests as state aids software engineers in organizing their deployments more effectively into logical units, and helps in increasing observability of what is currently deployed across different parts of their organizations.

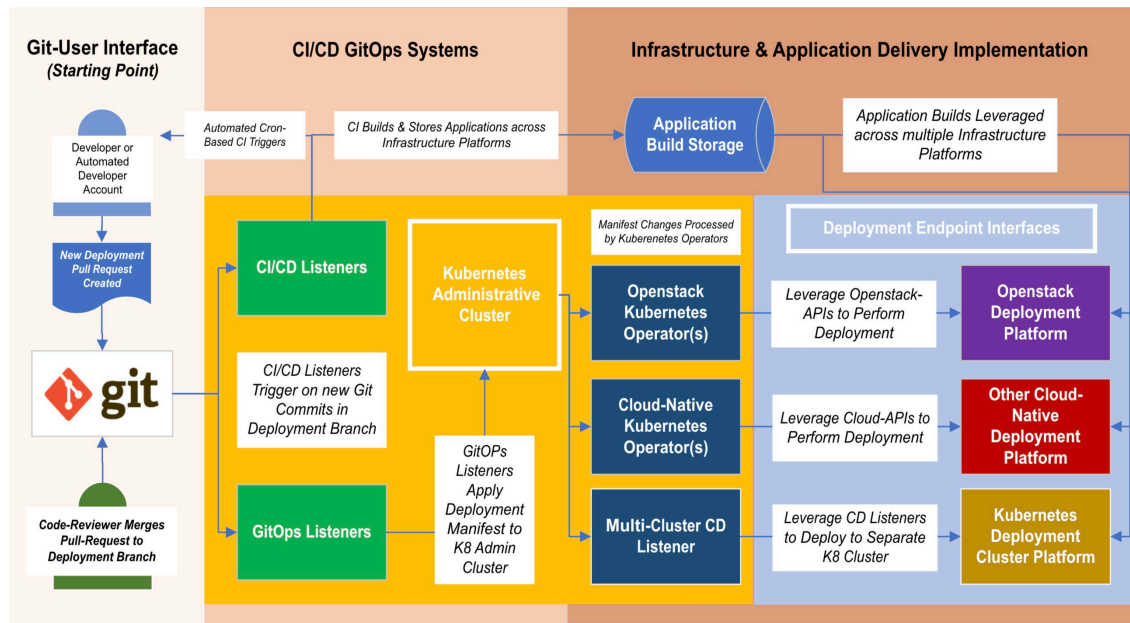

3. *Secure Deployment State*

From a security standpoint, most Git repository providers enable enterprise-grade functionality to log into repositories, pull down commits, and push new pull requests – just to name a few of the potential scenarios. In our case, by requiring pull-requests for changes to both infrastructure and application manifests, approvers can institute a code-review process that enforces certain requirements to deploy to different platforms or environments.

These three benefits serve to help mitigate many of the problems outlined in the introductory section's Fig. 1:

- (a) **System Component Complexity Problem:**
 - GitOps assists with reducing the number of components that store state in a deployment system.
- (c) **The Dynamic Security Problem:**
 - GitOps enables DevSecOps [35] via transparent declarative handling of secrets used in deployments.
- (e) **The Temporal Synchronicity Problem:**
 - GitOps can be used to aid in enforcing order of operations in deployments due to the time-based nature of Git and specifically because timestamps are associated with Git commits.
- (f) **The Observability Problem:**
 - GitOps enables high observability of deployment state in a Git repository using the Git CLI and related tooling.

3.2. Multi-Platform Deployments with CI/CD and GitOps

[36]

Figure 2 - CI/CD GitOps Multi-Platform Deployment Architecture

Combined with the popular Kubernetes Platform, GitOps provides consistent and highly observable deployment arrangements. In our proposed architecture, we introduce the unifying concept of the KADC, which is our continuous deployment orchestrator that leverages the following key components:

Git-based User Interface

The Git Interface serves as the deployment data-store that controls who has access to various repositories. Some examples of Git interfaces include on premise, cloud-hosted, and self-hosted systems. In our proposed Git interface, we envision the best-practice of developers using pull requests to commit infrastructure and application deployment changes after careful review from a group of authorized reviewers.

Continuous Integration/Continuous Delivery

The CI/CD Listeners' two responsibilities are to process application-builds within a storage context and to commit back to Git for cronjob-based automated deployment changes. For application builds, a CI/CD listener triggers build scripts upon commits to specific Git repositories. The build process may trigger testing and validation steps to verify that it is ready for deployment. Once ready, the listener pushes those built containers or images to an application build storage location.

Continuous Deployment using GitOps

GitOps Listeners enable continuous, asynchronous changes to infrastructure within targeted deployment environments based on Git repository commits. Engineers can program these systems to listen for certain changes and take automated actions. In our case, we designed the GitOps listeners system to deploy manifests (can be either YAML or JSON) into the KADC for further processing. If the manifests are Kubernetes native resources, they will be deployed directly in the target Kubernetes cluster; otherwise, these manifests describe resources deployed to non-Kubernetes platforms such as OpenStack or public clouds, and in this case KADC is used as a proxy.

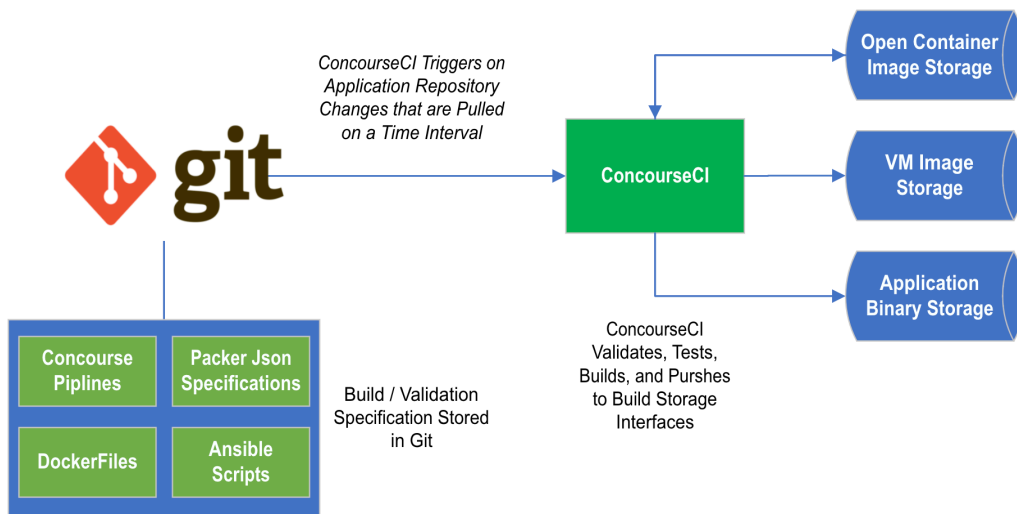

Application Delivery Implementation

The Infrastructure and Application Delivery Implementation contains the core logic to deploy manifests to various environments. This functionality is implemented with custom Kubernetes Operators in the case of OpenStack or public cloud deployments, and the built-in standard Operators in the case of Kubernetes. Depending on the *type* of manifest provided, either Kubernetes standard Operators or custom third-party Operators will handle the submitted manifest.

In all cases, Kubernetes resources hide the complexity of custom deployment logic with more simplified, declarative manifests that are easier to read than traditional procedural scripts.

4. CI/CD Listeners Implementation

While there are numerous options available that enable multi-platform CI/CD, ConcourseCI [37] and Tekton [38] were chosen for evaluation due to their maturity in the open-source ecosystem. In our implementation, we have narrowed down our scope to a ConcourseCI instance. We installed an on-premises instance of ConcourseCI inside our KADC, and also leveraged a shared instance installed on AWS. This setup acted as the “CI/CD Listener” noted in Fig. 2, and it accomplishes a variety of common application build, validation and integration tasks. The purpose of using this Kubernetes native tool is to further unify deployment state on top of a single platform. By implementing three key application-build types, as well as their corresponding testing and validation steps, we were able to integrate software build processes across the platforms listed in Fig. 2. (Kubernetes, OpenStack, and Cloud-Native) using industry-standard tooling:

[36]

Figure 3 - CI/CD for Multiple Platform Types

1. Open Container Image (OCI) Storage
 - Utilizes Dockerfiles [39] to create/push OCI container images
2. VM Image Storage
 - Utilizes Packer and Ansible Scripts [40] to create/push OpenStack VM images
3. Application Binary Storage
 - Storage of Application-Specific binaries (i.e. “.jar” file for Java [41], “.lib” for Golang [38]) that can be used by either a container or an virtual machine

Behind the scenes, ConcourseCI pushes the built container images into the OCI storage and pulls the necessary images from this storage to run each step of its pipeline. Therefore, there is a bidirectional link between ConcourseCI and Open Container Image Storage.

5. GitOps Listeners Implementation

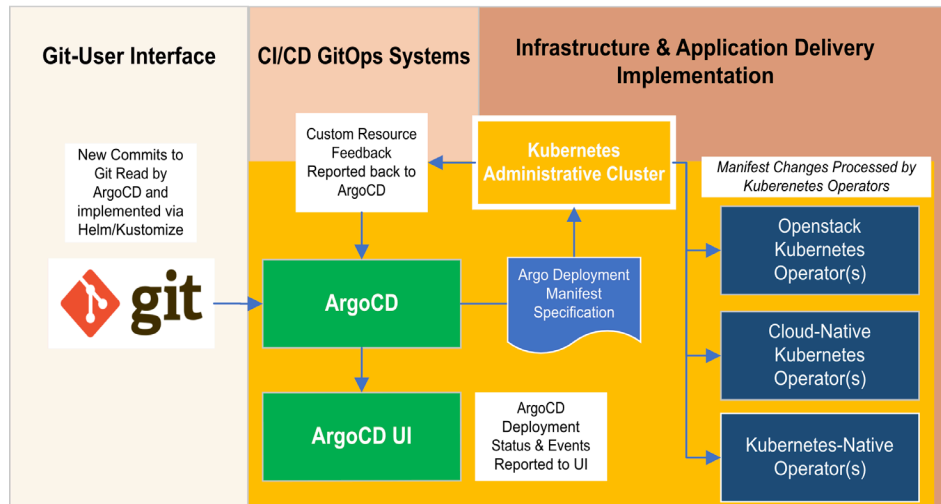

For the GitOps functionality abstractly mentioned in Fig. 2, two key opens-source DevOps components were chosen: *Argo Workflows* [5] and *ArgoCD* [4].

Argo Workflows accomplishes the orchestration of a full stack deployment in which there can be dependencies between stack components. For instance, the passing of information from one stack component to the other so the latter can be configured properly is one example of this dependency. This tool is also ideal for scheduled and repeatable deployment tasks that would otherwise burden teams with manual steps, such as scheduling the scaling up of the stack in anticipation of peak hour traffic or scaling down in the inverse case.

In comparison, ArgoCD was specifically chosen to perform the deployment of a single stack component for continuous deployment integrations. Dependencies between deployment steps are handled in this case by Kubernetes Operators that implement custom logic in a manner that is more complex than is practical to implement in Argo Workflows.

The settings for both software packages are stored and controlled by the KADC, and this design furthers our overarching goal of deployment platform unification.

5.1. ArgoCD Implementation

[36]

Figure 4 - ArgoCD High-Observability Architecture

ArgoCD Deployment Manifest Resource

An ArgoCD Application is a Kubernetes Custom Resource (CR) that reacts to changes within a specific Git repository. Within an ArgoCD Application CR, the most important attributes are: 1) the Kustomize/Helm directory to listen on, 2) the number of times to retry a CR change before declaring failure, 3) whether to auto sync changes, and 4) which deployment customization approach to use.

Kustomize [42] and Helm [43] are the two most popular open-source deployment customization approaches to use within ArgoCD at the time of this writing. While Helm is a templating solution for Kubernetes that allows for major deployment details to be highly-reusable, Kustomize is more of a patching solution that allows you to replace specific fields without a template on a more case-by-case basis.

The two CRs status fields for an ArgoCD Application are the sync and health attributes. Because an ArgoCD Application refers to a Git repository for either a Helm or Kustomize deployment, its health and sync status are “all or nothing”, meaning that for the Application to be considered fully deployed and healthy, all resources need to be successfully deployed *and* fully up to date with latest Git commit events. This information is propagated from the KADC into ArgoCD components for observability purposes.

ArgoCD UI

ArgoCD UI is the main user interface typically used to interact with for DevOps continuous delivery tasks. This interface provides a single place for both developers and DevOps engineers to view the status of their deployments of Kubernetes CRs.

The ArgoCD UI displays three key pieces of information that are useful to the end-user:

1. The health and status of each component of an ArgoCD Application
2. Kubernetes “Info” and “Warning” events associated with each component of an ArgoCD Application
3. The health & status of the overall ArgoCD Application

ArgoCD Health Checks

ArgoCD Health Checks are either Kubernetes-native (supported by ArgoCD “out of the box”), or custom-made with Lua [44] scripts for non-Kubernetes-native resources. For instance, we create several custom health checks for resources managed by our proposed OpenStack Operator.

ArgoCD Kubernetes Event Reporting

Kubernetes events are propagated to the ArgoCD UI for each CR deployed within a single ArgoCD Application. These events are published by a Kubernetes Operator and are meant to help users troubleshoot deployment issues and give more visibility into error details logged by KADC Operators.

5.2. Argo Workflows Implementation

Argo Workflows is an open-source container-native workflow engine for orchestrating tasks on Kubernetes. It is implemented as a set of Kubernetes custom resource definitions (CRDs) and its own custom Operator. The core primitive of Argo Workflows is the workflow resource, wherein each task of the workflow is implemented by a container, and the workflow itself contains a sequence of tasks with dependencies between tasks captured in a directed acyclic graph (DAG).

Argo Workflows was initially designed to run compute intensive jobs for machine learning or data processing but has been adopted to orchestrate continuous delivery tasks as well. In our proposed GitOps architecture, a workflow will be used to capture the steps required to deploy a stack of applications using a DAG. Each step of the DAG can have one or multiple success conditions that make sure this step is only considered as complete when its resources have been fully deployed and readily available. Each step is also typically responsible for the deployment of one component of the full stack, or a subcomponent of a complex component in the full stack.

Each workflow is captured as a Workflow CR in YAML format and can either be deployed to the KADC using an ArgoCD Application or directly into the KADC using a Kubernetes interface. The first approach is more appropriate when the component manifest requires much more information than is made available during deployment time. The second approach is more appropriate when the component manifest is relatively static and does not change often over time.

6. Custom Kubernetes Operators

KADC Custom Operators provide computational and logical separation of concerns for deployment to various platforms. These Operators come in the form of third-party software, and in the case of this paper, a set of custom Kubernetes Operators we developed that integrate with OpenStack. The “Operator design pattern” as described by the CNCF Whitepaper, splits functionality of CRs into controllers, which continuously reconcile changes from requested state to desired state in order to accomplish a deployment:

Figure 5 - Custom Operator Reconciliation Components

Operators can contain one or more controllers, which in turn typically manage one CR per controller. The controller is a code-bound component of a Kubernetes Operator and can be written in various languages that are compatible with the Kubernetes runtime. In our case, we chose the open source OperatorSDK Framework [45] and Golang Language [46], although any Kubernetes-compliant Operator implementation will work as well.

The fundamental primitive of a controller is the control loop, which reacts to state-change events until either the desired state is achieved (“reconcile” in Fig 3.) for a particular CR, or until it reaches a final error state. As the runtime-manager of CRs, the control-loop within a controller act as a time-bound polled reconciler of changes. It can also publish events that give a DevOps engineer further information about deployment checkpoint status or error details:

Custom Resource Definition Specification (CRD)

A custom resource is a conceptual representation of an object within Kubernetes. Included in a CRD specification are the structure of the object, the variables within the structure, and the datatype of each variable. Thus, this CRD primitive is highly configurable, and much like object-oriented programming, demands its own design considerations when developing custom controllers to manage them.

Event Types

Within a Kubernetes controller, there are three major events that are reconciled for the current state: 1) Create; 2) Update; and 3) Delete. The controller must have logic that handles each of these cases in a graceful manner for both happy-path and error-path situations so that it is reliable and feature-complete.

Current State

The current state is the latest requested state committed into the KADC. For instance, when the current state is updated, an update event is sent to the Kubernetes Operator along with the next state to be reconciled.

There are two forms of state that can change in a CR: 1) The specification field, and 2) the status field. The change of one of these fields will trigger the *Reconcile Loop*.

Reconcile Loop

The reconcile loop is a function that processes events in order to converge these events toward a desired state. Within a reconcile function, there are three possible outcomes:

1. Successfully process state event and don't requeue
2. Requeue the event to be processed again later in time due to an error scenario
3. Stop requeuing due to error scenario (with exponential backoff being an option for repeated errors)

With these three options, programmers can code controllers to be resilient to faults that may occur in the event of network issues or one-time errors, while also handling repeated errors gracefully with an exponential backoff option.

Operator services are hosted within the Kubernetes runtime as Deployments, Replica Sets, and Pods, and are easily configurable with the settings of these common Kubernetes resources. The main idea of hosting these Operators within the KADC runtime is to utilize high availability (HA) deployment capabilities inherent within the Kubernetes control plane that contributes to increased reliability of deployments.

7. Openstack Deployment Orchestration Architecture

OpenStack is a complex virtualization platform with many possible arrangements and use-cases. For deploying different kinds of workloads – namely VoIP and Web-Scale, it is important to first decide which API integration we wanted our Kubernetes Operators to interact with within the OpenStack Ecosystem. We could then decide how Operators should interface with this integration.

Upon careful exploration of available options, we decided to integrate with the popular Heat Orchestration Template (HOT or HEAT) APIs [47] because they leverage declarative resource templates that are more easily compatible with our chosen GitOps approach:

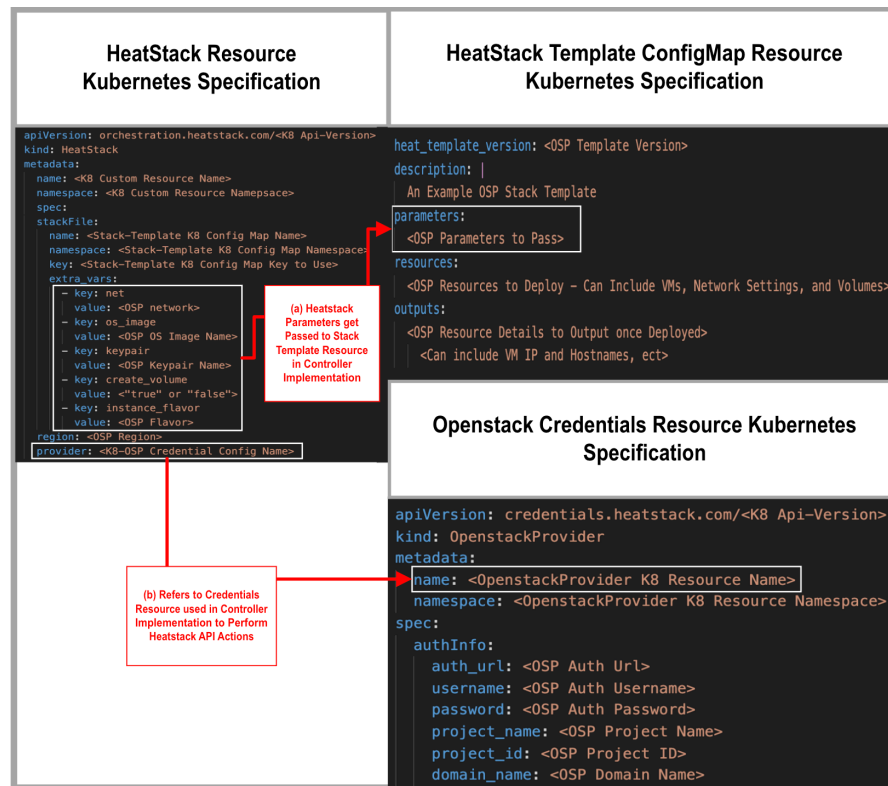

Figure 6 – Example Kubernetes Resource Specifications with Heatstack CRD

There are two essential components within our custom resource specification for OpenStack: 1) An orchestration template, and 2) An authentication template.

The resource scheme developed with the declarative specification listed in Fig. 6 allows for a high amount of flexibility in deploying key OpenStack resources. For instance, rather than having a set schema that declares which variables can be passed to a HEAT template, the “extra_vars” field in Fig. 6(a) can have an arbitrary number of parameters that work with a wide variety of Heat templates. The Heat-Template abstraction is then meant to be a highly flexible schema that serves a wide variety of use cases on the OpenStack platform.

With the “OpenstackProvider” resource listed in Fig. 6(b), we can further configure the authentication settings that we are using to interact with the HEAT APIs, which are needed for creation, update, and deletion of Heatstack CRs. This template-based approach is also applicable to other platforms such as cloud-native and other virtualized setups as well, as declarative API specifications have become popular within the IT Industry in general.

KADC resource specifications can thus be used to convert very broad requirements into specific ones, without a high amount of setup effort for simple deployments. In this example of a HEAT Template API interface, the outputs of the Heatstack Template are returned by the API, and these fields are populated as state in the Heatstack CR.

7.1. Core Deployment Orchestration

In this section we propose an opinionated way of utilizing the primitives we have designed in Fig. 6 so that we can create a base set of API interfaces with OpenStack for the HEAT Template primitive:

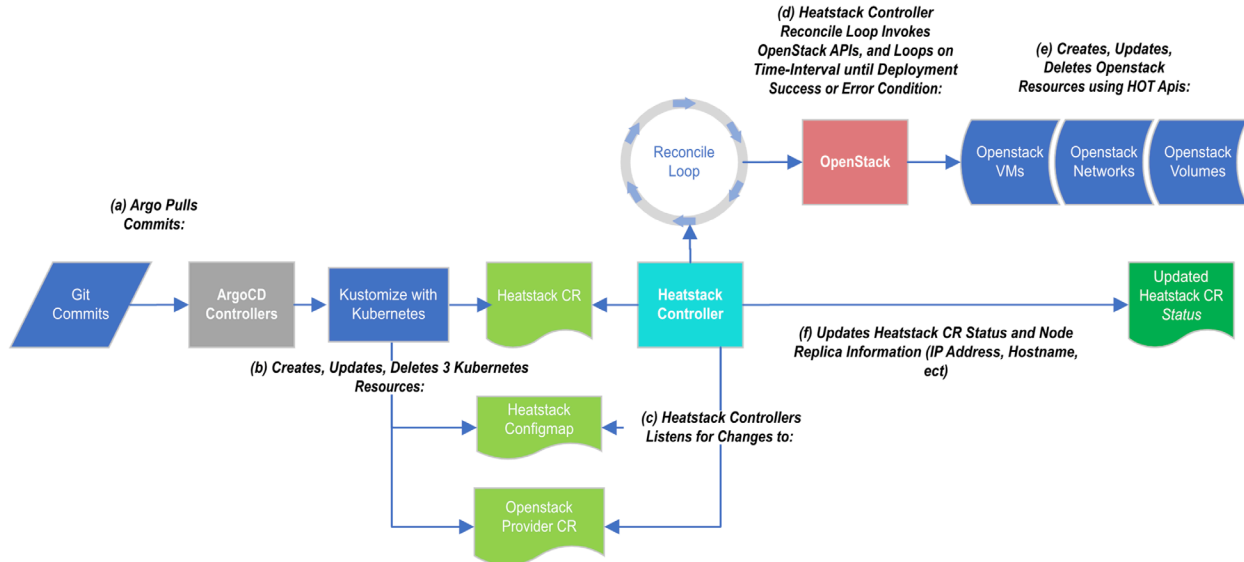

Figure 7 - Kubernetes Resource Specifications for Heatstack Deployment

With Fig. 7(a) and Fig. 7(b), we utilize ArgoCD's Kustomize interface (although Helm is also possible) to submit updates to each of the three Kubernetes CRs listed in Fig. 6. The controller then listens for change events for each of the custom resources and reacts to those changes in steps Fig. 7(c)-(e).

OpenStack API Control-Loop Logic

In the event of a bulk *create* event on resources, the Heatstack Controller reacts to the create events in Fig. 7(c), which will create the Heatstack CR, the Heatstack Config Map, and the OpenStack Provider CR as resources in Kubernetes. In step Fig. 7(d), the controller invokes an initial API call with the OpenStack API, however finalization of this API integration takes time. For example, a large-sized VM deployment can take a few minutes to a few hours to complete depending on the magnitude of scale you are targeting. Thus, it was important for us to design the Heatstack controller to poll the OpenStack resource it just created in order to validate the health of the deployment over time and report its state to our GitOps Listeners.

Heatstack Controller Status Update Implications

This idea of polling the HEAT-API for details on deployment state is fundamental to the implementation of resources that rely on the Heatstack, such as Load Balancers, TLS Certificates, and DNS entries, because each of these features rely on an up-and-running deployment. Even without these auxiliary features, reporting the status of the deployment back to ArgoCD via health checks enables better visibility of the deployment logic within the ArgoUI interface detailed in Section 5.

The status field of the Heatstack resource serves as the fundamental way that health checks are implemented, with a status field having to be “complete” for the Heatstack resource to be considered healthy in ArgoUI. Other details in Fig. 7(f) are also updated within the status field, as such:

1. deploymentStatus

- Can be either: IN_PROGRESS, CREATE_COMPLETE, UPDATE_COMPLETE, or ERROR

2. deploymentStatusReason

- a. A string field that indicates success or error reasons

3. outputs

- A list of key value pair objects that store critical data from HEAT deployments.

For each successful create, update and delete event, the deployment status gets updated with a simple tag that aids us in tracking the deployment status. The “outputs” field is updated in Fig. 7(f) with multi-VM IP and Hostname attribute details following a completed change event, which aids in health checks and further controller processing for auxiliary features.

Resilience Features in the Heatstack Controller Design

The control-loop approach for CR Status updates improves overall deployment resilience. Using control-loops, controllers can continuously integrate the latest changes committed to Kubernetes via ArgoCD while also validating previous changes or discarding them depending on the situation. This level of runtime control within our deployment implementation also allows for proper handling of errors. With exponential backoff capabilities within the control loop, we can eventually stop processing changes that are causing repeated and sustained errors over time, while also informing users through the “deploymentStatusReason” field of the underlying issue.

7.2. Auxiliary Deployment Orchestration

Operators leverage create, read, update, and delete (CRUD) APIs to orchestration HEAT-template resources. In our case, we have chosen to use a single controller within our OpenStack Operator called the “Heatstack-Controller” in order to manage these resources, while using other controllers as auxiliary integrations around this fundamental controller to supports dependent features.

Overall, the 5 key areas of solutions we incorporated into our OpenStack integration design via various APIs were:

Table 2 - OpenStack Deployment Architecture Components

Resource Deployed	API Used by Operators	Key Objective Accomplished	Leverages OpenStack API?
Heatstack(VM, Storage, Network Management)	OpenStack HEAT, aka “Heatstack Template” APIs	Orchestrate / Deploy VMs, Volumes, and networks to OpenStack using Images	Yes
Application Management	OpenStack Image APIs	Managed Packer-Built Images used by OpenStack VMs	Yes
DNS Management	VinylDNS API	Manage DNS Records in VinylDNS System	No
Certificate Management	Certificate Manager API	Manage Certificates tied to DNS Records	No
Load Balancer Route Management	Traefik Kubernetes CRD API	Manage Traefik-LB Routes Exposed on various HOT VMs	No

At the core of the deployment is the VM, Storage, and Network resource management solution, while several additional open-source ancillary components (VinylDNS, Certificate Manager, Traefik Kubernetes CRD provider) were chosen to demonstrate additional functionality [48-50]. These additional features were chosen because they are typically challenges that are faced by engineering teams in getting their applications to production and in managing complexity of common deployment setups on OpenStack. It is also important to note that these additional components may be replaced within this design with other software that has similar API functionality to support interchangeable components.

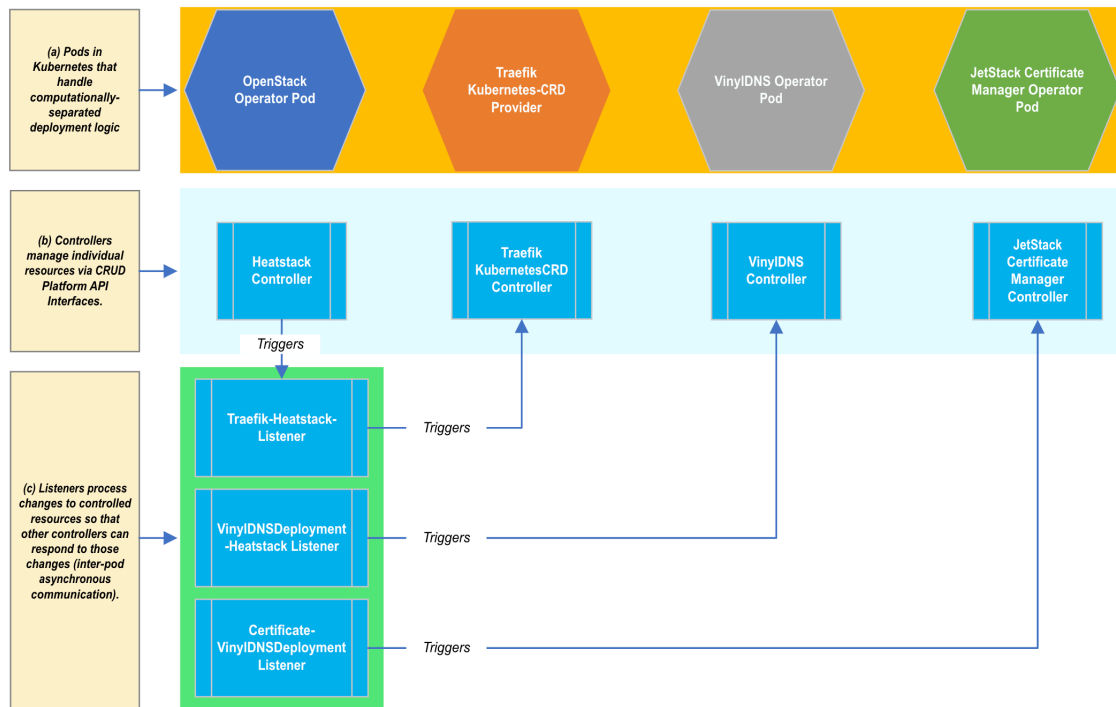

Figure 8 - OpenStack Kubernetes-Operator Architecture Components

There are two essential relationships between the resources listed in Table 2 and the Operator Architecture listed in Fig. 8, which are the *controller-resource relationship* and the *listener-resource relationship*.

In the *controller-resource relationship*, custom resources in Kubernetes are processed by various Operators to create new platform-specific implementations via their various API endpoints. In our case, the core resource being deployed is the Heatstack (described in Table 2) which supplies the declarative specification of resources supported by OpenStack. In the case of a Heatstack CR, a single controller will implement this relationship. In a similar way to the HeatStack Controller, the ancillary controllers - VinylDNS, CertificateManager, and Traefik, enable the management of DNS, TLS Certificates, and Load Balancing Routes.

In the *controller-listener relationship*, controllers listen to changes on *controlled* resources and react to those changes based on additional information captured through Kubernetes CR annotations to implement synchronous and orderly deployments. For example, the “Traefik-Heatstack-Listener” waits until a Heatstack has been fully deployed before exposing it through a Traefik Load Balancer Route using settings specified within the Heatstack CR annotations / metadata fields.

For each pod in Fig. 8(a), the controllers and listeners underneath match with the pod from a service perspective. This architecture separates concerns on both the computational level and from a logical standpoint. Using this clear separation of concerns, we built an architectural scheme with 4 pods that interfaces with OpenStack, Traefik, VinylDNS, and Certificate Manager:

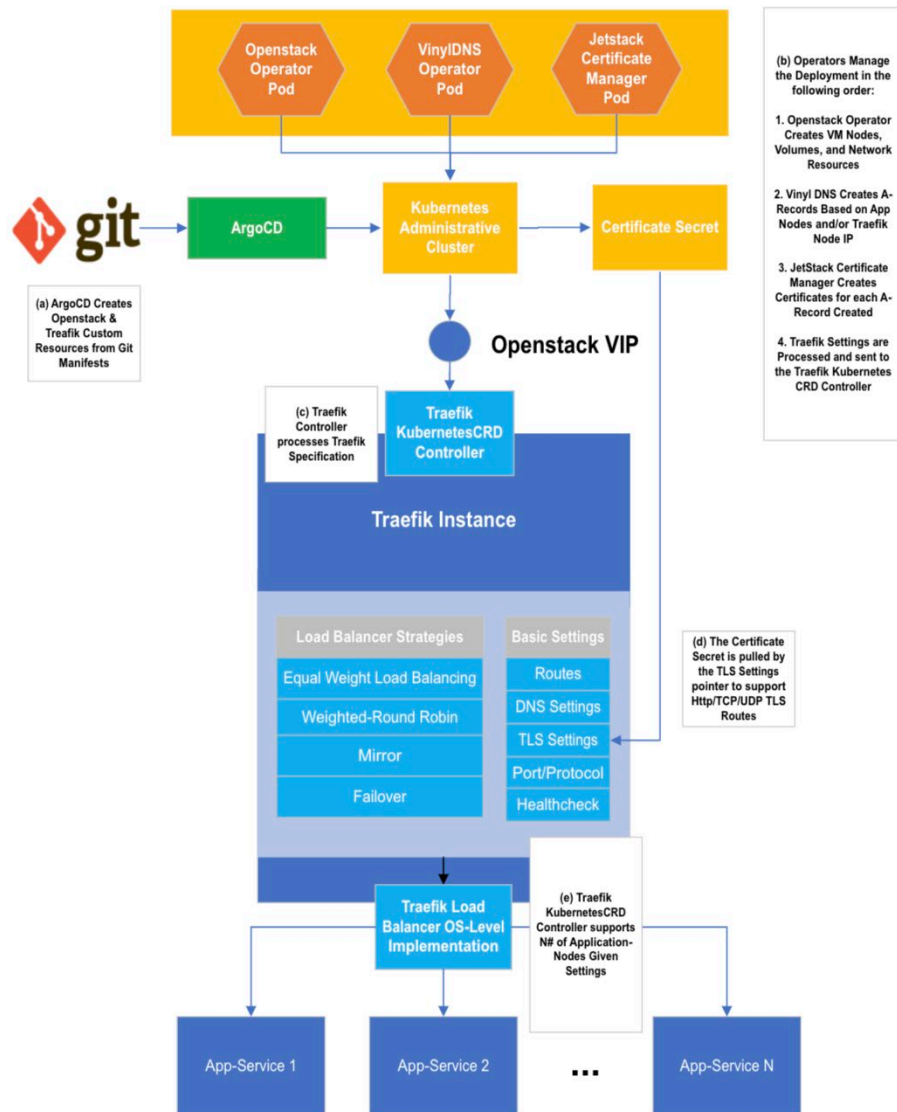

Figure 9 - Traefik Http-Route Integration with Auxiliary OpenStack Operators

Our GitOps implementation supports the synchronous processing of core and auxiliary components of a web-scale deployment as described in Fig. 9(a) and Fig. 9(b), and with all the components listed in Table 2. As mentioned earlier in this section, we leverage KADC Operators to ensure that core components are created before auxiliary components are processed. The key example in Fig. 9 is that Fig. 9(c) and Fig. 9(d) are processed after Fig. 9(b)1-3. This ensures that infrastructure VMs, VinylDNS and Certificates prerequisites are all created before services are exposed via the Traefik Load Balancer. After this initial work is performed, step Fig. 9(e) triggers with the settings passed to the Traefik KubernetesCRD provider-controller which exists on the Traefik Load Balancer instance itself, and this step processes the Traefik Route custom resources created by the Traefik-Listener controller in the KADC in order to expose groups of OpenStack VM services to load-balancer routes. The configurable settings within Traefik are listed in the Fig 9(e), split into load balancer strategies and basic settings for our ease of understanding. With a single exposed route, you can typically choose a single strategy to work with

depending on your needs, however virtually unlimited routes can be exposed with a single manifest specification in the KADC.

In addition to enforcing order in the bulk-create-case, in the case of a scalability update scenario the design also ensures zero-downtime deployments. This is accomplished with careful coding of custom KADC Operators for these common scaling cases:

1. **Scale up VM nodes:** Traefik listener will not process VM node scale-ups until the action is complete. Scaling up with the OpenStack HOT API does not delete existing nodes or recreate them, and thus this setup enables zero-downtime deployments.
2. **Scale down VM nodes:** Traefik immediately removes the necessary VM(s) from exposure in the event of a scale-down before the Heatstack-Controller deletes them. This also ensures zero-downtime deployments as well.

8. Advanced Deployment Capabilities for Web-scale Workloads

A web-scale workload is a component in many telecom products that use REST, gRPC, and other popular HTTP-based communication protocols. To demonstrate the augmentation of web-scale services with advanced load balancer strategies, we propose leveraging the weighted-round-robin strategy (listed in Fig. 9) within Traefik to allow assignment of different integer weights to groups service nodes, such that certain nodes can proportionally receive more traffic than others. Our aim in implementing this functionality is to demonstrate that our design can take advantage of the following advanced deployment capabilities not widely available in virtualization infrastructures and typically reserved for cloud-native/Kubernetes platforms:

- Blue/Green Deployment [51]
- Canary Deployment [52]
- Scaled-Rollout Deployment [53]

The general process by which the weight changes are leveraged is using the previously mentioned integration with Git in Fig. 2, which is accomplished with either manual Git commits, or with automated Git commits using a service account triggered by Argo Workflows or ConcourseCI:

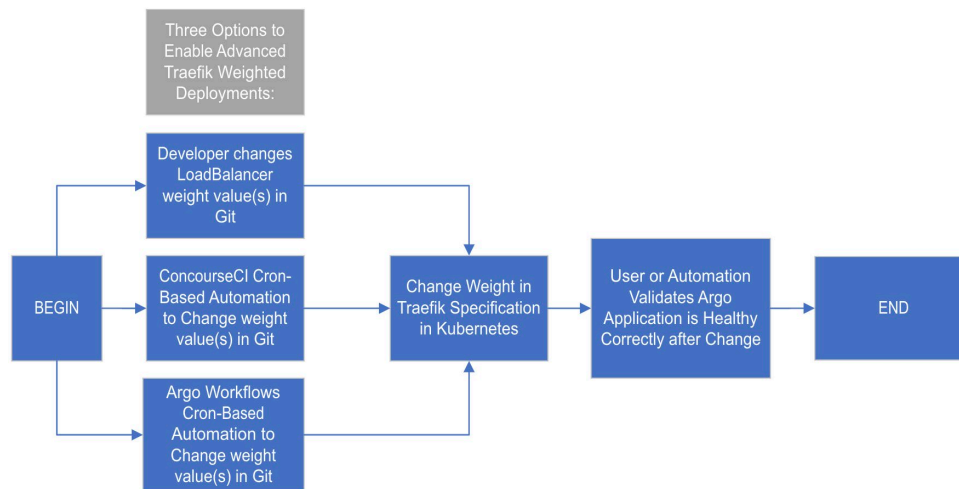

Figure 10 - A Simplified Advanced Deployment Process for Traefik Orchestration

Blue-Green Deployment

For a blue-green deployment, two separate weight changes for two groups of applications occur. Within the Traefik Load Balancer specification, we can group applications under label “A” and label “B” and give one group a weight of “1”, while the other gets a weight of “0”. This is implemented as a Kubernetes annotation on two separate HeatStack CRs, which correspond to the applications “A” and “B”. Using an atomic switch functionality implemented with our Heatstack controllers, we can ensure that A and B switch weights via the Traefik configuration in a single transaction, such that Traefik immediately switches over from A to B with zero downtime. Using the Operator framework and a Config Map lock, we can successfully process both weight changes via the Traefik Listener such that it is transactionally atomic, and thus accomplishes the goal of integrating Heatstacks with Traefik on OpenStack, while keeping processing scaling of each Heatstack independent of this functionality.

Canary Deployment

For a canary deployment, a similar technical scheme is used as the blue-green strategy in order to change the proportion of traffic going to services. As opposed to blue-green deployment where we perform an immediate switch-over from one application to another, in this case a new web application is introduced and validated over time with increasing levels of traffic so as to reduce risk of application issues in the event of a blue-green deployment.

As mentioned in Fig. 10, the process of committing weight changes to Git can be either performed through manual Git commits by a developer or Git commits via planned automation. In the case of canary deployments, it is preferable to use a platform such as ConcourseCI or Argo Workflows to perform the canary deployment changes so that incremental traffic changes can be automatically applied over time without human intervention. This was demonstrated in Fig. 10 with the “Automated Cron-Based CI Triggers”, which make it easier for planned changes to be continuously integrated based on a pre-scheduled change.

Scaled-Rollout

Scaling up / down actions can also be combined with load balancer weight changes to perform even more complex and useful arrangements of deployment schemas such as scaled-rollout strategies. As discussed earlier in Section 7, order is enforced in scale up and scale down situations between core and auxiliary components in Fig 8. This augmented functionality enables us to perform a scaled-rollout scenario with zero downtime, similar to how Kubernetes performs this same action for Replica Sets and Deployments.

With many open-source tools available at our disposal that are alternatives to Traefik, there are a whole host of different load balancers that could be very easily supported in similar ways. In fact, the popular open-source load balancers Nginx [54] and HAProxy [55] also provide Kubernetes manifest interfaces that would allow for similar scale up / down functionality, although the only caveat is that this support would require significant investment in Operator development to expand your load balancer option.

9. VoIP Stack POC Deployment using ArgoCD/Argo Workflow

As we called out in the introduction of this paper, most telecom workloads are still deployed on private on-premises cloud and running on virtualization solutions such as OpenStack. In this section, we will introduce a representative VoIP stack that is fully consisting of open-source implementations and mirroring of what a typical telecom provider might have in their network, and explain how to use the proposed CI/CD GitOps architecture to achieve end to end automation.

Figure 11 - Freeswitch-Openstack High Level Architecture

This VoIP stack consists of the following components: 1) FreeSWITCH SIP feature server [56]; 2) Kamailio SIP Proxy [57]; 3) Jambonz CPaaS solution [58].

FreeSWITCH is an open-source modular SIP feature server that can be configured in different ways to fulfill roles such as a call feature server, a voicemail server, a multi-party audio/video conference server, a media server, a transcoding SBC, or a WebRTC gateway.

Kamailio SIP Proxy is a very popular open-source SIP load balancer that can be used to front the FreeSWITCH and perform different kind of SIP load balancing. It is often deployed in a HA setup to allow for local redundancy.

Jambonz is an open source CPaaS platform that exposes Webhooks and RESTful APIs layer for invoking communication network capabilities such as call control, digit collection, or voice interaction. Underneath it is utilizing FreeSWITCH with additional modules to integrate with public cloud offering for text to speech, speech to text, or even voice dialog solution such as Google DialogFlow.

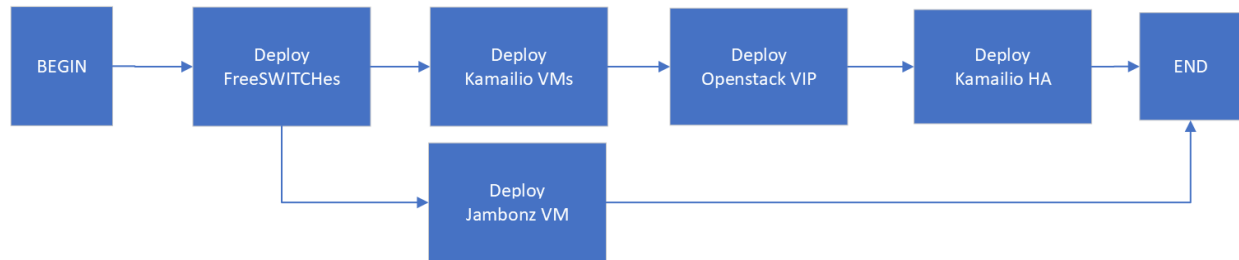

Figure 12 - Freeswitch-Openstack Deployment Process

The above Argo Workflow describes a desired deployment sequence of the VoIP stack and the dependencies between components.

- 1) The set of FreeSWITCHes will be the first group of components to be deployed; Those FreeSWITCHes will be created in Openstack using the same FreeSWITCH packer image we generated in the application CI stage but will be instantiated with the proper configuration depending on which role the VM install is going to play, for example, a voicemail server might load a voicemail FreeSWITCH configuration for it to load the required modules and the correct dialplans;
- 2) Once the IP addresses and SIP ports of FreeSWITCHes are known, we can deploy the two Kamailio SIP Proxy VMs using the Kamailio SIP Proxy packer image, each with the proper configuration to load balance SIP requests to the above FreeSWITCH instances.
- 3) Once the two Kamailio SIP proxy VM are created, the deployment process will need to acquire a VIP resource from the underlying Openstack infrastructure and modify the Kamailio SIP VM network port configuration so the VIP can be honored by those two network ports. The interaction with Openstack is done through Openstack CLI client running within an Argo Workflow container. This step is required before the next step HA configuration for Kamailio SIP Proxy.
- 4) With the VIP generated from Step 3, the deployment process can install keepalived on those two Kamailio SIP proxy VMs with the proper keepalived to monitor each other so they form a HA pair. Only one VM will be claiming the ownership of the VIP at a time, the other will only take over when the current one fails to respond to keepalive pings beyond a defined threshold.

- 5) In parallel to step 2-4, a separate deployment task will be used to kick off the Jambonz CPaaS API VM deployment using a Jambonz Packer image, and instantiated with the proper configuration to point to the FreeSWITCH IPs and Ports.

10. Impact & Caveats of Unified Deployment Strategy

In this paper, we presented two key methods of tackling the “Temporal Synchronicity Problem” in Fig. 1:

1. The Operator Design Pattern
2. The Argo-Workflow Design Pattern

The primary outcome of our efforts with these two patterns was the compression of complexity into manageable abstractions that help simplify the continuous deployment process.

10.1. Operator Design Pattern

With the *Operator Design Pattern*, we solve the “Temporal Synchronicity Problem” in Fig. 1 with independent controllers separated across fault-tolerant pods within Kubernetes. Operator architecture leverages clear separation of concerns as a key aspect of this solution, which was demonstrated in the Traefik Load Balancer example in Section 8. Combined with the GitOps methodology, the Operator Design Pattern also shines in its capability to *continuously* integrate with platform endpoints to ensure that actual state converges with latest state in Git over time. This enables easier handling of complex interactions between components, such as the interaction between OpenStack Infrastructure and DNS allocation logic where one step is dependent on another.

While it is favorable from an engineering standpoint to compress deployment complexity into the Operator Design Pattern to solve the issue in Fig. 1(a), there is admittedly a significant fixed cost in setting up the Operator infrastructure to support a new platform. In addition to this fixed cost, there are some variable costs to maintaining a deployment KADC platform Operator, however our evaluation is that this cost is minimal compared to maintaining a diversity of different DevOps tooling. The general rule of thumb we have discovered in designing and developing Kubernetes Operators for custom needs is that if you need a highly complex and continuously validated API-based integration with a new platform, Operators are probably your best option.

10.2. Argo Workflows Design Pattern

Whereas the Operator design pattern enforces deployment order through sub-patterns such as the resource-listener architecture, the *Argo Workflows Design Pattern* does so via its native “direct acyclic graph” compatibility, or DAG for short. DAGs provide a very powerful way to orchestrate both synchronous and asynchronous actions based on containerized workloads so that order may be easily implemented. Compared to the *Operator Design Pattern*, Argo Workflows does not require nearly as much custom coding and setup, as it is a template-based solution.

As most notably demonstrated with the VoIP Stack deployment in Section 9, Argo Workflows is leveraged in order to deploy various components within the proposed VoIP Stack. Due to the simplicity of this use-case where VM configuration needs to be updated, Argo Workflows shines with a short, containerized script that accomplishes a small set of tasks.

10.3. Resource Savings using Unified Platform Approach

Revisiting all the issues tackled in this paper listed in Fig. 1, the end-goal of solving these problems is to aid engineers within telecom organizations in ultimately saving time and effort in performing complex deployments. Having experimented with both manual and automated approaches in designing the proposed systems outlined in this paper, we can comfortably report those automating deployments with our proposed GitOps-based architecture speeds up our deployments significantly in the two examples we explored:

1. Web-Scale Deployment on OpenStack with Traefik
 - a. Without GitOps Automation: 1 Work Day Average
 - b. With GitOps Automation: 2 Minutes Average
2. VoIP stack on OpenStack
 - a. Without GitOps Automation: 1~2 Week Average
 - b. With GitOps Automation: 30 Minutes Average

In addition to the quantitative resource time-savings, we were also able to unify and significantly augment our current deployment capability from a qualitative standpoint. With improvements to the workflow of deployments and increased observability via GitOps Operators such as Argo Workflows and ArgoCD, we demonstrated a straightforward and streamlined method of deploying resources across platforms, while also abstracting away key details of deployment procedures from the deployer.

The OpenStack Operators listed in this paper further allowed us to augment our currently available deployment approaches with advanced methodologies such as blue-green, canary, and scaled-rollout strategies. Our goal in augmenting the OpenStack platform with the Traefik Load Balancer is to demonstrate that advanced capabilities are possible on virtualized platforms and can be reasonably implemented with speed and efficiency in mind. On the other hand, by using Argo Workflows as a multi-stack orchestrator, we demonstrated how resources could further be updated on a scheduled basis to remove critical manual steps from routine deployment situations.

11. Conclusions

One of our industry's most burdensome software-development trends is a diversity of application requirements that will continue to cause major strategic bottlenecks in deploying new types of workloads, while also driving increased long-term costs of sustaining older legacy apps of an assorted variety. In this paper, we have proposed a proof-of-concept solution that seeks to solve these problems by enabling increased platform deployment diversity and velocity by using a single administrative control-plane for both web-scale and VoIP workloads, as well as across different deployment use-cases.

With our proof-of-concept web-scale and VoIP Stack deployment approach for the OpenStack platform, we demonstrate one possible implementation for a variety of common telecom industry-specific scenarios. With a GitOps methodology for deploying OpenStack resources, we established that it is possible to create opinionated deployment abstractions that compress complexity into fault-tolerant Operator-pattern primitives, while allowing for extensibility and reusability of these primitive in an object-oriented manner. With a scheme of custom-resource organization, we implemented recognizable and easily understood constructs with general implementations of design-patterns to deploy compliant infrastructure and software across multiple platforms. By extending this approach into the realm of cloud-native and other more modern types of workloads, it is also easy to imagine adding similar ways to deploy to newer and more experimental, cutting-edge platforms through similar designs and architectures.

While the IT Industry moves toward GitOps as a popular methodology, we believe the key lesson for our telecom organizations is that it may be difficult to onboard complex applications such as VoIP Stacks to most platforms without better forms of deployment orchestration. While GitOps Operators such as ArgoCD and Argo Workflows provide a good starting point for abstracting deployment listeners, most of the DevOps work in our proposal resides with custom Operator development and sustainment for highly complex scenarios, while Argo Workflows shines in simple DAG workflow cases. This methodology provides a basis for future development with Kubernetes Operators or other chosen organizational constructs that are practical for software teams to adopt over time.

The decision to move toward multi-platform deployments will no doubt require careful thought and investment in compressing key implementation details of deployments into manageable abstractions. Within the realm of web-scale and VoIP workloads, it is important to appreciate the complexity of deployment logic, the tools available to solve common problems experienced by DevOps Teams, and the proposed solution's architectural tradeoffs. While the industry continues to move toward increased complexity of newer, more modern and powerful platforms, we should consider from a resource standpoint that managing all these systems can become unduly burdensome and subject to human error. Our hope for future research in this area is that it continues to find increasingly efficient and simplified ways to use GitOps, Kubernetes and similar tools that augment the overall DevOps experience.

12. Acknowledgements

We thank our colleagues who have contributed to our GitOps innovation work: Chris W., Johan C., Pawan T., Jaipal K., Eugene N., Robert S., and Sachin P. We also want to thank the Red Hat Open Innovation lab team for their constructive input and guidance with OperatorSDK. Finally, we want to thank John D., Arvind K., John G. and Brett S. for their continued sponsorship of the GitOps innovation work inside Comcast Communication Engineering organization.

1. Introduction

Every brilliant network deserves a brilliant onramp, one which makes it simple and easy for customers to get quick, ready- access to the services for which they are paying. This first interaction with services and products will leave a lasting impression that will be difficult to change if it isn't positive. At Comcast, teams are intently focused on ensuring that this onboarding or first-time user experience (FTUE) is frictionless and positive for our customers. We look to minimize customer interactions stemming from difficulties with onboarding and to direct as many folks as possible into the self-install installation route. This paper examines how we are using cloud native such as workflow orchestrators and Functions as a service (FaaS) to realize this goal. We will examine how previous paradigms employed for onboarding provided a foundation for the new workflow orchestration architecture presented here and helped propel us in that direction. From the perspective of software development, we wish to develop platform services that are robust, highly observable, scalable, quick and easy to modify and deploy, while providing the best customer experience.

2. Onboarding Process

The process of onboarding IP (Internet Protocol) gateway devices has evolved with changing technologies and business opportunities. Customers used to rely heavily on technicians to help onboard their equipment. Interactive Voice Response (IVR) systems were available to help customers who needed it. There has long been a web interface used by both customers and technicians to facilitate the onboarding process. With the advent of mobile applications, new business opportunities arose. Comcast introduced mobile applications and recognized the potential of the superior user interface there to improve the onboarding experience. This was also about the time when our advanced xFi gateways running the Resource Development Kit – Broadband (RDK-B) firmware were introduced. These gateways would necessitate changes to the existing onboarding process, as additional backend services were now involved. Initially only IP gateway devices that were leased to customers ran the RDK-B firmware and consequently our focus was solely on these devices. Onboarding functionality was implemented as part of the single Application Programming Interface (API) supporting most of the functionality for what was then called the xFi app. This paradigm served us well for a long time.

The success of the onboarding process in the xFi app encouraged the business to seek additional opportunities. Soon discussions were underway about how we could support customers who chose to bring their own device, so-called customer owned and managed (COAM) devices, when subscribing to Comcast High Speed Data (HSD) service. A growing percentage of Comcast broadband customers opt for this route and ideally their onboarding experiences are as consistently positive as those experienced by customers who lease gateways from Comcast. Concurrently, software engineers began to recognize the drawbacks of operating software as large applications performing many different functions and the era of microservice architectures dawned. As we contemplated adding support for COAM devices to the xFi application, we began examining how we could leverage the benefits of the emerging microservice architectures at the same time.

The decision was made to build the COAM activation as a collection of FaaS components that would then be orchestrated by an external workflow engine. Separating concerns in this way affords us a host of benefits which we shall examine in detail.

Onboarding requires asynchronous execution of a series of tasks to activate service, update core device configurations such as wireless fidelity (wi-fi) radio credentials, provision or update status of the device in a central device repository, and conditionally apply other device configurations. All of these functions could potentially be performed by

discrete functional units as suggested by microservice architectures. The decision was made to build the COAM activation as a collection of FaaS components that would then be orchestrated by an external workflow engine. Separating concerns in this way affords us a host of benefits which we shall examine in detail.

The COAM onboarding workflow was successfully implemented in this fashion and introduced into the xFi app. We were now able to provide the superior mobile application onboarding experience to both leased and COAM customers, so when the business value of facilitating onboarding of gateways for customers in Multi Dwelling Units (MDUs) via the mobile application became apparent we were well positioned to tackle that work.

3. Leased Gateway Orchestration

The introduction of leased gateway orchestration to the xFi mobile application was a large success. We were able to gain more insight into how the onboarding process was performing, identify opportunities to improve the customer experience and the orchestration of all the requisite back-office processes. Most significantly, customers could onboard their devices out-of-band, meaning without being connected to the wi-fi network broadcast by the IP Gateway itself. This opened many opportunities for an improved user experience in the xFi app and facilitated the increased use of Self-Install Kits (SIKs) for IP Gateway onboarding. SIKs meant fewer technicians visiting homes to facilitate the onboarding process. The leased gateway onboarding functionality was part and parcel of the platform API supporting the xFi mobile application. This single large software application was in line with how most folks were building software and made it easy to deploy and operate. Figure 1 illustrates this leased gateway workflow orchestration.

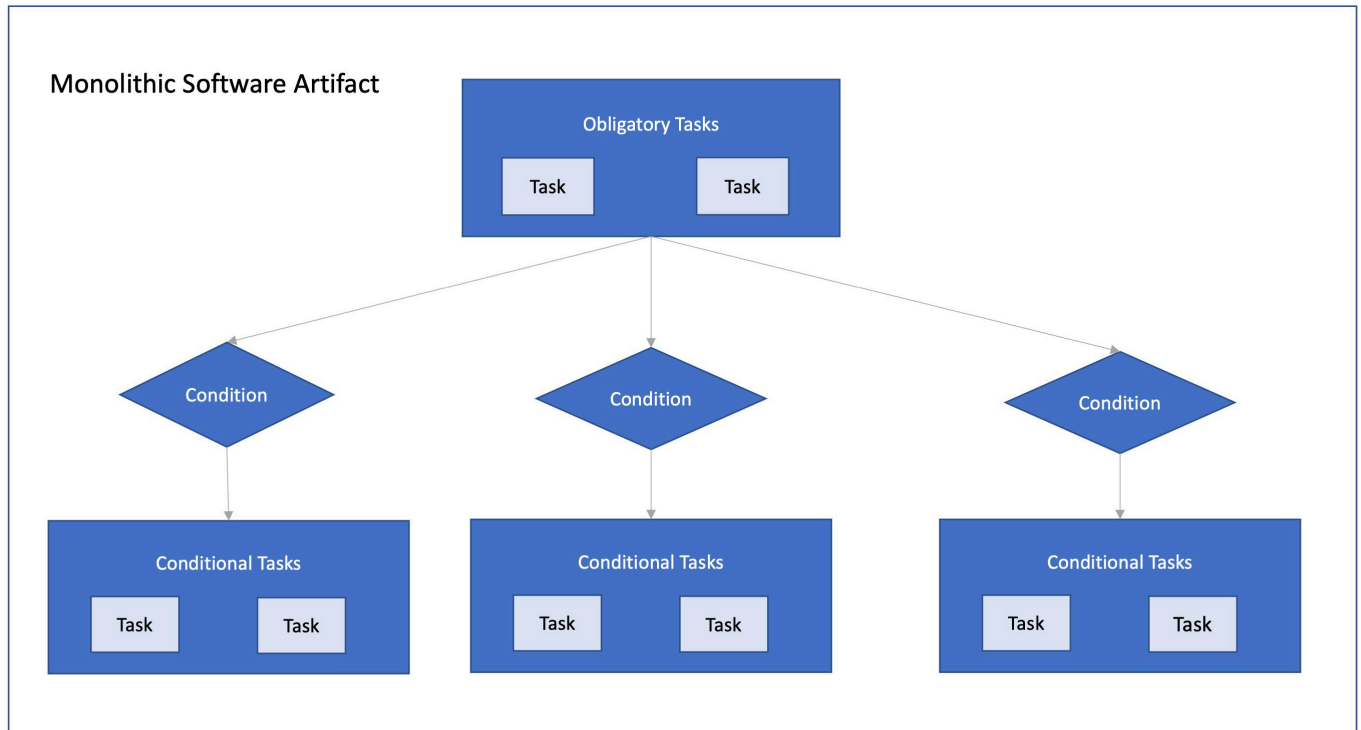

Figure 1 – Leased Gateway Workflow Orchestration

Our leased gateway onboarding implementation provided some great benefits as detailed here.

3.1. Observability

Because we were orchestrating the whole onboarding process from a single software workflow, we had great visibility into the whole process. A home-grown system for distributed tracing, named Money, which Comcast later open-sourced, allowed us to follow a request from the mobile application client through our orchestration to the various back-office services involved in the onboarding process. As long as the leased gateway flow was the only one supported this process worked well and gave us much insight into the onboarding workflow. As we added additional workflows for COAM and MDU devices we realized we had an opportunity to do better still and gain insight into how common tasks performed in aggregate across all the onboarding workflows.

3.2. Orchestration Modification

Once established, the leased gateway onboarding workflow changed infrequently. Within the xFi platform API, the code for the workflow was well encapsulated and could be modified when need be to support evolution of the onboarding process. The addition of the COAM workflow provided the impetus to extract the workflow definition from the code itself so that it could be managed and evolved independently of the code that implemented the business logic described by the workflow definition.

3.3. Workflow Testing and Deployment

While the leased gateway onboarding workflow was the only one we supported, testing and deployment was straightforward. Changes would be made, and the workflow would be tested via a mixture of automated testing and manual testing using the client interface. As we began to consider COAM onboarding, we looked for opportunities to manage the two workflows separately so they could be tested and deployed independently and changes to one workflow would not necessitate any testing of the other if the changes did not apply.

3.4. Workflow Composability

In the monolithic orchestration in Figure 1, the conditional tasks shown are responsible for additional configurations that fall outside of the primary onboarding function as previously discussed. The gateway device is onboarded and functional from the customer's perspective after the primary tasks in the orchestration have been successfully completed. The advent of microservices architecture and the emerging architecture for COAM onboarding would provide the opportunity to treat these conditional workflow tasks as independent workflows whose execution could be done independently of the primary onboarding workflow. This separation would allow each of the workflow to be given the retry semantics they required and provide greater clarity as metrics could be separated and tallied individually for each workflow.

4. Workflow Orchestration Architecture

The introduction of COAM onboarding in the xFi mobile application gave us the opportunity to implement the architecture we'd been formulating, built upon an external workflow engine and independently deployable FaaS components. This paradigm decouples the workflow orchestration from the task implementation. An externalized workflow engine handles orchestrating tasks for which implementation isn't coupled to the workflow engine in any way. Tasks are implemented as discrete deployable units that are likewise free of dependency on each other.

The implementation of a common task only needs to be completed once, and it joins a library of functionality from which engineers can draw as they build additional workflows. These workflows are expressed in a domain specific language (DSL) wherein the interactions between the tasks are described along with instructions about conditional execution of tasks, how to handle error conditions, and when to retry task executions. These workflow definitions are consulted by the workflow engine and used to determine which tasks need to be executed and in what order. This has allowed us to quickly support new device classes or types as they are introduced, and to build workflows that handle some ancillary concerns around gateway device configuration that often accompany onboarding, such as

The introduction of COAM onboarding in the xFi mobile application gave us the opportunity to implement the architecture we'd been formulating, built upon an external workflow engine and independently deployable FaaS components.

the conditional enablement of gateway agents according to business and product requirements. This paradigm also allows for greater visibility into workflow performance so that potential issues can be identified and understood quickly and addressed with minimal disruption to our customers. Additionally, it provides deeper insight into how each task of the workflow is performing, both in the context of a single workflow and in aggregate across all the workflows in which it is used.

A high-level view of our new architecture looks like the image below, where service is used generically to refer to independently deployable functional units. In our specific implementation we rely on FaaS:

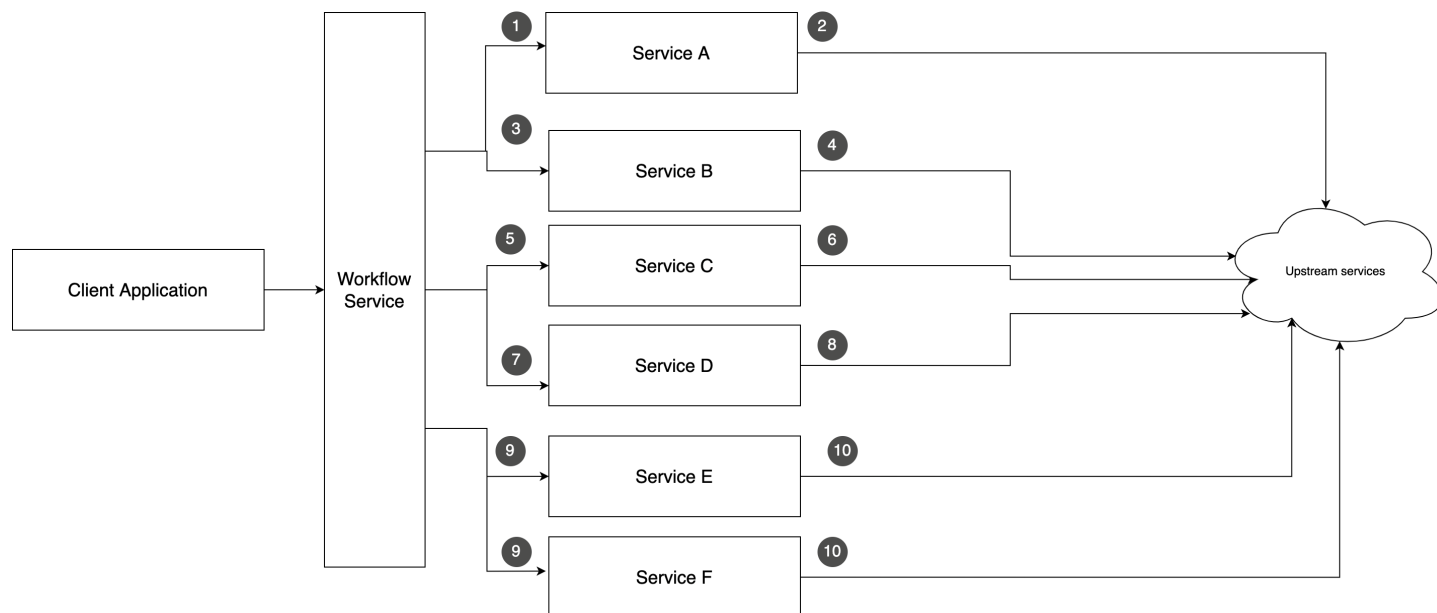

Figure 2 – Workflow Orchestration Architecture

4.1. Architectural Constructs

There are a few primary architectural constructs employed by our workflow orchestration architecture which are described here. From these basic building blocks, we can compose and execute new workflows, and reap other benefits, all of which we will examine in detail.

4.1.1. Task

A task is a discrete functional unit of work. In the onboarding domain this most often equates to a Hypertext Transfer Protocol (HTTP) interaction with an external service used to fulfill some specific, often repeated function. Examples include interactions to provision a gateway device in a centralized device repository, or to associate a gateway device with a set of configurations in a cloud database. Tasks should be generic enough to be reused by multiple workflows. If more than one workflow requires the same piece of functionality, they will ideally use the same task implementation to accomplish this work. The difficulty here lies in making tasks reusable without making them too large or generic. If tasks aren't granular enough, some of the benefits of the workflow orchestration architecture are lost, particularly the observability and state management functions we will look at shortly. In our architecture, task

implementations are typically done as FaaS. Serverless FaaS functions are cost-efficient as they only consume the computing resources they require. During periods of general inactivity, such as in the very early hours of morning when most people opt for sleep over onboarding of their gateway devices, little to no compute resources will be consumed. We've also done a good amount of work to standardize the request and response payloads each task uses so that communication between tasks and with the workflow engine is facilitated.

4.1.2. Workflow Definition

Workflows are defined in a DSL wherein the set of tasks comprising the workflow, the order of their execution, number of retries and retry semantics for each service, the inputs and output fields for the entire workflow, and the input and outputs required by each task are specified. The workflow definition may specify for each task, a fixed number of retries repeated at a fixed interval, an exponential back-off strategy in which each subsequent retry is delayed by an order of magnitude more time than the last, or even that no retries are warranted. The workflow can also specify that tasks be executed concurrently or serially and provide conditions that must be met before a task is executed. Exit criteria for a workflow may also be found in the definition. Certain task failures should result in termination of the workflow, while in other cases workflows may be able to continue after failure of a task that is optional or not essential to the overall workflow success. Our architecture uses a serverless cloud-based workflow engine as described in the next section. Each workflow definition can be managed via the cloud console or defined declaratively as JavaScript Object Notation (JSON) files and managed independently of the cloud console. This allows for automated deployment of workflow modifications. They can also be visualized using the tools provided in the cloud console.

4.1.3. Workflow Engine

Our architecture needs an engine to drive workflows. This engine reads workflow definitions to receive its marching orders and then executes the instructions defined in the workflow definition. It is the engine that orchestrates the task executions and applies the retry, concurrency, and conditional rules specified in the workflow definition. The workflow engine manage failures, retries, and parallelization as described in

the workflow definition so developers needn't be concerned with these ancillary functionalities and can focus instead on where they can produce the most value, namely in implementing the business functionality required by the onboarding process. All this functionality was provided by the initial leased gateway onboarding, but now it is handled as a separate component that can orchestrate many workflows and focus on its primary functionality without being bogged down with the details of task implementations or the business logic embedded in the tasks. Since the tasks use standardized request and response payloads the workflow engine simply feeds the output from one task to the next task in the workflow.

4.1.4. Workflow Integrator

The workflow integrator is a component that provides a means for client interaction. It performs several key functions that fall outside the purview of the workflow engine, the tasks, or the workflow definitions. Chief among these is authorizing clients wishing to initiate workflows, mapping client requests to workflow definitions, starting workflows via the workflow engine, and reporting status on currently

executing workflows to clients who request it. The workflow integrator maintains a mapping of APIs to workflow definitions. This mapping will also include data about what inputs are required for each workflow. The client application makes a call to an API exposed by the workflow integrator which consults its mapping, authorizes the client, verifies proper workflow inputs have been supplied, and starts the Step Function State Machine that correlates to the client request.

Our specific implementation of the workflow orchestration architecture looks something like this:

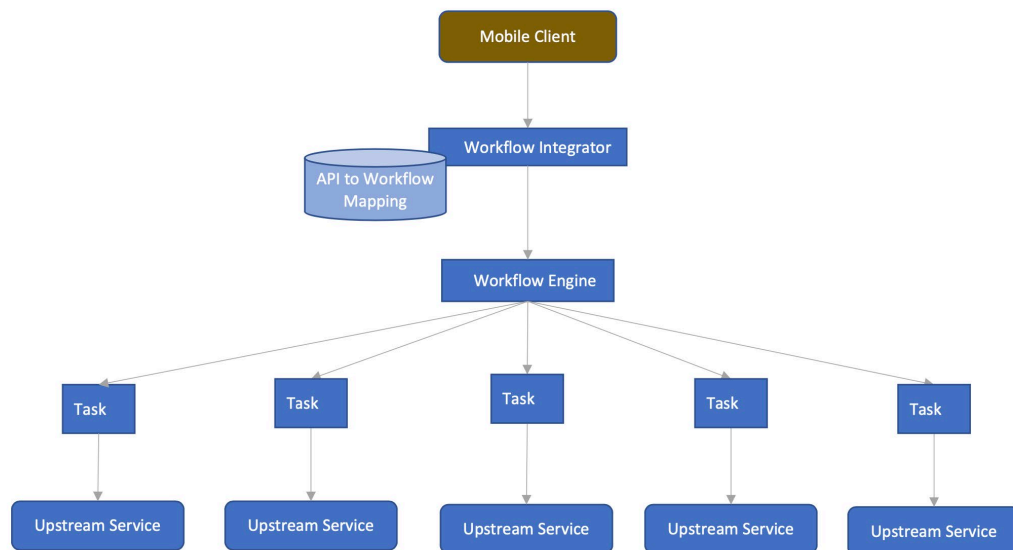

Figure 3 - Workflow Orchestration Architecture Implementation

4.2. Benefits

The workflow orchestration architecture has delivered handily on its promise. It is currently in use for both COAM and MDU onboarding workflows. Here we examine this benefits in detail.

4.2.1. Metrics and observability

With the modular units in our new architecture, logs are emitted to their own buckets in our log aggregator, making it easy to aggregate logs for a given task, or get details of how a given task is performing. Additionally, the workflow engine itself produces a wealth of data about the workflows it has executed. These metrics have been collected and exposed via dashboards in various observability tools, supplying great insight into workflow executions, and allowing us to find and address issues promptly.

4.2.2. Reusability

Separating orchestration from business logic implementation in the services has helped us reuse the same tasks for different onboarding experiences. For example, most onboarding experiences would involve associating cloud-based configuration with a gateway device. Since each task is concerned only with its specific business logic and does not have other dependent services, we can use the same configuration-to-device-association task in multiple workflows without the need for duplicated efforts.

4.2.3. Development agility

Given that we can reuse tasks very efficiently, writing new workflows, in the best-case scenario, has been reduced to writing a new definition file with references to the existing tasks that have already been developed and deployed. This makes it easy to update an existing workflow. As an example, if an existing workflow needs to change the order of the tasks it executes, the change is limited to changing a workflow definition file and deploying it to production with no code change involved. Conversely, shared tasks can be updated to implement some universal change, like a new endpoint or authentication mechanism for an upstream service or a tweak in the business logic without having to modify the workflow definition.

4.2.4. Ease of programmatic client integration

The clients who call our platform API which today include several back-office processes, and web interfaces in addition to the original mobile application client, have an easy intuitive point of integration. All workflows are initiated through API endpoints exposed by the workflow integrator and specified using well understood open-sourced standards like OpenAPI. We are able to generate the client code needed to interact with the platform API thereby eliminating a significant chunk of work the client development organization would otherwise need to undertake. Additionally, since clients do not interact with the workflow engine directly, workflows can evolve independently of and transparently to the clients so long as the responses provided or inputs required don't change. This allows for the tasks to add more features and functionality without impacting clients. If the contract between the workflow integrator and client application stays intact, there is no change needed on the client application and hence no updated version of the app to be released. Mobile application evolution is complicated by the fact that customers we wish to support may still be using older versions of the application. Being able to drive down new features to customers without a client application update helps us provide a more frictionless experience.

4.2.5. State management

With the new workflow-based architecture, the workflow service tracks the state of the workflow as it orchestrates the calls between multiple tasks. This allows clients to resume from the last successful task execution in an earlier attempt; customers need not start the entire flow from the beginning and repeat work they already completed. With the modular breakup in the new architecture, customers can resume from the place they had left off in their previous attempt and not repeat the steps that they had already done.

5. Case Study: Mesh and Advanced Security Firmware Agent Enablement

After a comprehensive discussion of the evolution of onboarding processes and the benefits of the workflow orchestration architecture, we look at a specific example of how the move from one paradigm to the other improved an important business process. The onboarding process involves the enablement of firmware agents to support certain valuable features of our wi-fi product, specifically mesh networking and advanced security. In our initial leased gateway onboarding, if conditions were met indicating the need for agent enablement, this would be tried as an optional part of the onboarding orchestration. It was optional in the sense that should these task executions fail, these failures weren't reported as such to the client, but rather as warning that these portions of the workflow had not completed successfully. Because of the single orchestration, it was not possible to apply different retry semantics to this conditional agent enablement or to allow customers to resume the workflow at these optional tasks so that any failures were left to be dealt with by other external systems outside the context of onboarding. This was expedient in that it allowed customers to accomplish their primary goal of getting access to their HSD service and allowed any trouble in the ancillary configurations to be dealt with independently without requiring action on the part of the customer or delaying their use of the HSD service. Figure 4 illustrates this process.

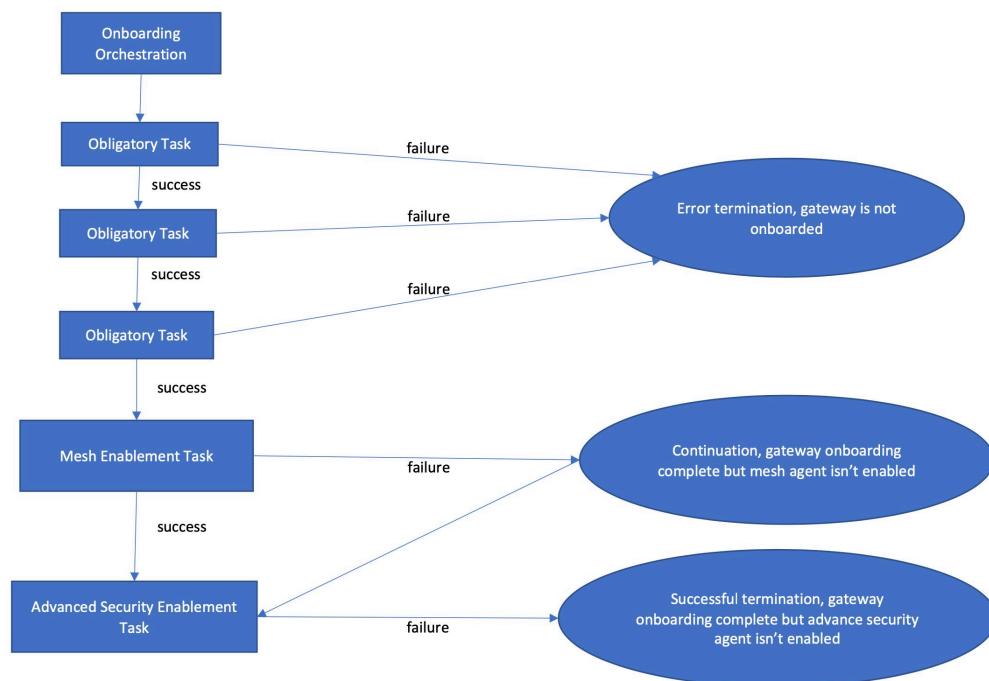

Figure 4 – Conditional Agent Enablement in the Monolithic Orchestration

The workflow orchestration architecture allows us to recognize the conditional enablement of agents as independent workflows, with their own retry semantics and definitions of success or failure. This still accomplishes the primary objective of avoiding a dependency on ancillary configuration before customers

can use their HSD service. The workflow orchestration architecture however, allows us to intelligently handle failures with the ancillary configurations and address them without reliance on external services. When the primary onboarding workflow has successfully completed, it produces an event to a message

Using the new workflow orchestration architecture for mesh and advanced security firmware agent enablement has resulted in better than 99.8% success for each of these processes.

bus which is then used to trigger the subsequent workflows to perform the agent enablement; the primary workflow is completely decoupled from the subsequent workflows that perform the agent enablement. Each can report success or failure on their own terms, and each can employ their own retry semantics. We can define appropriate retry semantics and ensure the enablement completes successfully. Further decoupling is achieved by inserting a message bus between the primary workflow and the agent enablement workflows. The primary workflow does not initiate the subsequent workflows directly. Each workflow has an initializer component that listens for events on the bus and initiates the workflow in response. This allows for externalized retries in addition to the ones defined for the workflow itself. This is particularly useful in a world where gateway devices may be activated prior to shipment to customers,

but agent enablement requires the gateway device to be present on the network. The independence of these agent enablement workflows has also allowed us to introduce incremental improvements to them while leaving the primary workflow untouched. Figure 5 illustrates these improvements facilitated by the workflow orchestration architecture. Using the new workflow orchestration architecture for mesh and advanced security firmware agent enablement has resulted in better than 99.8% success for each of these processes.

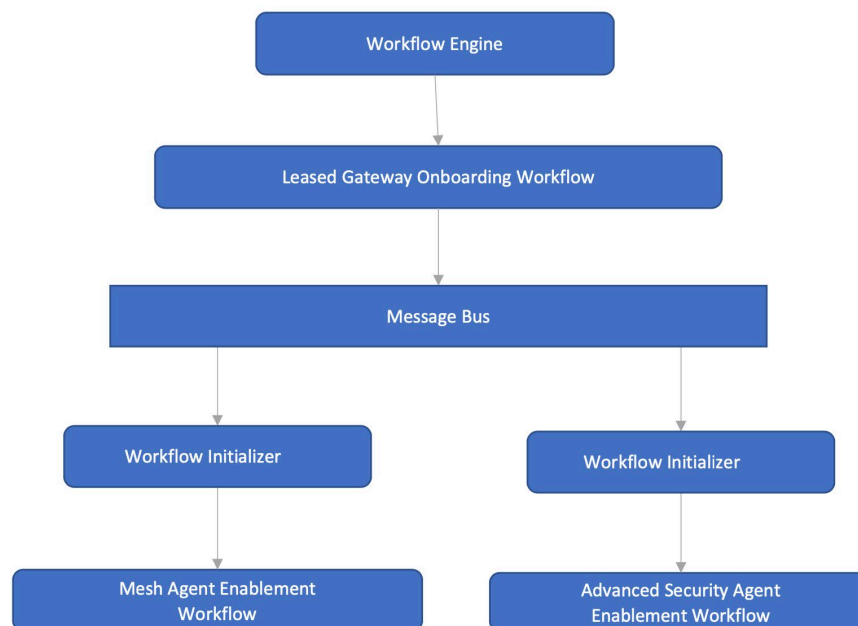

Figure 5 – Agent Enablement with the Workflow Orchestration Architecture

6. Unified Client Interface

As the onboarding process evolved, client interfaces needed to evolve along with them and means of interaction with the platform in presenting the onboarding experience to customers varied. Because of the nature of business process and software evolution, the differing onboarding processes discussed in this paper have and will continue to live concurrently for some time. This diversity in client interfaces is exacerbated by the independent evolution of business and product requirements for different channels, such as mobile clients used by customers versus the web interface used by technicians, or the tools employed by care agents to aid customers with onboarding trouble. Two disparate activation and onboarding platforms have consequently emerged, with some level of interdependency. As new products and devices are introduced, each channel needs to be modified to satisfy the latest requirements. While this has allowed each channel to deliver the appropriate experience, the workflow orchestration architecture gives us the chance to improve this situation. A single client interface for all activation and onboarding needs across all products and devices would be preferable. Having different platforms also increases the potential for customer experience inconsistencies and variance in how the different channels achieve the onboarding process. Figure 6 depicts the crisscrossing interactions that result from the current path.

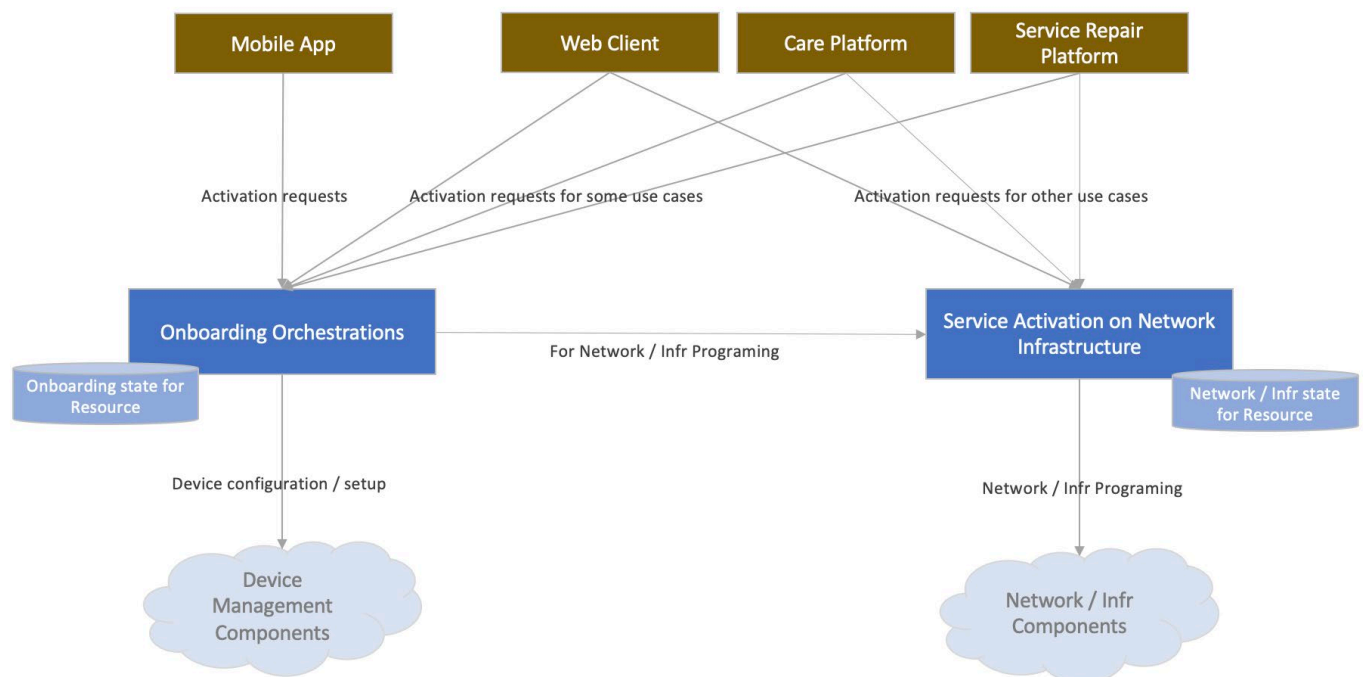

Figure 6 – Channel, Product Specific Client Onboarding Interfaces

To realize the opportunity that now presents itself, the teams responsible for these two platforms have carefully crafted a plan to launch one onboarding hub for all products and devices that can be used by all channels. While offering unified client interfaces, the hub will allow for channel-specific onboarding

considerations while relying on single components for common functionality. Figure 7 illustrates how the divergent platforms coalesce to provide the desired common client interface.

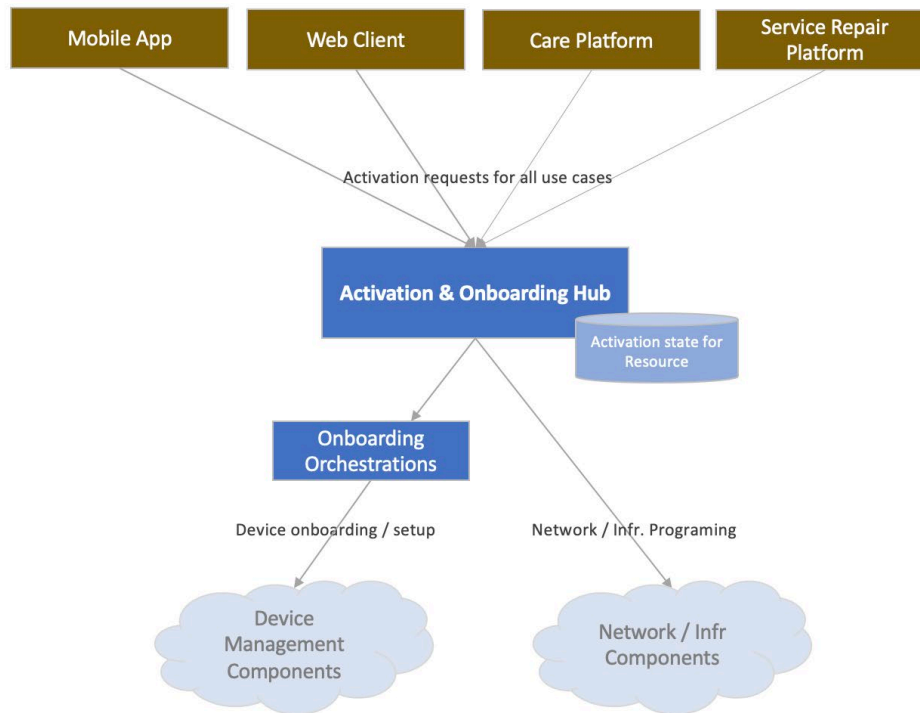

Figure 7 – One Onboarding Hub for all Channels and Products

7. Conclusion

The workflow orchestration architecture we have introduced for onboarding processes has paid great dividends. We have gained great insight into the functioning of workflows and the tasks of which they are comprised. We have a library of discrete functional units that are used to compose new workflows as required. We can quickly and easily modify these functional units apart from the workflow definition itself and vice versa. Workflow specifications can be read and understood apart from the code. We can implement different functional units in whatever programming language is most appropriate for the specific functionality they provide. All of this is helping us to deliver the best possible FTUE to our customers. We have seen steep improvements in onboarding success for COAM customers who can now leverage the Xfiniy App for onboarding. The process is continually evolving but we have the proper tools at our disposal to ensure the onramp to the network shines as brilliantly as possible.

1. Introduction

This paper describes an effective agile process for teaching *technical* subjects in the workplace. For example, data security, machine learning, cloud computing are technical subjects.

With the advent of Big Data and with today's breakneck speed of technical innovation it is more important than ever to provide the technical workforce with continuous education.

But many questions need answers: how frequently should a full-time employee be diverted from work due to their education? What budget should be assigned to the continuous education of technical employees? How can the teaching material be always kept up to date and relevant to the company?

As we were tasked to teach machine learning to a large portion of the software engineering workforce, we had to ask ourselves these questions and more, and after a few iterations we reached our current process which seems to “just work”: no extra budget and an average student's NPS (net promoter score) nearing 100%. The process uses in-house technical experts to design and teach short lessons, and it uses past graduates to act as mentors for new students. In addition, the process has the originally unplanned benefit of favoring networking among employees from different parts of the company.

Encouraged by our successes we recently applied the same teaching process to new technical domains: Data Science and Full Stack DevOps, again, it seems to just work. No extra budget and an average student's NPS in the 90s.

In this paper we answer the above questions and more, we detail our teaching process, and we share some quantified results.

2. Dialectic of Teaching Alternatives

As we embarked on our task of teaching machine learning to a large fraction of the software engineering workforce, we had to evaluate the then current legacy teaching structures. This evaluation led us to attempt a somewhat formal description of teaching alternatives, with the purpose of identifying what would work best for our task.

2.1. Legacy Teaching Structures

Two very distinct teaching programs existed when we started.

The first was akin to a university course but only for the selected, high-performing employees. Over the span of nine months, a carefully selected few employees are gathered in a classroom with an external adjunct teacher with a curriculum that is optimally designed to match Comcast needs. The rather trivial problem with this program is that it is not scalable, not only on the “horizontal” view of fulfilling the education of many employees, but also on the “vertical” view of the continuous education of one employee. Nevertheless, this is a successful and coveted program, and it is being continued today.

The other was open to all employees: it is a selection of online teaching materials. The problem with this totally async approach is that students that can learn on their own don't necessarily need this pre-selection, while students that would need some help do not get it.

Table 1 – The two Legacy Programs

	“Selected Employees” program	“Open to All” program
Instructor led	Yes	No
Duration	9 months	Async
Budget	Expensive	Cheap
Scalability	Low	High
Effectiveness	High	Low
Resilience to changing needs *	Ok	Chaotic

** The AI domain is rapidly evolving. How quickly can a program be updated to include the teaching of new concepts or tools*

The stark contrast between these two legacy programs incited us to attempt to formally describe teaching alternatives.

2.1. Attempt at Formalizing the Alternatives

This section attempts to be somewhat formal in listing teaching possibilities. Having a clear view of the pros and cons of all alternatives is helpful in designing the right teaching process.

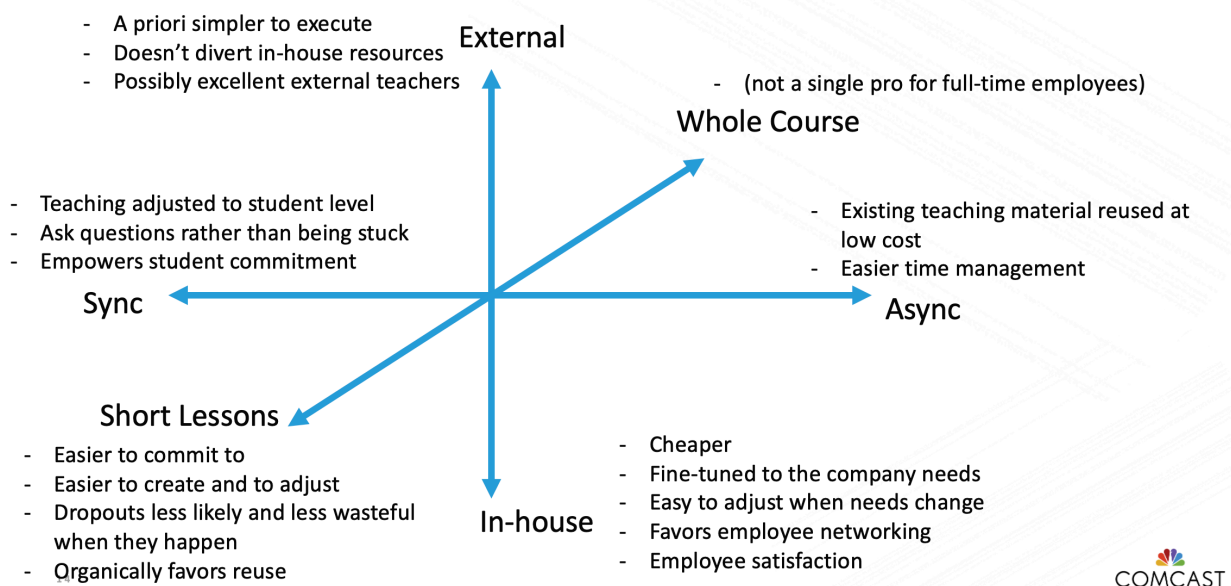

Figure 1 – Dialectic of Teaching Alternatives

2.2. Sync / Async dimension

Technical subjects are complex, and students will benefit from all the help they can get.

Sync means teacher and students are interacting in real time. Async means the student is consuming a previously prepared material. The async version may include some domain expert helping the student, for example by answering questions on a messaging app. We will call such an async helper a “soft mentor”, or a mentor for short.

Note: in our use of sync/async *the interaction* between the teacher and the students is key. If the information flows in only one direction (teacher to a large class that is not expected to interrupt) then it practically matches async teaching.

Sync: the teacher can adjust what is being taught to the level of the students.

Sync: students do not get stuck because they can ask the teacher for clarification.

Sync: empowers student commitment.

Note: student commitment is key, otherwise continuous learning risks of being a farce, a mean for the student to check some educational boxes. The teacher empowers student commitment by interacting with every student in the class, by asking short, simple questions in some round-robin fashion.

Async: time-management is easier for full-time employees.

Async: existing teaching material can be reused without extra costs.

Conclusion: both sync and async have merits. Possibly both can be used for the successful continuous education of full-time employees: a short sync class followed with a mentored async practice.

2.3. Short lessons / Whole course dimension

Throughout our younger lives we have all been educated with *whole courses*: long duration, well designed material that teaches enough facets about a new subject for the learner to get a good logical understanding of the whole. Yet, long duration courses are clearly not ideal (even incompatible) for full-time employees. So, we explored the alternative: *short duration lessons*.

An example of a whole course would be “Machine Learning”. An example of a short lesson would be “Random Forests”.

What is short? Our experiments showed that up to 8 hours spread over one week is favored by full-time employees.

Short lesson: easier to commit to for full-time employees.

Short lesson: easier to create and to adjust.

Note: we mentioned earlier that the AI field changes at breakneck speed. For example, it is easier to create a new lesson about Attention and Transformers rather than adjusting a well-designed coherent whole course with the new content.

Short lesson: student dropouts are less likely and are less wasteful when they happen.

Short lesson: organically favors reuse.

Note: a whole course about machine learning and a whole course about data science might both have a section about Python. The content about Python could be almost identical, but there is no easy way to reuse here. Instead, with a collection of short lessons, the Python lesson is already there and available: organically favoring reuse.

Short lesson: scalable.

Note: spawning the same short lesson multiple times throughout the year to reach more students is doable because it is short. Spawning a whole course multiple times is hard and limited because it is long duration.

Conclusion: For full-time employees we did not find a single *pro* for the *whole course* alternative. In the enterprise, short lessons are always to be favored instead of whole courses. The disconnected nature of a long list of short lessons can be resolved by having the company's educational website somehow link the available short lessons into coherent wholes.

2.4. In-house / External dimension

The course material and its teaching can be developed in-house, or it can be selected from external sources.

Note: The analysis and conclusions about this In-house/External dimension depend heavily on the prior selection between *short lesson* and *whole course* (described in the previous section). Here we assume that the teaching solely consists of short lessons. A few weeks per year an in-house domain expert will have to spend up to 8 hours teaching. This is done without much impact on the employee's regular activities. The design of the short lesson is somewhat more involved, but it happens only once. Sometimes the domain expert selects an existing online source material, in which case the design of the short lesson is even less time consuming.

External: a priori simpler to execute.

In-house: cheaper.

External: doesn't need to divert in-house resources.

In-house: fine-tuned to the company needs.

In-house: easy to adjust the teaching material when the needs change.

In-house: favors networking among employees from different parts of the company.

External: external adjunct teacher can be excellent at teaching.

In-house: sense of satisfaction for the domain expert employee thanks to being selected to teach to the whole company.

Note: after running our agile teaching process for a while, we noticed this sense of pride forwards to the employee's leadership as well.

Conclusion: while there are benefits to both, a company should favor the in-house alternative. For this to be feasible the teaching material should be restricted to short lessons.

3. Student's Practice

To be a practitioner of a new technical skill, a student learns the relevant technical material, but also spends significant time practicing the new skill. Anything long duration that is imposed on full-time workers is best implemented in async mode. Therefore, after completion of a short sync lesson, we do encourage the employees to practice their new skills, but the frequency and total duration of the practice is up to the employee.

Whenever possible, a short sync lesson should be accompanied with async practice exercises (sometimes this can be a simple link to already existing online material).

3.1. Capstone projects

A Capstone project is a bigger, more significant mean of exercising a new skill. Each student decides when and how frequently they will work on their Capstone project. There is no need for a time limit.

The completion of a Capstone project should be a formal event so that the employee rightfully feels a sense of accomplishment. This can be done with a ceremony, grouping together multiple recently completed projects, where each graduate describes their project to the group. At the end a diploma is handed to each employee.

Capstone projects also give structure to an otherwise long list of disjointed short lessons.

Figure 2 – A Capstone Project and its Soft Prerequisites

Each oval is a short lesson. The arrows represent soft prerequisites. Soft means that an employee does not have to enroll in a short lesson if they already know the subject. On the company's educational website, a Capstone project is roughly equivalent to a short lesson. The entry should list all the soft prerequisites.

Students can enroll to the Capstone project and their duty is to complete the project and to create a presentation of their work to be shared during the graduation ceremony.

While practicing, whether with a Capstone project or with simple exercises, the student can get help from mentors.

3.1. Mentors

As with any new knowledge, students should practice what they learned if they want to become proficient. Practicing alone can be hard, as the chance of getting stuck is high when dealing with something new. Having mentors to help students practice is extremely useful. The word mentor here should be understood as a soft mentor, or a learning assistant.

This is great in principle, but how is scalability resolved? With continuous learning there is a continual flow of active students. Our solution to the scalability of mentors is to ask select graduates if they are willing to mentor future students. Through time, as the number of students grow, the number of available mentors grow as well, resolving the scalability issue.

A company-wide messaging app (Slack, MS Teams) is used to interact asynchronously between practicing students and mentors. Domain experts (i.e., the teachers) sometimes join a conversation as well.

This process has the originally unplanned benefit of favoring networking among employees from different parts of the company, of building a community that is excited by the same technical domain (machine learning in our case).

i have tried doing pca, the explained variance is so l

Tsung-hsiang Hsueh 🏠 10:55 AM

Yes, but you can see that some attributes have much more variance than others. Are these normalized?

Prasad Menon 10:56 AM

yes i used standard scalar before going with pca

Tsung-hsiang Hsueh 🏠 11:03 AM

Some experiments you should try:

Do you get different results if you use for example t

Figure 3 - Example Interaction between a Student and a Mentor

4. The Agile Teaching Process

The Agile Teaching Process implements the best practices discovered in earlier sections:

- Short lessons rather than long duration courses
- Sync teaching followed with async practice
- In-house domain experts encouraged to teach their expertise
- Past graduates encouraged to mentor new students

The process is best explained by following the journey of all parties involved: administrator, leadership, students, in-house domain experts, and mentors.

4.1. Administrator journey

The administrator typically belongs to the education side of the company. The administrator role is key to ensure that the agile teaching process is successful. As such, the administrator, directly or indirectly, must be in contact with all participants. Administrator responsibilities are highlighted in the subsequent “journey” sections and are not being duplicated here.

4.2. Leadership journey

Leaders must be convinced that it is worthwhile for their expert employees to be sometime diverted from their daily activities to teach their expertise to the rest of the company. This radical meshing of activities across orgs with well-defined boundaries is best started by the administrator introducing the new process as a long-term pilot.

The administrator should provide the leaders with a quarterly update.

4.3. Student journey

Employees are made aware of the available short lessons by browsing the company’s educational website. The administrator ensures the website is kept up to date.

How frequently should a short lesson be instantiated? This depends on its popularity: the administrator monitors the number of students that are registered to a class. To maximize the effectiveness of sync teaching a class should be limited to a maximum of roughly 25 students. The administrator will increase or decrease the frequency of a class based on the number of registered students. But, prior to this adjustment, the administrator should verify that the number of registered students indeed reflects the popularity of the class rather than being due to the students not noticing the class; this is particularly true for new classes. The administrator should maintain a growing mailing list of potential students. When the number of students being registered to a class is low, before reducing its frequency, the administrator will email a reminder about the class. In our experience, this often results in many more students registering to the class, proving that the lack of popularity was due to lack of employee awareness rather than a class being instantiated too frequently. This description implies that the teachers must show some flexibility with their calendar planning; this is an agile teaching process, and the administrator should from the start make everyone aware that some agility is to be expected.

For full-time employees, to be able to benefit from sync teaching, the class duration must be short. From our experience, a maximum duration of 8 hours spread over one week works well. Always favor spreading the learning hours over multiple consecutive days. For example, teaching 2 hours during 4

consecutive days is to be preferred to teaching 8 hours within a day. There is only so much a brain can learn in a day.

Courses are recorded allowing students to play or replay the lessons in async mode.

To learn new skills, practice is key. Many short lessons should be accompanied with exercises for the student to complete asynchronously after the class is over. The student is free to do it at any time. Jupyter notebooks are perfect mediums for holding the exercises (and for holding the course as well). If they have difficulties during the completion of the exercises, a student can ask mentors for help. A company-wide messaging app is used for the interaction between students and mentors. The student asks a question and asynchronously a mentor, or more, answers it.

Students can more thoroughly practice their newly learned skills by completing Capstone projects. Capstone projects have their own entries in the company's educational website. A student must register to a Capstone project. There are no teachers for Capstone projects. Instead, the Capstone project's entry in the educational website describes the required knowledge by listing the relevant short lessons. These lessons are only "soft" prerequisites, e.g., if an employee already knows Python, they do not have to register to the Python prerequisite class. There is no time limit for the completion of the Capstone project, it is up to the student. Students working on a Capstone project will frequently communicate with mentors through the messaging app. In addition to completing the project, a student must also prepare a presentation describing how this was done. Once enough Capstone projects are completed, the administrator organizes a graduation ceremony where each student describes their project to the group and at the end receives a diploma.

4.4. Teacher journey

In this agile teaching process, all teachers are in-house domain experts. It is the domain expert, in coordination with their leaders, that decides what new lesson should be developed. They know what knowledge is needed for the company technical employees. They are the first to notice the advancements in the state-of-the-art or the emergence of new, better, tools. The administrator is responsible for reminding domain experts and their leaders of the company's technical educational needs and of their duty within this agile teaching process. Our experience shows that most domain experts are excited about the opportunity of teaching their art across the company and their leaders are honored by their group being acknowledged as an important source of knowledge within the company. This motivation can be boosted further by explicitly listing the teaching of one's art in the yearly goals of all technical employees above a certain level. We do believe that this process brings a sense of purpose, builds a community, and ultimately strengthens retention of employees.

Once a new lesson has been agreed upon, the administrator helps the expert commit to the design of the lesson and of the accompanying exercises by setting up a schedule to which the expert can comfortably adhere to. The total duration of this schedule varies but it takes around 3 months on average from the original idea down to its completion.

During the course design a specialist helps the expert with good education principles. Two of the most important educational principles are 1) the teacher is not in the class to bombast his knowledge but rather to adjust it to the current level of the students and 2) the teacher maintains students' attention by continuously forcing them to participate with short simple questions in some round-robin fashion.

In our experience failed teachers are rare, as proven by an average NPS from students that is above 90%. When it happens, the administrator gently discards the failed expert teacher and finds a replacement.

4.5. Mentor journey

When practicing new skills, it is crucial to have some assistance to help avoiding “being stuck”. Our use of the term *mentor* in this paper means exactly this: a practice assistant.

The agile teaching process ensures that every student has helpful mentors during practice. How is that scalable?

After graduating a student may be contacted by the administrator about the possibility of becoming a mentor to future students. It is the administrator’s responsibility to notice which students have superior skills, as poorly done mentorship could be counterproductive. The administrator will consult with teachers to confirm the appropriateness of a student to mentorship.

Once selected, and willing, a past graduate is promoted to mentor. The duty of a mentor is simple: monitor the company-wide messaging app for student questions and answer the question and be generally helpful. Thus, the total number of mentors keep growing, resolving the scaling issue.

While not necessarily intuitive, this mentorship by past graduate, in our experience, is working very well. A few star mentors are quickly answering most of the questions (even though the interaction is not expected to be real time) and the students are very happy with the help they are receiving.

In our experience, most contacted graduates were excited to become mentors.

5. Pilot Results

The last 4 years were exciting as we kept fine-tuning the methodology for teaching machine learning at Comcast. In this section we share some numerical results.

5.1. Ability of in-house domain experts to create teaching material.

The pilot switched to the current version (in-house experts preparing short lessons and teaching them) just 2 years ago.

Table 2 – Size of the Catalog of short Lessons

Number of Short Lessons in the Catalog (as of this writing)	Average time to add a new Lesson
25	< 3 months

5.2. Ability of in-house domain experts to teach

The table below shows the average students’ net promoter score in the last 3 months. The score is quite stable over time, between 90 and 94%.

Table 3 – Student NPS

	This Agile Process	Legacy “Democratic”	Legacy “Best and Brightest”	Education global
Student NPS	91%	Not tracked. Mainly constructive feedback	85%	55%

5.3. Ability of the agile teaching process to scale to more students

Yearly course completion or students per year:

Table 4 – Students per Year

	This Agile Process	Legacy “Democratic”	Legacy “Best and Brightest”
Students per year	500+	100+	30

5.4. Retention

Anecdotally the fraction of mentors and teachers that leave the company is less than the average of all employees.

6. Challenges

For convenience we gathered here the challenges to this agile teaching process.

Administering an in-house teaching process is demanding. The tasks include: consulting with business leaders and experts about courses that should be developed. Finding an expert that is willing to design and teach the course. Tracking the progress of the course design. Ensuring that employees are aware of the list of available courses. Sharing results with business leaders.

In house expert resources are diverted from their regular duties. This is facilitated by leadership agreeing that knowledge sharing is an official part of an expert’s duty.

Assumption that domain experts are apt at teaching. This was a major unknown at the beginning of our pilot, but the results are positive. At least in technical fields, most experts can teach efficiently (based on the student NPS scores for experts vs. external faculty classes). Still, we had to cancel about 10% of experts due to their inability to teach.

A minority of employees prefer async training. An easy remedy is to record the classes and let each employee decide whether they prefer to join a sync class or to listen to the async material.

What happens to their class when an expert leaves the company? It happens, and the administrator must find a replacement expert to teach the same class. The replacement expert is made aware that the course material is now theirs and that it is within their rights to adjust the material to their teaching style.

7. Business Impact

For convenience we gathered here the impact to the business of this agile teaching process.

Mastering data driven decision making. Some parts of our big organization have business leaders that push for more data-driven decision making. The progress toward that goal was slow and the reason might have been due to the engineering workforce, on average, having a lacking knowledge in AI/ML. After three years of applying this agile teaching process we have boosted the knowledge of machine learning to more than 500 employees. Many of them are now genuinely excited by this technology, and now push for data-driven decision making from the bottom-up as well. Compared to a few years ago, our company is noticeably more agile in extracting knowledge from data. It is hard to quantify how much of it is due to our application of this agile teaching process.

Low dollar cost. Not having to pay for external faculty is a cost saving. Even async teaching material can be expensive. With this agile teaching process, the dollar cost is replaced with the in-house experts being diverted from performing their regular duties. This “cost” is welcome if leadership agrees that knowledge sharing is an official part of an expert’s duty.

Scalability with no cost increase. If it is in the business interest to spread some knowledge quickly, or simply if a class is very successful, the expert will teach more frequently, say 8 hours per month instead of 8 hours twice per year.

Expert employee retention. While anecdotal (this one pilot cannot be considered statistically significant) it seems that designing and teaching a course has beneficial effects for expert employee retention. If true, it is likely due to the combination of two psychological effects: the pride of being selected to design and teach complex material to the rest of the company; as well as the significant increase in connections, sometime even new friendships, between a teacher and their many students.

Significant gains in NPS performance. Based on the students’ NPS ratings, their least favorite method of learning is asynchronous, where the company selects some async training material (sometime quite expensive) and the student is left on their own. Next up, with a significant NPS jump, is external faculty teaching. Lastly, the agile teaching process described in this document with its in-house expert-based teaching, has the highest NPS scores.

8. Conclusion

In this paper we described an effective agile process for teaching technical subjects in the workplace.

This process is scalable, it closely tracks the educational needs of the business, it empowers the continuous education of technical employees, it builds a community with the same passion, and it does not require any additional budget.

How? By leveraging the expertise that already exists within the company.

In-house domain experts design and teach short lessons. Because the teaching material is being built by the company’s employees, it is always fine-tuned to the company needs. Because each lesson is short, it can easily be scaled up to more iterations for classes in high demand.

Students are grateful because they have a sync teacher and can ask questions but also because the course material is cut in small lessons and easier to fit within their busy schedule. But learning is only half of the path toward proficiency. The other half is practice, and practicing new skills is hard. When to practice is completely up to the student. Yet, the student can still get async help from mentors through a company-wide messaging app. Select graduate students are asked in turn to become mentors, making the whole process scalable. Student's satisfaction is clear given that their average NPS is above 90% promoters.

Lastly, and this benefit was not originally planned, we found that this process forces the interaction between experts, students, and mentors and organically builds a community with the same passion and ultimately is likely to strengthen employee retention.

Abbreviations

SME	Subject matter expert. For clarity, in this paper, we use “in-house domain expert” instead
Mentor	Learning assistant
Sync	Teacher and students are interacting in real time
Async	Student is consuming a previously prepared material
NPS	<p>Net Promoter Score:</p> <p>Students rate a class from 1 to 10.</p> <p>Total = number of student ratings</p> <p>Promoters = number of ratings equal to 9 or 10</p> <p>Detractors = number of ratings equal to 6 or below</p> <p>$NPS = (Promoters - Detractors) / Total$</p>

1. Introduction

The proliferation of microservices as a dominant IT architecture has created opportunities as well as challenges for operations teams responsible for maintaining software reliability. When production systems deviate from service-level objectives, operations teams must detect failures and discover their root causes to promptly resolve the issue. These teams are most often focused on minimizing mean time to resolution (MTTR) or mean time between failures (MTBF). The process of identifying, diagnosing, and resolving issues in cloud microservice architectures largely falls into two phases: anomaly detection (AD) and root cause analysis (RCA).

AD is the process of identifying anomalies that correspond to system failures. RCA is the process of determining the reason why an anomaly occurred and identifying the originating service or system. Anomalies are typically detected by defining margins of normal operation on key performance indicators (KPIs) and setting alerting thresholds that generate notifications. RCA is then typically performed by inspecting the system that generated the alert and tracing the problem back to its source. Operations teams use log, trace, or metric data sources, often displayed in dashboards to diagnose and debug problems.

However, there are several problems with this and related existing approaches:

- (1) ***Simplistic AD still dominates:*** State-of-the-art failure detection is still based on simple thresholding, which is prone to drift, and fails to capture low-frequency events such as weekends, holidays, or special events. Failure detection based on simple thresholding, misses opportunities to preemptively diagnose problems, thereby increasing MTTR.
- (2) ***Manual RCA still dominates:*** Root cause analysis is the most time-consuming step of issue resolution, largely due to a reliance on a human in the loop. When an alert is received, reliability engineers spend significant time identifying the root cause by looking at numerous plots, traces, and logs. This work is repetitive, tedious, and ripe for automation.
- (3) ***Excessive alert volume:*** Operations teams often receive a large volume of alerts, many of which are false or redundant. These are generated by rules that often remain unchanged for the life of the application. Further, the volume of services in a microservice application makes it difficult to know if a service has failed on its own or as part of a cascade.
- (4) ***New deployment challenges:*** When a new product or service is deployed, the operations team keeps a closer eye on the alerts, metrics, and system performance. The decision to move forward to 100% general availability (GA) or roll back to a previous version usually takes unnecessary lead time, which may create negative customer impact.
- (5) ***Institutional knowledge monopolies:*** Often the knowledge needed to quickly debug operational problems is held by a small number of individuals on the team. Root cause analysis can be time-inefficient except for the few individuals who hold a monopoly on that knowledge.

According to the report by Smartsheet [1], nearly 70% of employees say that automation reduces the time wasted on repetitive work, and out of which nearly 60% believe that if repetitive jobs were automated, they would save 6 or more hours (almost a full workday) each week. This brings huge opportunities for AIOps.

1.1. What is AIOps?

AIOps (AI for IT Operations) uses artificial intelligence and machine learning (AI/ML) and big data analytics to identify or predict IT operations issues in a timely manner and help the DevOps team quickly identify the root cause of the issues. A machine learning model can learn the conditions that lead to an alert and can predict when an alert is about to occur. When an alert does happen, ML based RCA is used to generate candidates of sources of failure to be diagnosed by a human operator. Thus, it can reduce MTTR by automating repetitive jobs, present failure, and provide better decision making.

AIOps has recently received extensive attention from industries and academia. According to a survey by Reportlinker – “AIOps Platform Market Forecast to 2028 - COVID-19 Impact and Global Analysis by Component, Deployment, Organization Size, and Vertical” [2], the AIOps platform market size is expected to grow from \$ 2.8 billion in 2021 to \$ 19.9 billion by 2028. It is estimated to grow at a compound annual growth rate (CAGR) of 32.2% from 2021 to 2028. Apart from the market growth, its impact can save much more than that by providing the predictive abilities which will lead to efficient utilization of resources so that companies are able to cut additional costs related to overprovisioning of their cloud and other resources. It will also help in better application maintenance resulting in a better overall customer experience, thus positively contributing to business revenues.

1.2. The Difference from MLOps

The terms “AI” and “ML” are interchangeable in many contexts. In this context, however, the meaning of MLOps and AIOps are significantly different. MLOps refers to machine learning model operations, from data acquisition to model development, testing, validation, and deployment. MLOps seeks to increase automation and improve the quality of production ML models, by focusing on the operation of ML models, and leveraging the continuous integration/development (CI/CD) practice of DevOps in the software field.

The AIOps methodology is applicable to any IT operations, including MLOps. AIOps could make ML model operations more reliable and cost effective. On the other hand, the MLOps pipeline could be leveraged to make the operation of AIOps itself more efficient and reliable.

1.3. Why AIOps?

AIOps aggregates data from multiple sources and provides context and insights when problems occur. It improves the visibility (observability), reliability, availability, and cost of IT operations. In general, AIOps provides the following key business benefits:

- (1) **Improved system availability:** AIOps improves availability by reducing MTTR in several ways. First, predictive AD can intelligently identify issues before they occur, automatically categorizing issue criticality, and preventing unnecessary escalation of issues. Second, automated RCA significantly narrows the scope of the problem on which a human operator must focus, greatly reducing the amount of time needed to reach resolution. Third, capturing institutional knowledge to a model means faster issue resolution, even if less experienced operators are on call.
- (2) **Reduced operational cost:** There are multiple ways AIOps reduces operational cost. First, as AIOps sends out fewer alerts and automates RCA, the resulting reduction in workload could potentially reduce the headcount of operations teams. Second, as ML models can predict the pattern of traffic from historical data, AIOps can help to orchestrate resources more intelligently for cost savings. Third, AIOps helps to quickly identify any potential issues within limited

deployments and provides better insights and decision making before promotion to GA, reducing unnecessary use of valuable human and computing resources.

- (3) **Improved employee experience:** The reduced number of false alarms creates more efficient (noise free) work for reliability engineers while lowering the overall work volume. Online learning models eliminate threshold drift and reduce manual effort. The AIOps system can act as a partner in a pair-debugging strategy, that enhances the capabilities of the human operator. The overall reduction in issue volume results in a happier, more productive operations team by eliminating pager fatigue, allowing them to focus on more meaningful tasks.

Our AIOps team is striving to help address the operational challenges with AIOps. We have explored and experimented on several use cases including:

- (1) **Intelligent Infrastructure Monitoring (IIM):** We built the state-of-the-art anomaly detection technology to alert the DevOps team with detected anomalies based on load and resource utilization to prevent application failure as early as possible.
- (2) **Root Cause Analysis (RCA):** When there is an anomaly or a failure in the operation, we correlate the system and application log data with the detected anomaly and help the team to quickly identify the root cause and recommend the correct actions to the team.
- (3) **Release Management (RM):** We use ML to help manage the release by quickly identifying when a gap occurs with a partial rollout.

In this paper, we will give an overview of AIOps use cases and summarize our findings from several practical case studies from IoT (Internet of Things), content discovery, and RDK (Reference Design Kit) applications.

2. AIOps Platform Architecture

In this section, we describe the high-level AIOps platform architecture we built, as shown in Figure 1.

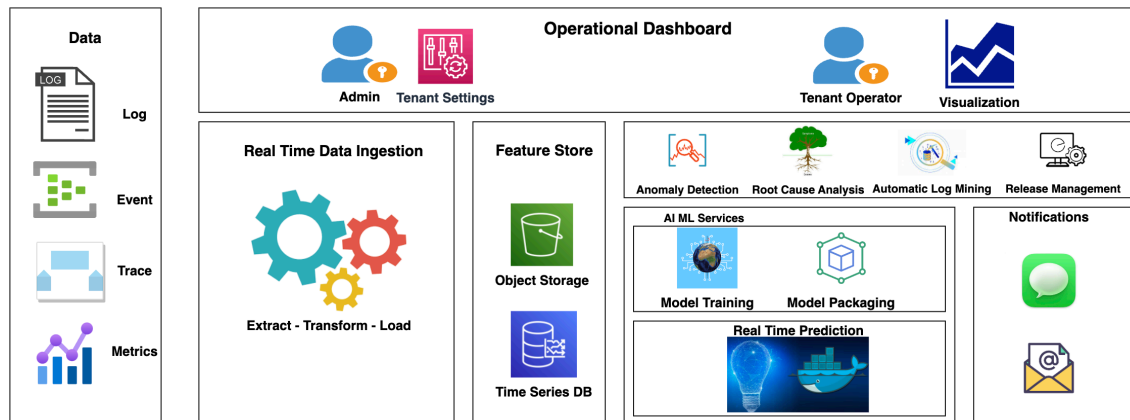

Figure 1 – AIOps High Level Architecture Diagram

AIOps architecture address end to end solution right from data ingestion to data transformation, data storage, model training, real-time prediction, fine tuning of model and notifications.

The data layer is composed of the data from different tools (e.g., metrics and log data sources) and systems, internal or external. This data may include a large scale of logs, events, traces, and

metrics data from applications onboarded onto the AIOps platform. Data transformation layer performs required transformation on the data and load to Feature Store. The data is ingested into the backend, and further engineered (e.g., transformation, aggregation) to store in the feature store (Object Storage or Time Series Database). AI/ML Service is the core of AIOps that enables model training, model tuning and real time inference for any selected operational metric from the feature store. Model training layer gives the ability to an operator to select, and tune required model to trial run and fine tune until the operator satisfies with required precision, recall against operational metrics and save the configuration for real time prediction. Model training can be supervised, semi-supervised, or unsupervised. The real time prediction layer performs prediction on the scheduled frequency against the scheduled time and stores the results. High level use cases like Anomaly prediction, Root cause analysis, automatic log mining, release management is performed. Notification layer alerts users on the configured channel like messenger, email etc. The data can also be visualized via an operational dashboard. The dashboard also provides a visualization of the output generated from the AI/ML engine and allows operators to provide feedback which can be incorporated in the models for better AI/ML predictions. With some business logic or high-level rules, we also allow generation of a report, which will alert the operations team via e-mail, SMS, or messenger. The major challenges in building AIOps architecture are listed in the following subsections.

2.1. Real-Time Data Processing

Real-time data processing is critical for AIOps, as timely prediction of application issues and outages brings strong value to the operators. This involves designing suitable architecture that can handle complex tasks including data ingestion, model prediction, and alerting in real time.

2.2. Scalable Architecture

Scalability is another key aspect in AIOps since the architecture must handle thousands of metrics coming from different application services, ingesting real-time metrics every second, and inferencing anomalies at seconds' level. For example, for a scale of one thousand metrics that are ingested every minute and inference also made at minute level, we are looking at more than 1 million model inferences per day.

2.3. Data Storage and Retrieval

As data is the key for any ML tool, access to historical data will help the ML model train over a longer duration which can lead to a better model fit and reduced bias. AIOps architecture facilitates data storage and retrieval for longer durations with the ability to retrieve data with minimum latency.

2.4. Real-Time model training and model packaging

With AIOps, operators can experiment with multiple machine learning models, train a model for a specific metric with historical data, package the model for inference instantly, and schedule the model for real-time inference on that metric. Operators can also provide feedback on the test inference and fine tune the model in real time. So, real-time model training and packaging is one of the core requirements fulfilled in our AIOps architecture.

3. AIOps Use Cases

Through AIOps, we are aiming to empower DevOps teams to perform their tasks efficiently. The following are the major use cases which we plan to incorporate in the AIOps platform for the benefit of operators:

3.1. Proactive Monitoring

Operation teams have been using monitoring system and observability platforms to configure alerts for their applications. The drawback of such an arrangement is that the alert threshold remains static, whereas the applications, or their usage, evolve over time due to various reasons requiring operations teams to regularly adjust their alert thresholds to avoid noise caused by false alarms. Also, there can be cases where certain problems in the system go uncaptured.

For example, batch jobs happening at a specific time can create a spike in application metrics. Spikes during that time would not be an anomaly since it's an expected behavior but at other times it could be an anomaly. Perhaps the batch job is taking a longer time than expected and if so, this is an anomaly to notify. In a traditional setup, this could be missed since thresholds are static and don't take into account such changes in data behavior.

AIOps learns from historical data. Especially in this case, the model would learn from the time-series data pattern and seasonality trends to capture these abnormal behavior and notify accordingly.

3.2. Smart Alerting

Alerting in conventional systems is based on static limits. In AIOps, we take advantage of AI to have dynamic thresholds depending on the trend of data. Apart from the metric threshold rules, we can also have rules based on model confidence. Confidence of model can be described as the certainty or strength in prediction done by a model on certain data, whether it is anomalous or not. This confidence is developed by the model learning from historical data over a period of time. This can even surpass human performance since sometimes it's not possible for the operators to continuously monitor such high loads of data manually, whereas ML models can do that easily.

This feature is useful in predicting potential system latency or downtime which normally wouldn't be captured using metric threshold-based rules. Thus, this feature helps DevOps with such cases and in turn, improves the customer experience with our applications.

3.3. Topology Analytics and Root Cause Analysis (RCA)

Topology analytics is used to establish a dependency topological graph of application, network, and infrastructure for a complex system, and to drill down to the root cause of the issue. Since AIOps is ingesting live metric and log data, AI models can predict anomalies in real time. These predictions are further used to correlate anomalies between various system metrics using statistical techniques such as Pearson Correlation Coefficient [6], and give a list of most probable root causes. It will be a much faster process compared to the operator doing RCA manually over thousands of metrics at a time. This feature will immensely help the DevOps team in automatic identification of problems and help them reduce MTTR in general.

3.4. Log and Trace Analytics

Each application may also have an immense volume of application-specific log and trace data. By leveraging Natural Language Processing (NLP) tools, we can extract the log metrics and their context from certain error/warning entities present in such data and perform anomaly detection against it. Additionally, we can also do correlation analysis to correlate the log anomaly with application metrics anomaly which can help the operations team to quickly identify the root cause of the issue. Similar analysis can also be done for trace data.

3.5. Cohort Analysis

Building on top of RCA, cohort analysis can provide further insights into system performance. It can point the team towards the probable issue in particular parts of their system even though they haven't received any specific alerts on them.

Multi-variate time-series analysis, i.e., time-series analysis done simultaneously on multiple metrics and clustering on anomalies as well as error logs, can correlate and identify such groups of metrics or systems that are causing problems, and can notify the team accordingly in advance for better maintenance of their application, all leading to better customer experience.

3.6. Automated Remediation

Consider a case where an application is deployed in a Kubernetes cluster, a group of nodes used in a Kubernetes deployment. Assume there is a 'garbage collection' system metric emitted from the cluster pods indicating one of these: application might go to a bad state or there's a problem with the pod itself. In general, this metric count is ignored since it's a normal behavior of the application. In some cases, though, it could actually be a problem with the cluster pods. Time-series models can detect such changes in data trend patterns and provide alerts to the team. Going one step further, the system can automatically take some actions (e.g., auto-restart) for remediation before it results in any application downtime or customer impact.

3.7. Smart Orchestration

Many teams use major cloud providers' auto-scaling features or their own customized rule-based scaling for their application resources. Through AIOps, we provide them with more intelligent auto-scaling abilities. Since the model will be able to forecast demands by learning the pattern and behavior through historical data, it will recommend the most efficient option available. This will ease the load on DevOps in their capacity planning for their cloud and other such resources, and provide significant cost-savings for the application team. In this manner, AIOps will be useful for an organization to reduce their software operational costs.

3.8. Release Management

When new software or firmware is deployed, it is often done in a phased manner. After a small portion of deployment occurs, AIOps can be used to analyze the difference between the new deployment and the previous version using machine learning models. If there are some significant changes, the model will identify which parameter or characteristic has changed. These insights would help the operations team to make a decision on whether to continue with the deployment or to roll back to a previous version.

4. Anomaly Detection

Anomaly detection is the key for proactive monitoring. It can be used for data quality monitoring, and fault detection of IT operations. Anomalies can be observed in tabular data, timeseries, or temporal data, as well as in graphical images. However, when it comes to fault detection in IT operations, data is typically in the form of time-series and so time-series anomaly detection is performed in AIOps.

Anomaly detection refers to identifying any abnormal behavior or pattern of data from the learned normal pattern from historical data. These anomalies may indicate a problem or an interesting event. The learned model can be used to detect anomalies with varying degrees of probability, and to predict future data with certain confidence.

4.1. Anomaly Detection Algorithms

When it comes to detecting anomalies in time-series data, the task can be performed either in a supervised, a semi-supervised, or an unsupervised fashion depending upon the dataset.

- (1) Supervised anomaly detection is possible when we have annotated data of anomalies available. We can split the data with anomalies into train and test data, and train a machine learning model as a binary classification problem, which means, training a model to predict whether a point is an anomaly or not using the labels available as feedback to train the model. This method can be performed using any machine learning model that can be used for binary classification such as Deep Neural Networks (DNN), Support Vector Machines (SVM), Random Forest, Gradient Boosted Tree (GBT), eXtreme Gradient Boosting (XGBoost), and others.
- (2) Semi-supervised anomaly detection can be performed when we do not have labelled anomalies, but we have a significant amount of data that is normal and do not have many anomalies that we can use for training a model. This model is trained supervised using the normal data and it learns the normal data behavior. It then detects anomalies when any deviations are observed. A DNN model like Autoencoder, which is a kind of neural network that learns a pattern and tries to replicate it, can be used for this. We can also use other DNN models like Long short-term memory (LSTM) and Deep convolutional neural network (CNN) (e.g., DeepAnT [3]). One-class SVM, Gaussian Mixture Model (GMM), Kernel Density Estimation (KDE), and others can also be used for performing semi-supervised anomaly detection.
- (3) When we do not have labelled data, as in most practical situations, we use unsupervised anomaly detection techniques. In this, the train or test data may or may not have anomalies. The models in this class generate an anomaly score for every data point and we can select a suitable threshold depending upon the data to classify points as anomalies or not. This can be accomplished using statistical methods like simple Moving Average model or complex ones like Prophet Forecasting Model [4] (uses Fourier series) or SARIMAX (Seasonal Auto-Regressive Integrated Moving Average with eXogenous factors, an extension of the ARIMA model - Auto-Regressive Integrated Moving Average). These approaches learn the periodicity or seasonality and the trend of the time-series data, and detect when the data deviates from the normal pattern. Density or distance-based outlier detection algorithms like k-Nearest Neighbors (kNN), Isolation Forest, or Local Outlier Factor can also be used to perform unsupervised anomaly detection.

With users' feedback, the detected anomaly can be labelled as true or false detection, and stored in the database. The historical annotations of ground-truth labels can be useful to evaluate the performance of the anomaly detection model in terms of evaluation metrics like Precision, Recall, and F1-Scores [7]. Also, they can be used to train a classification machine learning model for performing supervised anomaly detection. By getting feedback from the user (an

operator) for false positive detections, we can also adjust the threshold for anomaly detection, which is particularly beneficial to improve the accuracy for semi-supervised and unsupervised models.

4.2. Anomaly Detection Platform

We built an anomaly detection platform for proactive monitoring (Figure 2) with the following functionalities.

- (1) **Algorithm selection:** We allow the user to select among multiple algorithms, which run in real time by learning the seasonality and trend from data. We have options to perform either unsupervised, semi-supervised, or supervised anomaly detection depending on the use case.
- (2) **Special events:** There can be cases when irregularity is expected on days like deployments, holidays such as Christmas, or special events such as a key NFL game. Anomaly detection algorithms, like Prophet or SARIMAX, will consider these as special events. We have the option in our AIOps platform to provide such dates in advance to prevent false alarms as the model treats such days differently than a normal day.
- (3) **User feedback:** The tool can also take feedback from operator if they feel that certain prediction points are false positives, i.e., false alarms or shouldn't be anomalies from their subject knowledge.
- (4) **Intelligent alerting:** We provide three rules for the user to configure alerts. They are:
 - a. **Everytime** – To trigger alert notification everytime a model detects an anomaly.
 - b. **Interval Threshold** – To send alert notification only if the percentage of anomalies detected by a model out of all the data points present over a certain time period (10 minutes, 1 hours, daily) specified by a user, exceeds a certain threshold (0% – 100%) which is specified by the user as well.
 - c. **Score Threshold** – To send alert notification if a model predicts an anomaly score (based on model confidence) greater than a specified score threshold which is greater than or equal to the anomaly detection score threshold.

We allow the user to configure one or more such alerts for a single prediction model depending upon their needs. We also let the user choose the severity of the alert (low / medium / high) which they can configure accordingly.

- (5) **Messenger notification:** We send alerts to the operations team via messenger with a snapshot of the data (and potentially root cause analysis report) and a link to the data dashboard. We also provide 'Pause Alert' buttons at different durations for the operator to pause alerting for a specific metric prediction.
- (6) **Alert history:** We store all the historical alerts for all metric predictions for the user to view from the dashboard anytime. In addition, we also allow the operations team to collect the alerts as a metric data into their metrics endpoint, if required.

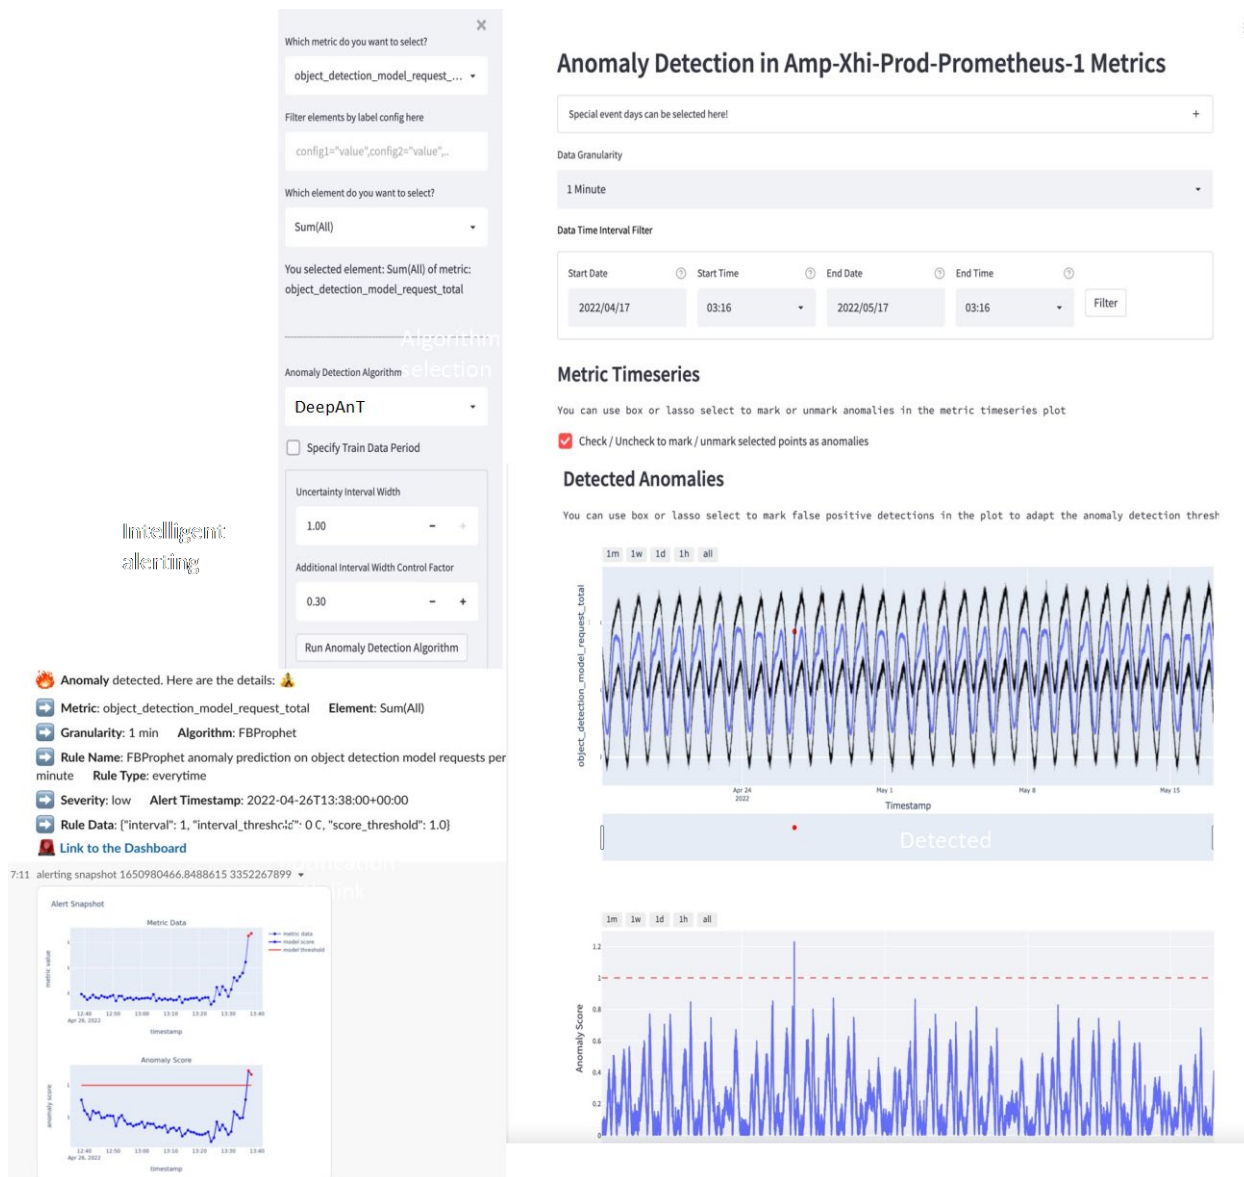

Figure 2 – Anomaly Detection Platform

5. AIOps – Operators' Perspective

This section describes AIOps from an operator's perspective as they will be the primary users of our platform, interacting with it in their routine work. This includes things that they need to know to onboard their application onto the AIOps platform, to configure anomaly thresholds, to provide feedback while evaluating a machine learning model against a specific metric, and to configure alerts for notification.

5.1. Onboarding a tenant

To onboard an application or a tenant, the AIOps tool needs read-only access to metrics data and log data sources. Log data is required if we are enabling automatic log mining to correlate with anomaly metrics. Operators can view the list of available metrics from an end point and start experimenting with specific metrics. After enabling the permission for AIOps to fetch data from their application tools, they need to provide a config file stating which metrics to pull and the endpoint configuration related details. Upon submission of this, the AIOps tool starts the data ingestion in real time.

5.2. Training a metric with model

The next step for an operator after onboarding an application is to configure an AI model. For that, they can choose the metric of interest and preview the metric trend over a selected time period. They can then preprocess the data, like aggregations, over a period and experiment with the choice of machine learning algorithms available in the AIOps platform.

The operator can perform model training live on the chosen data and preview the results on the fly. They can provide feedback like false positives or negatives to fine tune the model. After this, they can also validate the model with some test data on a certain duration of data. This process can continue until the operator is confident with the results for the data selected. Finally, if satisfied, the model can be packaged and deployed as it is ready for real-time inference.

5.3. Schedule a metric for real-time inference and prediction

With the AIOps platform, the operator can schedule one metric or a group of metrics for real-time inference configuring the frequency in any duration. Once configured, the AIOps platform will continue to run the selected model for metric anomaly analysis in real time.

5.4. Configure Alerts and RCA

Alerts can also be configured for the detected anomalies along with the severity and the considered interval or a model score threshold. The corresponding alerts can be notified to clients using messenger via their web APIs.

Root cause analysis can be performed automatically where the system performs correlation calculations on multiple anomalies detected on the metrics around pre-selected specific periods. This is performed by correlating the anomalies detected with the errors observed in log data in order to identify the most probable source error logs that could have caused the anomalies through a scoring mechanism which helps to rank the root cause errors. The AIOps tool recommends a possible hypothesis that corresponds to the most probable root cause of the problem which an operator can easily pick up for subsequent actions towards resolution. In this way, MTTR can be reduced greatly by using our AIOps platform.

6. AIOps Case Study: Connected Living Object Detection Operation

For our Connected Living business, we have millions of cameras in customers' homes. Our customers would like to get notification when objects (e.g., person, vehicle, and pet) or events (e.g., package delivery) of interest are detected from their cameras. The AI for Connected Living

team built the state-of-the-art house object detection algorithm which is used to efficiently detect person, vehicle, and pet.

The main challenge for the object detection operation are as follows.

- (1) There are many metrics to keep track of such as load (request per second), latency (upstream, downstream, and inference), CPU, and memory for each node.
- (2) The load (request per second) changes dramatically between day and night. There is a greater load in the daytime than in the night which is reasonable as generally human life is busier in daytime. The previously used static threshold rule-based alerting is not adaptive to address this issue.
- (3) The application has lots of log data. It logs the interactions of the object-detection module with the input metadata (from camera and the backend platform). Once there is an alert, the operations team often needs to dig into this log data to identify the root cause.

We onboarded this application onto the AIOps platform to help the operations team by addressing the above challenges. In that, we deployed time-series anomaly detection algorithm to alert the operations team in messenger, and then correlated the detected anomaly with log metrics anomaly to report what error messages are the probable root cause.

6.1. Connected Living Object Detection Operation

The metric data¹ of concern for this case study is the number of object detection model requests per minute. This metric captures the information of the load and has a well-defined daily seasonality pattern as we can see from the sample metric time-series plot shown below in Figure 3.

Figure 3 – Metric in Object Detection Operation

In the Figure 3, we can observe the metric time-series data plotted in blue. As we can observe, there are situations that lead to some sudden dips or spikes in the metric values that are of concern for the operations team to monitor. The points marked in red dots are the annotations

¹ We collect, store, and use all data in accordance with our privacy disclosures to users and applicable laws.

provided by a user by using a lasso or box selection tool available in the plot in the dashboard. By default, the metric data fetched from the metrics data endpoint will be unlabeled. Since this metric data is unlabeled and it has a well-defined seasonality, we chose an unsupervised anomaly detection algorithm for this case study. Prophet [4] is one algorithm that can be used for univariate time-series forecasting as it fits on the historical data and forms an additive model of the trend, daily, weekly, and yearly seasonality components, as well as holiday effects, and additional regressors that are available and learned from the data. By fitting such a model over this data for a training period of at least two weeks, we get an accurate model that learns the seasonality and forecasts with anomaly scores that can be derived from the uncertainty bounds generated by the model. The anomaly score is controlled by the interval width factor (which represents the percentile values) and an additional multiplicative factor controlling the width of the model prediction bounds. Since the model generates samples by Maximum A Posteriori (MAP) or Markov Chain Monte Carlo (MCMC) sampling techniques, along with the expected predicted value, we can also get the percentile values that are used for generating the uncertainty bounds and in turn, the anomaly scores. We can observe the predictions made by the model in the following time-series plot in Figure 4.

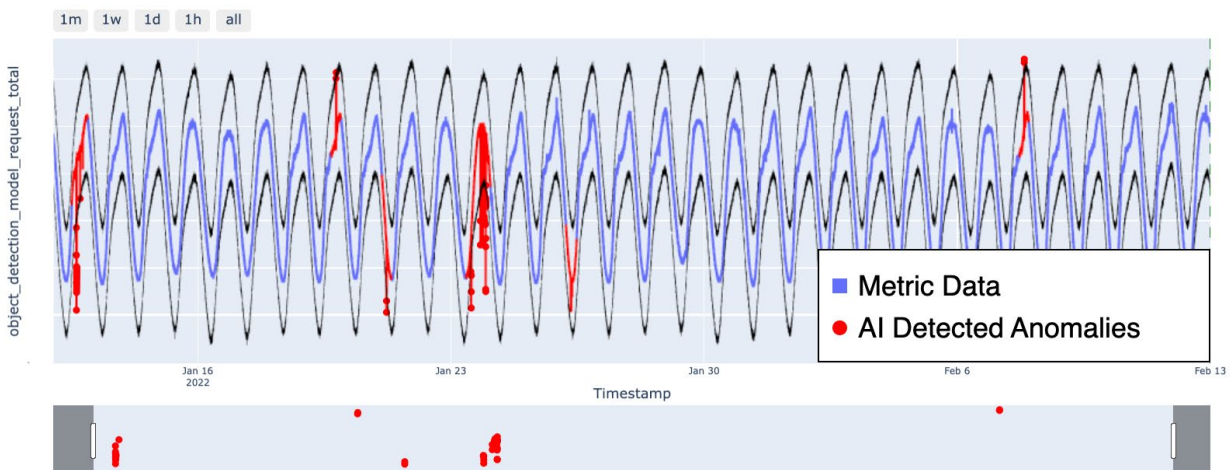

Figure 4 – Anomaly Detection Predictions in Object Detection Operation

We can see the points that are marked in red, and they represent the anomaly detections made by the model. Since the ground-truth labels are annotated in the metric plot, the sections of the time-series data where labels are provided have been marked with red lines while the other sections are in blue. These sections represent a tolerance interval to evaluate the model performance in terms of Precision, Recall, and F1 Scores. Having a tolerance is generally followed for time-series anomaly detection evaluation as forecasting anomaly in advance proactively, or after a pre-defined delay, is generally acceptable [5]. So, predictions happening within such contiguous tolerance intervals are all considered as precise predictions while evaluating a model's performance. Since this is followed in literature and by popular service providers, we have followed a similar approach.

The model evaluation is subjective to the dataset and what the operator chooses to mark as actual anomalies. Therefore, we cannot have evaluation metrics for all the models at all data periods. In

this section of the data shown in Figure 3 and Figure 4, however, the evaluation metrics are as follows:

- Precision: 1.0
- Recall: 0.87
- F1 Score: 0.93

Just as we can annotate labels in the metric plot shown in Figure 3, we can also annotate false positive predictions in the plot shown in Figure 4. That feedback is used to adjust the anomaly score thresholds to predict those points as normal. We fitted our model on this dataset and adjusted the thresholds to have a good prediction model that can accurately detect anomalies and alert the operations team for further investigation by setting an alert after the training and fine-tuning activities of the model are completed. The alerts are sent to a messenger channel with the information of the alert and the metric data and provides a snapshot of the metric and anomaly scores. There is also a shortcut link provided to the operator for them to look at the data dashboard directly from the message. As we can see from a sample snapshot of the messenger alert shown in Figure 2, the operations team was notified of the alerts in real time by the application and they were able to check why the object detection requests suddenly shot up. This real-time data pulling, model inference, and smart alerting capabilities that are provided by the application helped to ease the monitoring task performed by the operators for this case and provided timely alerts for them simplifying their operations.

6.2. Log mining and Correlation Analysis

Beyond anomaly detection and timely smart alerting, one of the common situations faced by an operations team when they encounter such alerts is finding the root cause for an anomaly. This operation is not straightforward, and the DevOps team will have to manually look over the log messages to identify the errors and warning messages in the logs within the period closer to the timestamp when the alert occurred. This manual operation is usually time-consuming and may also critically impact the businesses if the resolution or remediation cannot be taken within a certain time. A sample of such an operation has been shown in Figure 5.

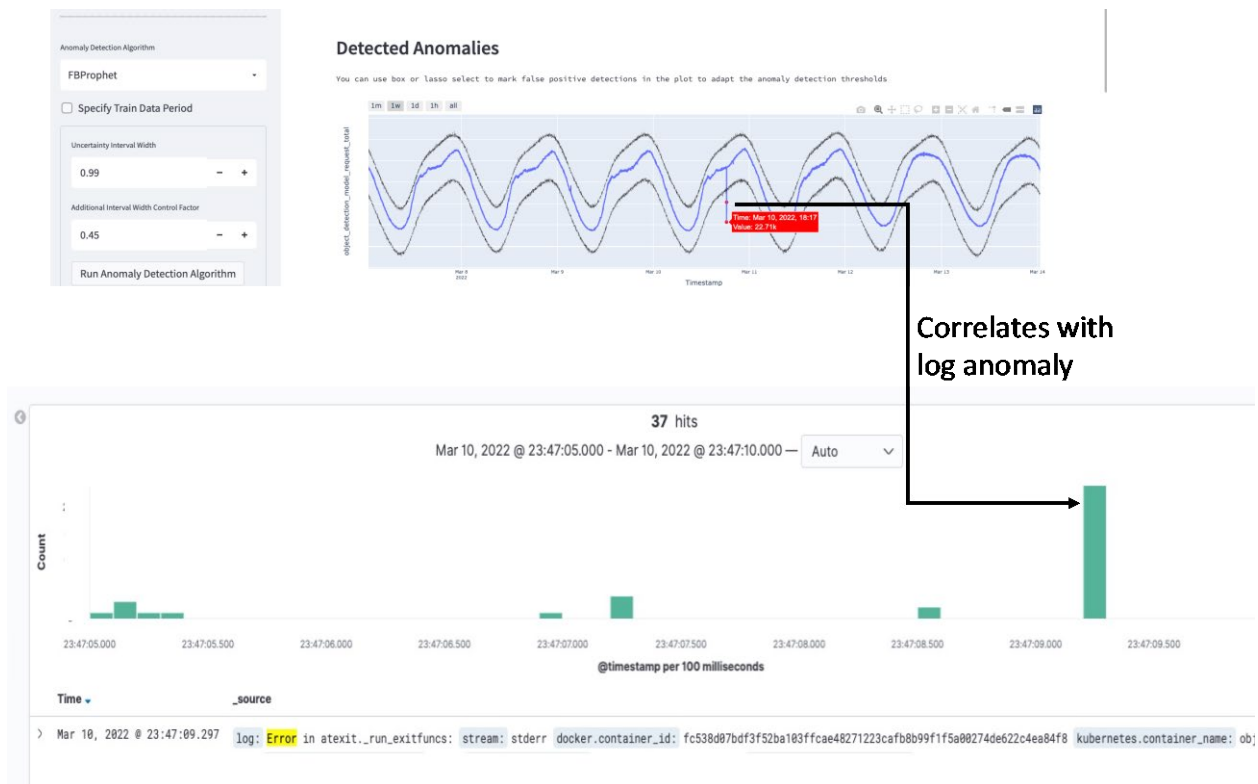

Figure 5 – Manual Log RCA in Object Detection Operation

In this Figure 5, we can see that an alert has been sent to the operations team of an anomaly detected in the object detection requests per minute metric. In order to find the root cause, the log messages in the dashboard were scrutinized and the team was able to identify a unique error log message that was logged near the timestamp when the anomaly was detected. As we can see that the requests had suddenly dipped, we observed that it was due to a deployment that had taken place at that time that was causing some errors from the Kubernetes pods running the object detection model containers. To reduce this manual effort, for this case study, we worked with the operations team to help them solve this problem using intelligent log mining and automatic root cause error analysis, in addition to anomaly detection and alerting.

In our application, we added the feature to pull and store log messages in addition to pulling and storing metrics data. We do not store every log message but only error and warning log messages through smart keyword searches for such terms in the logs. Apart from pulling and storing the logs, we also do intelligent text parsing to identify different kinds of log messages. With this method of segregating the error logs and labeling each type uniquely, we create error log count metrics for each error log message type, and store them as a separate metric.

So, the outcome of intelligent log mining provides us the error log metrics that can be used to individually train anomaly detection models to predict and alert whenever a pattern changes or an appearance of an error log message occurs. In addition to performing anomaly detection on them, these metrics can also be used for root cause analysis when anomalies are detected in metrics as we have a mechanism to correlate anomalies detected on a metric with other metrics over a selected data period and provide a ranked list of correlated metrics as probable root causes, as we'll see in the next case study.

Even though the error log metric creation gives us two potential use cases, the primary objective of log mining is to perform intelligent instant root cause analysis directly from the log messages when anomalies are detected in metrics, and to notify the operator of the alert along with the probable root cause error log messages in the messenger notification. For this, we have some scoring mechanism that is used to rank the error log messages that appear in the recent past period from the time the alert was identified, by comparing the frequency and distribution of the same over a much larger previous historical period. This helps us provide the operations team with the limited set of the most probable root cause errors instantly that they can quickly identify and perform remediation. The dashboard has the option to let the user select any alert that occurred in the past and view a more detailed root cause analysis report by showing the error log trends of each of the recently observed error logs as well the raw log messages as shown in Figure 6. This implementation reduced the time taken for root cause analysis tremendously and helped the operations team to be more productive.

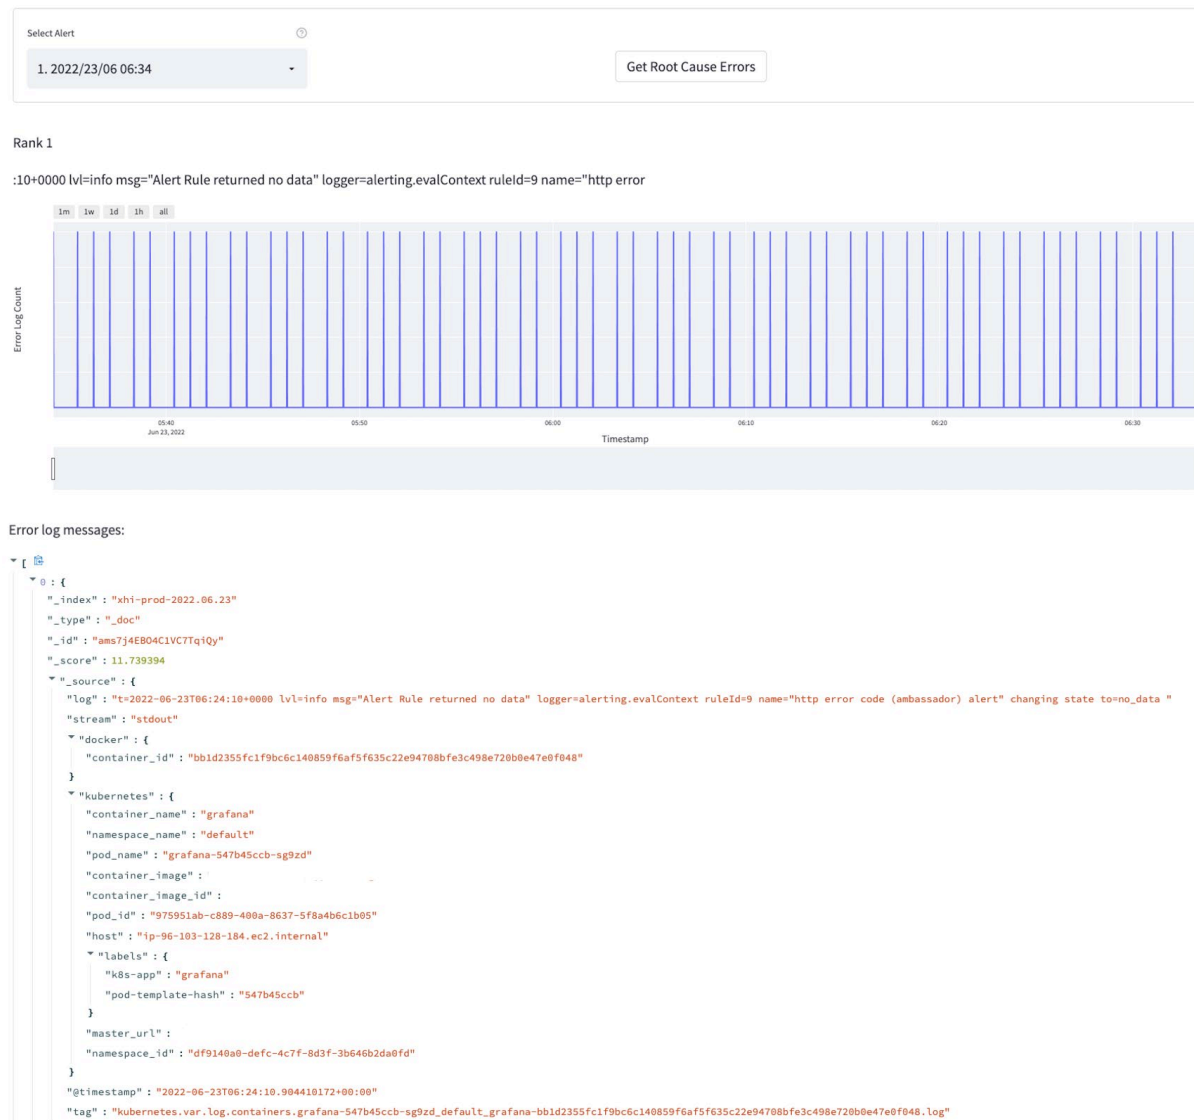

Figure 6 – Automatic Log RCA in Object Detection Operation

7. AIOps Case Study: Rex Browse and Search Operation

We have a large number of customers using an Xfinity box for cable TV and video streaming purposes. Here, the Rex platform is providing the video discovery features for X1 boxes. Specifically, Rex offers Keyword Search and Menu Browse services to X1 video clients. The platform also provides support for Video Recommendations, Personalization services and Video Metadata service.

Rex is deployed in several datacenters across the globe to cater to our business needs. Due to this, the DevOps team can handle significant complexity between various system metrics flowing from several sources. Their major pain point is performing RCA, especially in critical situations when there's time-constraint if the issue has a direct customer impact.

Let's take a look at an example using the below Figure 7.

Figure 7 – Manual Flow of Issue Root Cause Diagnosis by Rex Operations Team

Figure 7 shows the investigative steps performed by the operations team after a long diagnosis of an issue (dip in a system metric) affecting customers using Rex features. We can observe one of the regular flows of issue triaging and diagnosis performed by the Rex operations team in case of an issue. At each of those steps, the operator has to go through hundreds of metric graphs before drilling down to the next level of the problem. This process involves significant delays and inefficiencies. Because it is a customer facing application, time is of the utmost importance and MTTR converts to business value; the lower the MTTR, the better the customer experience. Through the AIOps tool, we provided features which greatly assisted the operations team in their routine work as we'll see in next sections.

7.1. Dependency Graph

The dependency graph of a system denotes the hierarchy in which different services inside the system are interlinked with each other. The network calls go from the top layered service to bottom layers according to the service dependencies. Let's look at a structure of a graph we had generated in a Rex case study. We have masked the names of the actual micro services used in Rex and have provided the contextual details alone for confidentiality concerns.

Figure 8 – Dependency Graph Created in Rex Case Study

In Figure 8, we can see the dependencies among different services (MS – Micro Service, used in the general sense of software engineering literature) and also the error flow denoted by color code (red – error, green – ok). This graph was constructed by our AIOps team using domain expertise from Rex technical operations team. We aim to automate the process of generation of such graphs in upcoming releases of the AIOps platform.

The benefits of having such dependency graphs for operations work are:

- This can be used by operations team to have a bird's-eye view on the entire system.
- Using such a hierarchical system topology i.e., hierarchy within system services, and applying RCA at each level, will help in swift identification of root cause. Also, the error flow captured will help the operator perform faster and detailed resolution.
- In this way, we are reducing the time and effort required by DevOps in their normal work, thereby reducing MTTR.
- Also, this graph can be used for efficient scheduling of on-call rotations since we know from the diagram what the affected systems are, and can estimate the efforts and expertise required to address those cases.

In the next section, we will see how we leverage AI techniques in our platform to help the Rex team with RCA.

7.2. Root Cause Analysis with Dependency Graph

As we observed in the earlier sections, manual RCA work required a great deal of time and effort by the operations team, increasing the time taken for tracing and resolving the issue. We have a feature for automating the RCA task in our AIOps platform. We performed anomaly detection on all the relevant metrics that we ingested into the platform. These are the metrics used for monitoring by the Rex operations team and are mostly custom configured metrics using queries. We then correlated the anomalies detected in one metric over a time period with those of other

metrics and generated a ranked list of probable root causes. Figure 9 shows the results of performing automatic root cause analysis using the AIOps tool for Rex case:

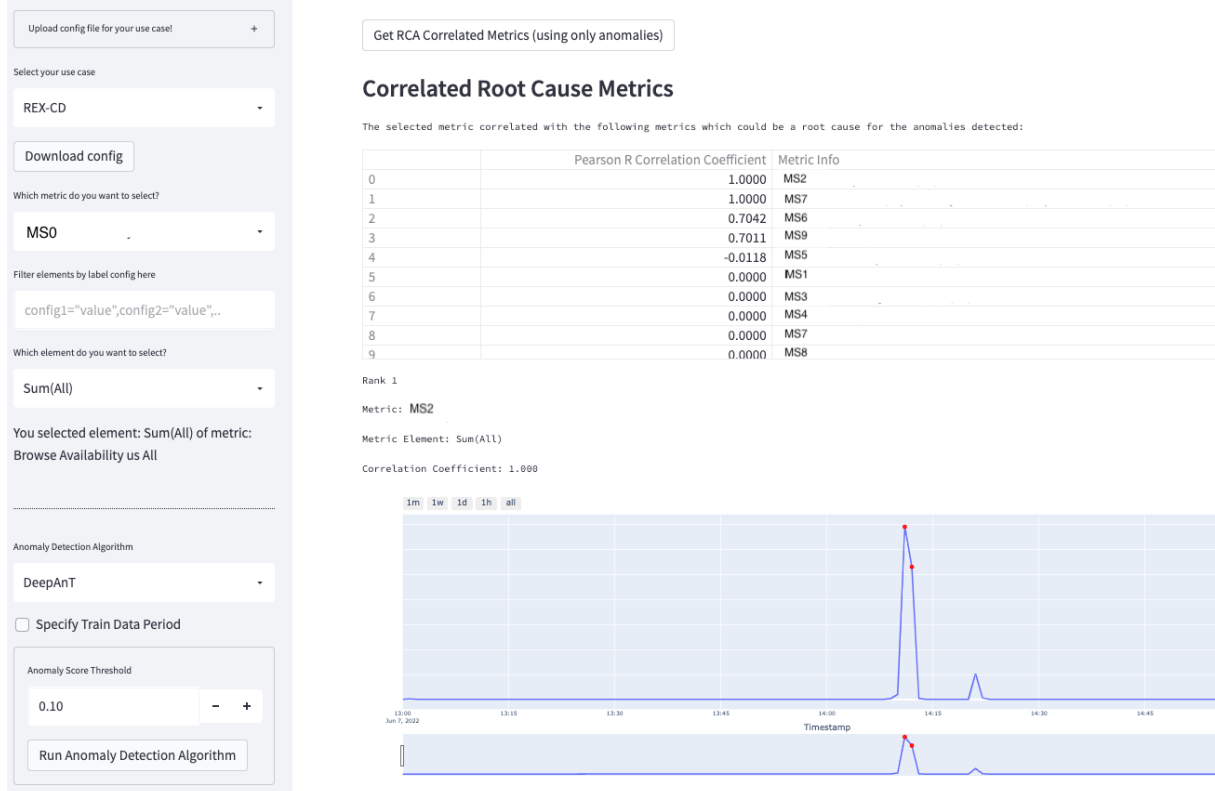

Figure 9 – AIOps Showing Automatic RCA Correlated Ranked List

As we can see from Figure 9, the tool showed the ranked list of metrics whose detected anomalies correlated with the anomalies detected on the selected metric. If we take a metric from one microservice, say MS0, when anomalies are detected and alerts are notified, the operations team can check for all other metrics from other microservices like MS1, MS6, and others where we observe correlated anomalies.

The AIOps tool shows the Pearson correlation coefficient score in the ranked list for the operator to understand how well the metrics correlate. In addition to showing the ranked list, the tool also shows the individual metric time-series plots of the correlated metrics in the same ranked order, for the operations team to quickly verify the correlations and drill down further. We can see the further list of correlated metrics in Figure 10.

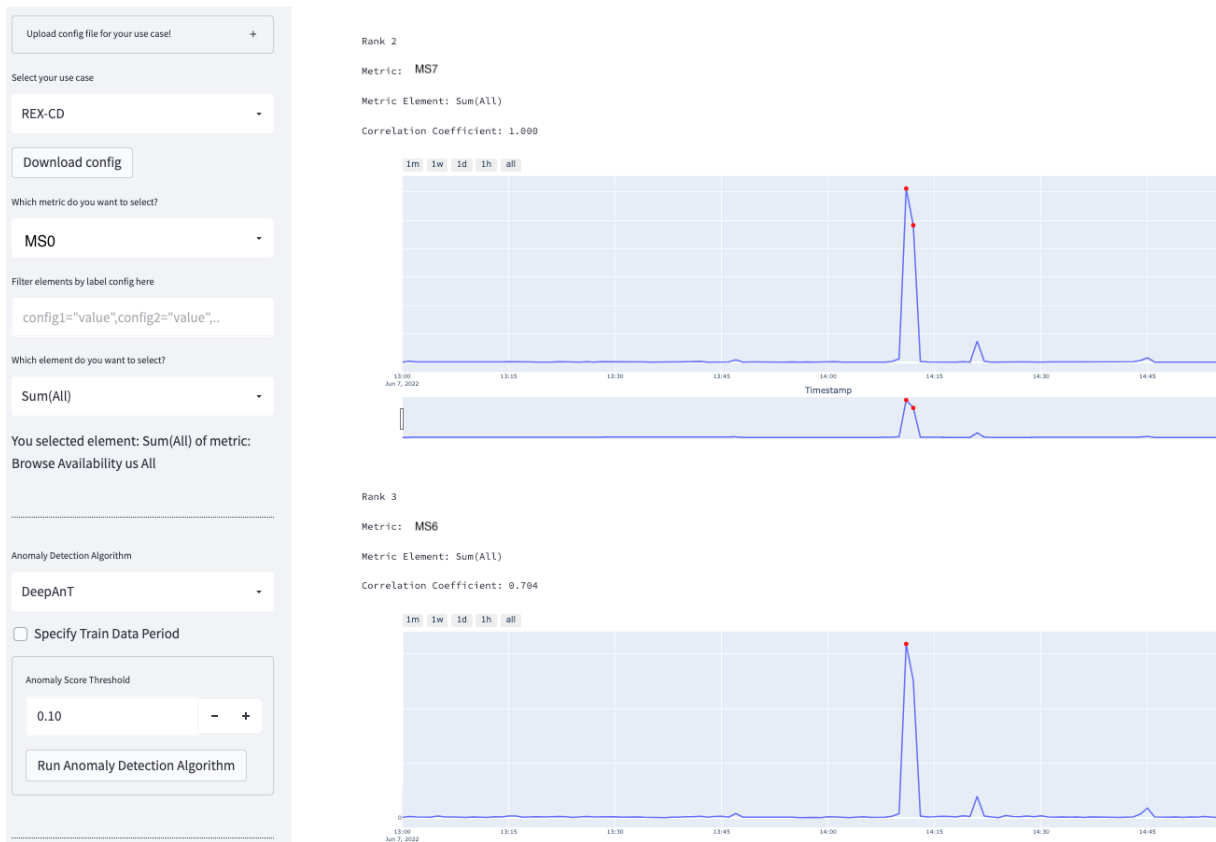

Figure 10 – AIOps Showing Probable Root Cause Metric Time-series

As per the manually identified dependency graph, we observed the root cause metrics to correlate well with the parent metric. As automatic dependency graph generation from user input is something we have in our pipeline, currently the correlations are shown across multiple levels of the hierarchical topology. However, we plan to improve the application to perform this root cause analysis at each level with only their dependent metrics (immediate child nodes) and after identifying the most probable root cause(s) with some threshold, automatically drill down further from that level and so on using dependency graph traversal as shown in Figure 8, instead of performing a correlation over all the metrics across all levels of hierarchy. This way, the operation will be optimized in the application when we have a smaller beam width for searching.

7.3. Failure Prevention and Auto Remediation

The Kubernetes pods run on Java Virtual Machine (JVM). They periodically collect garbage when requests sent by clients back up and physical memory runs low. Excessive Garbage Collection (GC) can also be a sign of the overall service going into a bad state. One or two pods collecting garbage at one time is not problematic, however GC running for hours unchecked in a self-reinforcing loop can infect other nodes. It is at this stage that drops in a metric like availability become noticeable. Any pod doing abnormal GC should be restarted after a preset period, but only if the outage is isolated to it. To accomplish this goal, we maintained a count of nodes doing GC at any given time. A two-pronged approach was used to highlight pods that can be restarted:

- First, we ruled out a system level outage by looking at the percent of pods doing GC as shown in Figure 11. The normal threshold can vary by the microservice and data center. Some data centers which are physical and running older, slower machines can be more failure-prone than others. Some microservices may be more memory intensive. Checking every such combination manually was not possible.

Figure 11 – Percentage of Pods Having GC activity per 5-min Period

- Second, assuming that there was no system level outage, we sought to find the pods with anomalous GC activity. This is a user input, defaulted to x standard deviation multiples of normal GC activity. The on-call messenger channel was alerted with the IP addresses of pods exceeding this threshold with the suggestion to reboot. The kill signal was also sent automatically as part of an auto remediation AIOps use case.

Figure 12 shows some of the malfunctioning pods. We had significantly narrowed down the list of potentially malfunctioning pods to around 2% of all pods, saving precious time during monitoring.

8. AIOps Case Study: Release Management for RDK Firmware

When a new RDK firmware version is released for Camera (RDK-C), Broadband (RDK-B) or video (RDK-V), we usually adopt a phased rollout. Usually, a small portion of customers with random selection (1%, or 5%) will be first deployed with the new firmware, and the operations team will closely monitor potential performance issues.

The challenges lie in several aspects:

- (1) There are often increasing device-specific issues, such as performance or stability, and at the same time there are hundreds of telemetries and parameters for the operations team to track. Some key parameters to monitor for each firmware version include VOD (Video on Demand), Linear, WHIX (Wi-Fi Happiness Index) [8], SpeedTest, CPU (Central Processing Unit), and Load among others.
- (2) Identification of new release issues are heavily dependent on Call-In-Rate (CIR) and high-level call movers/truck rolls, i.e., no-signal and no-block-sync. This results in long lead time for another iteration.
- (3) RCA and triaging need manual review of multiple boxes/examples. This is time consuming.

The RDK team deployed our release management AI component to drive release decisions in an automated manner. We can evaluate the impact on sub-populations (e.g., targeted/control for the specified segment such as region, CMTS (Cable Modem Termination System) version, HDCP (High-bandwidth Digital Content Protection) version, or accounts with pods) and firmware segments. Thus, the operations team can identify the anomalies with limited deployment, identify the root cause, and respond to the events quickly.

8.1. Machine Learning Model

We built a non-linear classification model to classify gateways with two firmware versions using one day's data where a new firmware version was deployed into the field. We focused on gateways with the same model to minimize hardware specific difference, and we additionally balanced the dataset such that the quantity of gateways with old version was roughly the same as those with new version.

The labels to the classifiers were the firmware versions. There are two major types of model features: counts of RDK-B telemetry key occurrence and certain measures on gateway usages (e.g., CPU usage, memory usage, Wi-Fi signal strength). Features were engineered from telemetry aggregated within a time window of 24 hours. Specifically, for a gateway with new version, features were collected within the 24 hours when the new version was deployed, and during the same 24-hour period, features were also collected for gateways with the old version. Our hypothesis was that if the version changes caused unexpected errors or performance change, then the classifier using RDK telemetry would be able to accurately differentiate the two firmware versions and indicate what telemetries were significantly impacted by the version change, and possibly point to the root cause.

8.2. Model Results

We built the model on a sample of approximately 200K gateways of a specific type. Our model was able to differentiate the two firmware versions with a high accuracy (Figure 13 Left). Based on feature importance score from the model, we were able to rank the features based on their

impact on the model performance. One of the top ranked features was the Wi-Fi signal strength on 5G band (5GRSSI_split). We further investigated that feature and found that there was a significant shift between overall signal strength distribution before and after the version change (Figure 13 Right). Here the old firmware version is 3.3p19s1, and the new one is 3.4p3s1.

Figure 13 – Precision Recall Curve for the model (Left Figure); 5G WiFi Signal Distribution for Old Firmware Version and New Version (Right Figure)

We confirmed the change with RDK-B team and learned that the shift in distribution was due to a bug fix on the reporting of Wi-Fi signal strength, i.e., old version tended to artificially report better signals with a 10 dB difference. The machine learning model we developed here not only helped us to gauge whether a new firmware release might cause significant difference in gateway performance, but also helped RCA for further investigations.

9. Conclusions

We presented an introduction to AIOps, and discussed our AIOps platform, which includes anomaly detection, root cause analysis, and release management, among many other use cases. We onboarded three applications using the AIOps platform and demonstrated the effectiveness of the platform regarding improvement in the experience and productivity of operation teams, and potential reduction in operational cost. As next steps, we would like to further evaluate the impact of AIOps quantitatively.

10. Acknowledgements

We would like to thank the following teams for the discussion and close collaboration with AIOps team to onboard the application: (1) AI for Connective Living team, especially Noam Krendel, Don Tolley, and Luke DeLuccia. (2) Rex team, especially Li Cao, Dirk Walter, Luciano Polo, and Albert Ogonevskiy for brainstorming the use case, and (3) RDK Analytics team, especially Matthew Long. We also thank Jan Neumann and Amit Bagga for their guidance.

1. Introduction

Folks already know that the speed limit in the Universe is the Speed of Light ... nothing is faster. However, many will be surprised to know that light travels slower in an optical fiber than it does in free space! Due to light-matter interaction, the speed of light, which is about 300 million m/s in free-space is 'only' 200 million m/s in glass. But in a world that prizes getting the latest information fast, this fundamental additional latency can sometimes be limiting for many applications. This was dramatized best in the Selma Hayek movie the "Humming-Bird Project", where she builds a set of line-of-sight microwave links to eliminate milliseconds worth of latency between the Chicago and New York bourses.

In this paper Comcast introduces Hollow Core Fibers and the cutting-edge work being done to reduce this fundamental latency and enhance capacity all at the same time. New fiber technology creates a fiber guiding mechanism that has a core that is hollow and consequently allows light to travel in the hollow of the fiber as-if in free space, but along the fiber path!

We describe a system which is a hybrid of hollow core fibers and standard single-mode fibers. Keeping in view that Comcast operates core and access networks this system has amplified and unamplified bidirectional Coherent systems of 400G and 100G wavelengths along with direct detect systems of 40G, 25G and 10G wavelengths all simultaneously on a single strand of fiber, in what we believe to be the first such system in the world.

In addition to describing our test system and initial results, we also analyze some of the benefits in addition to latency reduction that are related to reduced optical non-linearities and other effects and the wider spectrum and the consequent Capacity enhancements possible. Practical deployment strategy of fibers is essential at Comcast, the ability to use a portfolio of fibers for some of the emerging low latency market while also driving fiber technology deeper into the network is of the essence of our approach towards the industry initiative of 10G.

2. Background

Everyone likes to peer into the future, that most inscrutable of entities right in front of all of us. In real life, all of us generally uncover it along with everyone else, but efforts to glimpse it just before everyone else is a passion that drives great technology.

The fastest way for information to travel is at the speed of light in vacuum, that speed, set at 299,792,458 m/s is a universal constant. In other transparent media, the speed of light is slower due to light matter interaction defined as the refractive index of light. Refractive index of light is the ratio of the speed of light in the medium vs. the speed of light in vacuum. For water this number is 1.3, and the mismatch in the speed of light in air and water is what makes a straw in water look like it is shifted. Furthermore, the same effect also allows for reflections at the boundaries and these features are exploited to build optical waveguides to help guide light along non-rectilinear paths.

Optical fiber waveguides were conceived around 1965, and single mode optical fibers, a type of optical waveguide have become the premier means of data transmission for the past 5 decades or more. A careful tradeoff on the geometry, the refractive index differential between the core and the cladding gives rise to our modern Solid Core Single Mode Optical Fiber (SCF-SMF). Standard Single Mode Fiber typically consists of a slightly higher refractive index glass core no more than 9um in diameter surrounded by a slightly lower refractive index glass of 125um cladding. Many different types of optical fibers all more or less following the method outlined above, such as non-zero dispersion shifted fiber and large effective area fibers have been constructed and some of them are in use today as well. In the past 5 decades, every

single aspect of the optical fiber has been studied and analyzed, every material composition and build has been researched to create a fiber that has the lowest transmission loss, the highest micro and macro-bend performance and the greatest tensile strength for deployment across the world.

Around 1995, there emerged a revolutionary new concept of optical waveguides, in what looked like a solution looking for a problem. What if instead of solid waveguides guiding light, the light were guided within holes of an optical fiber! Among other things this was a radical concept because it was assumed then that light guiding could only occur when the core had a higher refractive index than the cladding, in this case the situation seemed to be the reverse.

These early fibers were called ‘Holey Fibers’ for the holes in the fibers. Soon reduced latency, higher power delivery possibilities came to be identified with these fibers. But before that, significant issues associated with fiber attenuation, micro and macro bend losses, and production techniques would need to be solved, and are discussed next.

3. Holey Fibers to Hollow Core Fibers

Fiber attenuation is always of prime concern for any optical fiber. Optical fibers have minor imperfections in the core composition, and these lend themselves to light scattering and reflections of very small magnitudes called Rayleigh Scattering in optical fibers. Over long links of fiber, these scattering effects diminish the amount of light that can get thru to the other end and are a primary cause of fiber loss [1,2].

When holey fibers came about initially, they were very hard to build, but in addition the built fibers had very high losses. Some of these fibers were 10 or 20dB/km of loss, while the standard SCF-SMF was then at around 0.25dB/km or less.

There was a new evolution in holey fibers that enabled this loss to become dramatically less, and it was based on creating a lattice like structure in optical fibers. These fibers are called photonic bandgap fibers (PBG) shown on the right in Figure 1. A large central hollow core followed by a lattice structure around would effectively confine light in the hollow of the core and enable light guiding in the transverse direction (i.e., along the fiber length). Such fibers when originally manufactured had lower loss than holey fibers. Furthermore, the micro and macro bending losses of these fibers were quite good. In principle, since the core confinement of light was good or in other words Confinement Loss (CL) is minimal, it was theorized that the fiber loss could be arbitrarily low. However, it was found experimentally that the surface scattering loss due to imperfections in the surface of the lattice structure was so great that the Surface Scattering Loss (SSL) would be a dominant mode of loss of the optical fiber limiting its minimal loss to around 0.65dB/km. This loss value although not very good by SCF standards is still very good for low latency applications and is in use today for various such applications which will be discussed later in the paper.

Figure 1 – Illustrating different approaches to Hollow Core Fibers [3,4]

Around the mid 2010s a new type of hollow core fiber has emerged that has the potential to offer lower loss. This is the Nested Anti Resonant Nodeless Fiber (NANF) shown on the left in Figure 1. In analyzing the SSL of the PBG fiber it was found that most of the entire lattice structure did not really do much to guide light, but actively participated in increasing SSL. And furthermore, it was found that having fewer non touching capillary structures guided light just as efficiently without spilling light. It is helpful to think of the light confinement as a series of Fabry Perot structures reflecting light and holding it in the hollow core of the fiber. A further innovation of using nested capillary tubes in the fiber improved core confinement and reduced Confinement Loss. By playing with the capillary thickness and placement further improvement occurred continuous single mode low loss operation across the O and the C bands.

Figure 2 – Hollow Core Fiber Loss over the decades [3]

Figure 2 is a graph of the impressive improvement in anti-resonant fibers in the past decade and a half. True to form, at the post deadline paper at the OFC this year, there were reports of a double nested anti resonant nodeless fiber (DNANF) of 0.17dB/km thus matching the loss of SCF-SMF fiber at the C-Band and at 0.22dB/km at the O-Band thus breaching the loss of the SCF-SMF [5].

As discussed before, the total loss of optical fibers are due to intrinsic mechanisms comprising the material purity and Rayleigh scattering loss, confinement loss and surface scattering loss and extrinsic losses due to micro and macro-bending loss due to cabling or installation. In the HCF, Rayleigh and surface scattering losses are very low, and confinement loss can be decreased by double nesting as well as by increasing the core diameter. But increasing the core diameter would probably increase the bend losses while multiple nestings could increase manufacturing complexity. But in any case, the idea is to let the industry know that such fibers are on the horizon.

4. Latency, Capacity and Reach

Our work on Hollow Core Fibers has primarily focussed on the NANF type of fibers. These fibers offer the potential for low optical loss, have low Chromatic Dispersion, have high power handling capability, a wide bandwidth covering the C+L band, all while having latency that approaches the fundamental limit of speed of light in vacuum. Of these, latency reduction is of fundamental importance, while other limitations such as higher losses or bandwidth could be overcome by optical amplification or higher allocated fiber counts.

4.1. The Latency-Capacity Continuum

Today it is common to see 100Gbps, 400Gbps and even 800Gbps type of transport rates per wavelength on core and access networks. But the rise in 5G and other such technologies has also focused our attention on latency or responsiveness of a network. With the understanding that latency and capacity form two independent metrics that define the quality of our network and there are many applications that require one or both metrics.

CAPACITY ==> High Low <==	File Transfer	Hollowcore Fiber-HFT/5G
		HSD-Com
		HSD-Resi
		LEO Sat
	GEO Sat	
	IOT	Ionosphere RF-HFT
	High <== LATENCY ==> Low	

Figure 3 – The Latency - Capacity Continuum

Consider Figure 3, in which Internet of Things (IoT) characterized by low traffic capacity needs and slow update requirements result in it being in the lower left quadrant. High Frequency traders and 5G with their need for high capacity and very low latency will fit in the upper right quadrant, these are best served by hollowcore fiber links. Businesses and campuses which do file transfers during the off-peak hours might benefit with very high capacity links but without the responsiveness of low latency needs. RF transmission utilizing the reflective properties of the Ionosphere for low capacity high frequency traders fit in the low capacity and low latency bucket in the bottom right.

Latency is a rather complicated topic depending upon multiple variables. At its most fundamental, it depends upon the time of flight of the physical medium, secondly, it depends upon the variopus electronic switches and routers that make up the circuit. Finally, it depends upon the various queues and buffers that form at the near and far side that gate information transfer. It is not surprising that industries with tight latency requirements have made great strides in reducing latency of their switches, thus some switches that are used by HFT are directly written in FPGA code and can approach ns latency. The latency of the the physical medium however is of fundamental importance and is described next.

4.2. Comparing SCF, LEO and HCF Latencies

As we have said before, light travel at roughly 300,000km/s or 300m/us in free space, but travel at ‘just’ 200,000km/s or 200m/us in SCF-SMF fibers. And the low Earth orbit call Leo is approximately 550 km above the surface of the earth. Therefore with this understanding we can now understand the latency implications of the three scenarios described in Figure 4. The left figure corresponds to time of flight latency of a conventional fiber, the middle corresponds to time of flight latency for a low earth orbit satellites free space links and the one on the right describes latency in a HCF system.

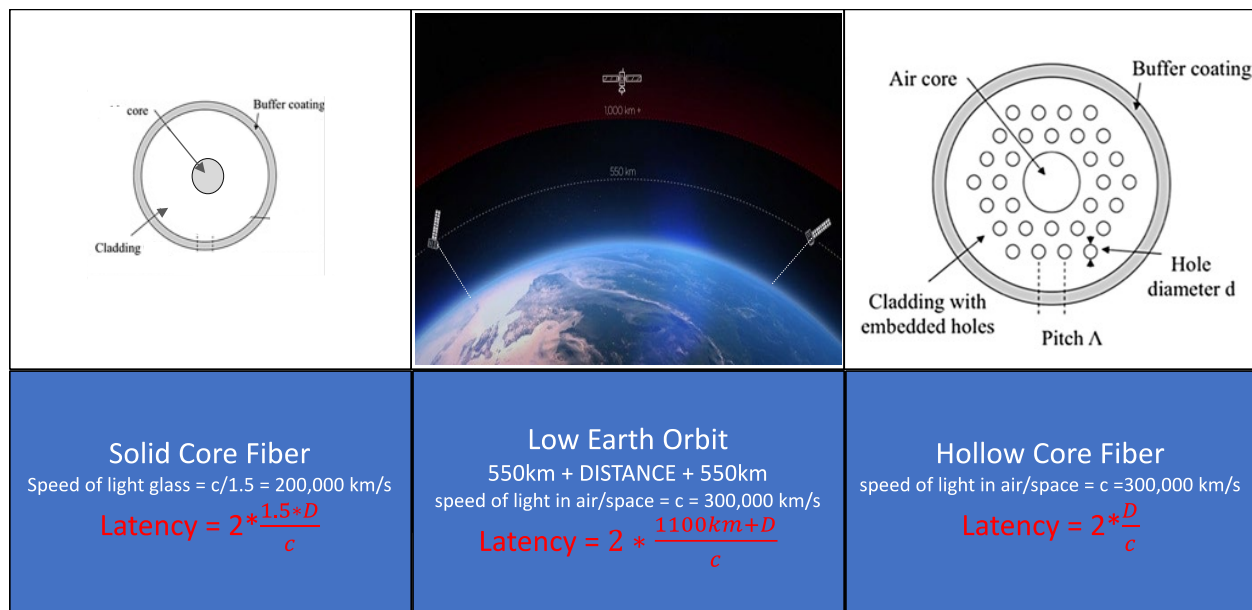

Figure 4 – Solid Core, Low Earth Orbit and Hollow Core Approaches to Latency

In a regular SCF-SMF, the two-way latency is just twice the distance divided by the refractive index of fiber material, which happens to be around 1.5 (actually ~1.4684 in the 1550nm region).

Many years back, satellite communication was rather latency prone since satellites were located at the geosynchronous/geostationary orbit around 36,000km above the earth accruing a delay of 250ms which

rather limited the scope of it in high-capacity communications. Recently, low earth orbit satellites have been launched which are just 550km away, the idea being to cover the earth in a sheath of LEO satellites to offer connectivity around the world. Furthermore, these satellites also can have inter-satellite communications, typically using 100G CFP2 type dual laser bi-directional coherent optics (a more detailed treatment is presented at a different paper in this Conference). Note that inter satellite transmission happens in free space where the refractive index is 1.0. In this case, the latency is significantly reduced, and in the limit may be as small as an additional transit time of 550km to go to one satellite and come back to the earth with the same 550km. Note there that we have not taken into account the processing time in the satellite opto-electronics.

Finally, use of HCF enables one to use the same geographical lines as the SCF-SMF, but with hollow core fiber. Thus, the time of travel is just twice the distance divided by the speed of light.

Figure 5 – Comparing Latencies of the Various Approaches

As summarized in Figure 5, HCF is ALWAYS the link with the least latency, but for very short distances, the delta between SCF and HCF time of flight is small, but always 50% faster in HCF than in the SCF. LEO Space communications, on the other hand start out with a higher latency, but by around 2500km, space communications becomes faster than SCF-SMF communications.

The implications of this are vast. If specific companies can figure out LEO sat communications that have very little optoelectronic delays in inter satellite communications, then they would have a huge ability to ‘see’ the future between the bourses of London and New York for example, which are more than 2500km apart. Within the US, for all locations West of Denver relative to Philadelphia, the LEO communications would have been the same! A hollow core fiber deployment on the other hand along straight line would always have a lower latency and would be at the universal speed limit and would never lead to such arbitrages.

While the case has been made for long haul transport, similar is the case within access networks as well. In the case of 5G front haul, where due to dispersion and latency, around 15km is an accepted distance between towers and central offices, the use of HCF can legitimately increase distances traveled to over 25km for the same latency envelope effectively doubling the area under reach for the cell towers connected to each central office. There is one other aspect of HCF that relating to fiber dispersion which will be described in a later chapter.

4.3. Geographical Flexibility

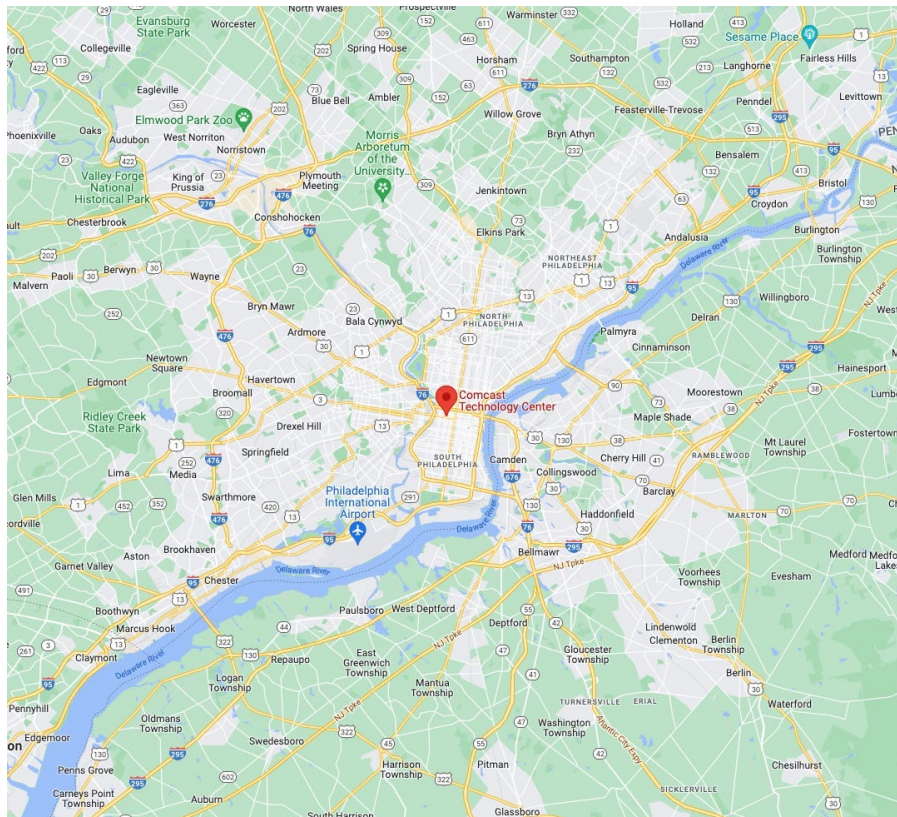

Figure 6 – Increasing the Latency Envelope and Enhancing Geographical Flexibility

There is a geographical flexibility case to be made here for the HCF as well. If we consider that a specific latency is needed from place A to place B, based on standard fiber, but the line between A and B is cut by additional natural or artificial barriers unanticipated at the time of design. In such cases, making a section of the path HCF could give a much-needed latency reprieve and enable the existing design to proceed naturally.

This concept of latency reprieve or latency trade can also be applied to a system in which the number of transactions is also a figure of merit. Here, the lower latency translates in quicker transactions, which in turn could enable - say - high frequency traders on HCF refine their positions continually many more times than the traders on SCF based on the much more rapid conversations.

4.4. Critical Infrastructure Implications

We previously discussed that the backward compatibility enabled the use of same terminal equipment. While this is true a potential additional benefit in the form of power savings might accrue on account of

the fact that individual DSP chips in pluggables may not need to work as hard to compensate for dispersion and optical non-linearities leading to less complex (and lower cost) pluggables and lower critical infrastructure costs.

5. Features of Hollow Core Fibers

The previous chapters have described in detail the evolution of Hollow Core Fibers and the most fundamental advantage of HCF, regarding the ability to offer the lowest latency possible. It turns out that in addition to this fundamental benefit, there are several secondary benefits that make the deployment of HCF (especially NANF) attractive in both core and access networks, what are discussed next.

5.1. Taxonomy of Optical Impairments

Presented below is the well-known ‘taxonomy of optical impairments’. Linear impairments such as chromatic dispersion and optical loss along with optical passives are presented in on the right-hand side, while non-linear impairments that depend upon the of light intensity in fiber are arranged to the left. Specifically, we distinguish between non-linear effects due to single wavelength and non-linear effects due to multiple wavelengths one below the other.

Describing effects of nonlinearities and their impact is an interactive process and will only be summarized here in the context of HCF. It must be emphasized that many of the linear and non-linear effects which are much more important for analog transmission of light that is characterized by high power levels and high optical performance requirements have been thankfully reduced in the migration to digital, but yet, many limitations unique to digital transmission still remain and may add up to significant power penalties reducing reach or capacity.

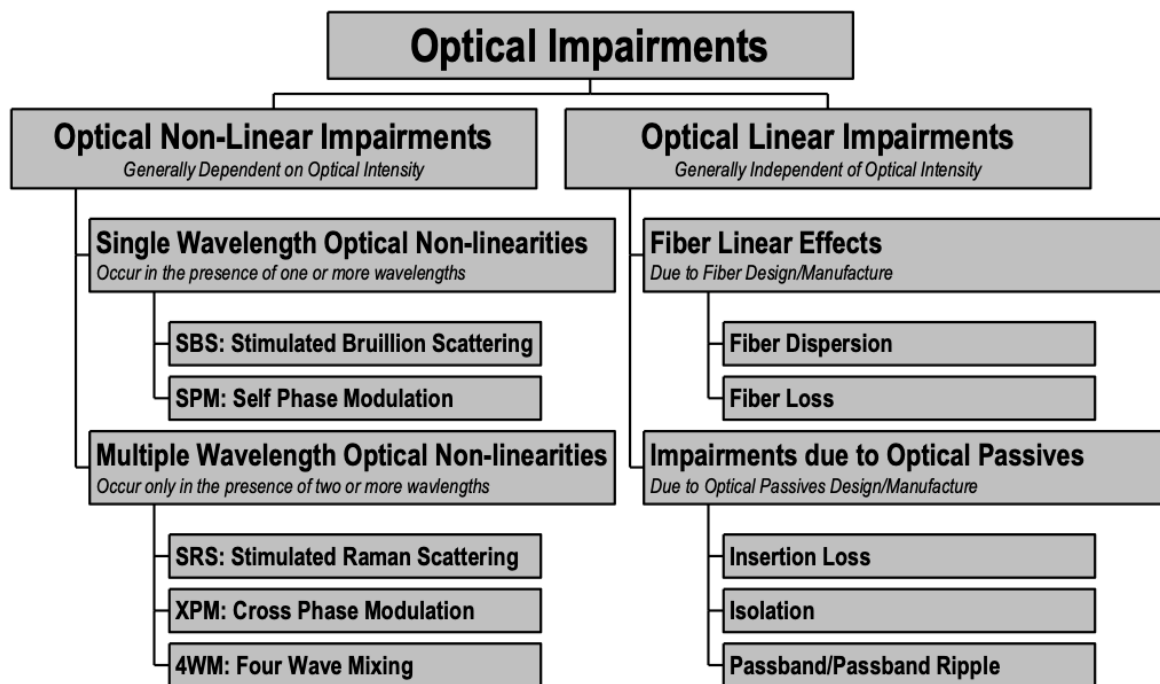

Figure 7 – Taxonomy of Optical Impairments

5.2. Linear Impairments: Fiber loss

Linear impairments are led by fiber loss concerns as fiber loss in present generation of HCF is around 1.5dB/km which limits deployment of long distances without amplification. The generation of dual nested fibers sport a loss of 0.17dB/km, which approaches the loss of SCF-SMF and will be quite suitable for long distance deployments. The current generation of fiber is good however for shorter distances and to proof out a number of other parameters that bear validating. It is important to note that the fiber has a continuous operational single mode region that cover the C and L bands. The bump in loss at the water peaks is attributable to the presence of water vapor (OH ion) in the hollow of the glass, one that may potentially be reduced by an appropriate purge of the core.

Figure 8 – Illustrating fiber loss vs. wavelength for various fibers [3]

5.3. Linear Impairments: Fiber Dispersion

Hollow core fiber has dispersion that is around 2.5ps/nm.km. For comparison, the SCF-SMF has a dispersion of around 17ps/nm.km in the C-band, yielding a 7x benefit of the dispersion parameter. In real life, this translates to longer reach for baseband transmission where the fiber reach decreases as the square of the ratio between baseband speeds as illustrated in this log-linear graph in Figure 9.

Figure 9 – Illustrating dispersion and Latency envelopes for SCF and HCF

For example, 10Gbps baseband signals routinely transmit over 80km, can now traverse 100s of km with minimal dispersion penalties on the HCF. Similar is the case crucially with 25Gbps which is an eCPRI standard was previously limited to 15km of transmission as that was what was possible over standard fiber, this can now transmit to over 80km as illustrated above. A point to note here is that the latency envelope of eCPRI can now be 25km rather than 15km with the HCF as well, thus indicating that HCF could bridge both the latency and reach envelopes as indicated above for various speeds.

In order to verify the benefits of the HCF fiber in access network applications, we verified error free performance of links using SFP28 DWDM CPRI and 40G QSFP DWDM optics over 20km of HCF currently deployed in the Comcast campus. In this verification optical amplification was required to overcome the HCF insertion loss. For comparison purpose we also ran performance tests with 10 and 20km of SMF and, as expected, we could verify the SMF dispersion limitation leading to system breakdown at 7 and 13km of standard fiber, respectively, without dispersion compensation. These results are presented in a later section, Wideband Direct Detect with HCF.

5.4. Linear Impairments: Fiber Splicing and Backwards Compatibility

It is common to find specialized fiber ribbon splicing equipment and software that can splice 12 or more fiber cores at the same time. Similarly, splicing equipment and software is available to field splice HCF.

Figure 10 – Splicing HCF-HCF and HCF-SCF fiber cores

But splicing a HCF to SCF is much more complicated as the geometry of the two fibers are different. Therefore, fiber adapter cables that have HCF on one end and SCF connectors at the other end are specially made in the factory and then used to light up fibers with conventional optical equipment in headends, hubs and nodes. This keeps ALL of the terminal equipment completely backwards compatible with all other equipment while enabling the use of HCF in the field.

In other papers in this conference, we have presented on new underground construction method called the CiC in which micro-fibers re-enter the conduit already holding RF cable and reuse the duct/conduit infrastructure already in use with minimum disruption. Most micro-fibers have 6 tubes within with 12 fibers each in each tube. In this case, one or more tubes could be dedicated to hollow core fibers while others for standard fiber and thus a portfolio of fibers may be installed when the conduit is re-entered. This type of innovative deployment may help bring fiber to the neighborhood where high-capacity latency sensitive endpoints may be located. This concept of a portfolio [6] of fibers is more general of course and may be used in other deployments as well in core and access fiber platforms.

5.5. Non-Linear Impairments:

Optical fibers provide excellent light guiding but in doing so also provide a long interaction length for light-matter interaction. When optical intensities increase in an optical fiber, this leads to non-linearities. All Non-linearities increase with fiber intensity. Some such as SBS stimulate the reflection of light back to the source, others depend upon the non-linear index of glass, which increase with optical intensity. Also called the Kerr effect, this has the unfortunate result that the light speed is modified by the light intensity. When this happens, either due to the self-channel intensity or adjacent/cross channel intensity, a range of non-linear effects arise. But the worst non-linear effect by far is the Four Wave Mixing effect. So called because the fiber itself generates ‘beats’ due to multiple wavelengths that can have a catastrophic effect on transmission. To make matters worse, these non-linear effects also interact with linear effects such as dispersion and polarization and can be intermittent. To tamp down on these effects requires a deep understanding of all effects and with it an effective wavelength plan and robust modulation format.

With fixed locations for amplification and the rise of flex grids and the desire to use C and L Bands together, the practical outcome of these non-linearities is unfortunately a rather severe limit on launch power. But low launch powers have the adverse effects of needing multiple amplification spots and the consequent degradation in signal quality. Furthermore, many non-linearities get exacerbated with the optical amplifiers themselves as these are also fiber-based devices. The net result is a delicate balance.

Not so the case in HCF. Since the core is hollow there is the elimination of light matter interaction. Furthermore, the non-linear index of air/vacuum is non-existent, therefore quite a large amount of light can be packed in to the HCF. The ability to launch larger amounts of light could lead to sparser amplifier spacing and in turn lead to longer reaches.

6. Hollow Core Fiber in Comcast

Late last year, Comcast acquired 20km of cabled HCF, of which 10km was cabled for inside plant performance and the other 10km for outside plant performance. These fibers were terminated in SC-APC adapters via the HCF-SCF adapter cables mentioned before. We began by ensuring that the fiber was reciprocal, by which we mean the loss tested identical from either side of the fibers. It turns out that both fibers had approximately 1.5dB/km of loss and the HCF was indeed reciprocal. Having done that, we deployed the fiber in Comcast.

The HCF was then deployed in a system comprising multiple direct detect and coherent systems. The configuration was 10km of the ISP HCF followed by various lengths of SMF and then finished up with the 10km of OSP fiber. All ends of the fibers are all connected with standard SC-APC connectors thus ensuring total backwards compatibility for this hybrid SMF and HCF system.

Figure 11 – Block Diagram Illustrating the Comcast Deployment

OTDR scanning of the HCF is a surreal experience as illustrated in Figure 11. Since there is no Rayleigh scattering in HCF, the entire section of fiber of 10km shows as if it is ‘cut’ on the OTDR trace. The only indication that the fiber is fine is based on the reflective peaks on the trace at the ends of the fiber due to the SCF-HCF adapter cables. The next 20km of fiber is unremarkable given that it is a standard SMF fiber with nominal loss of 0.25dB/km and its associated Rayleigh scattering. The last 10km of HCF fiber is similarly to the first 10km appears ‘cut’ save for the reflective peak at the end of the total 40km of cable. One other point to remember here is that the HCF although 10km long, appears to be just 6.8km! This is because the refractive index in the OTDR is set to that of 1.4684, if on the other hand it were set to 1.003, which is the refractive index of air, the result would have been that the HCF would show 10km, but the SMF would then have showed 14.7km.

Figure 12 – Illustrating various direct detect and coherent spectra and the passives passband

In a different paper at this conference, we have discussed Comcast plan to converge various wavelengths onto a single optical fiber in the access plant [7]. The picture above shows that the optical filters used in the access plants can handle all wavelengths up to 400Gbps a fact also tested in the system here.

A unique feature of our system is that it is bi-directional, where a single fiber was used to interconnect the two end points. The main reason for the BiDi approach is the need to understand how such systems perform using HCF with the possibility of preserving fiber, HCF or SMF. The system described in the figure below describes the BiDi system where coherent links are combined with direct detect system of 10G, 25G and 40G wavelengths to deliver different types of services simultaneously (DAAS, BERT testing, etc.) in the same string of fiber. We believe that is the first implementation of such system in the world. The optical spectrum analyzer capture depicted in Figure 13 shows the actual spectrum utilization for this trial.

Figure 13 – Bi-Directional Optical Wavelengths over the Comcast HCF Link

Towards that end, as the spectrum graph above shows, we tested bi-directional transmission on a single fiber comprising

- Coherent 400Gbps using 16QAM 63GB system
- Coherent 100Gbps using QPSK 32GB system
- Direct detect 40Gbps NRZ
- Direct detect 25Gbps NRZ to simulate CPRI data
- Direct detect 10Gbps NRZ

And were successful in closing all the links over 20km emphasizing the viability of Comcast vision over multiple fiber types.

6.1. Establishing Latency Improvement using a Hybrid Loop Test

To verify the latency improvements in our system we devised a test set-up using standard 10G test equipment. The approach consists in cascading the 10G traffic from a traffic generator back and forth using back-to-back the 10G optics connected to the CFP2 optics through an aggregation switch. The diagram below shows how the 10G traffic is propagated back and forth through the CFP2 to produce the 100G traffic. In our implementation we actually used a loop test with the same 10G traffic to go back and forth over 20km of fiber 40 times with the 80 10G SFP+ devices aggregated to 8 of the 100G CFP2 devices. Overall, in this hybrid fiber/electronic loop test [8], we actually propagated the 10G signal through

$2 \times 20 \times 40 = 1600\text{km}$. We then repeated this test with standard single mode fiber as well and used the test equipment to track packet errors, latency and jitter.

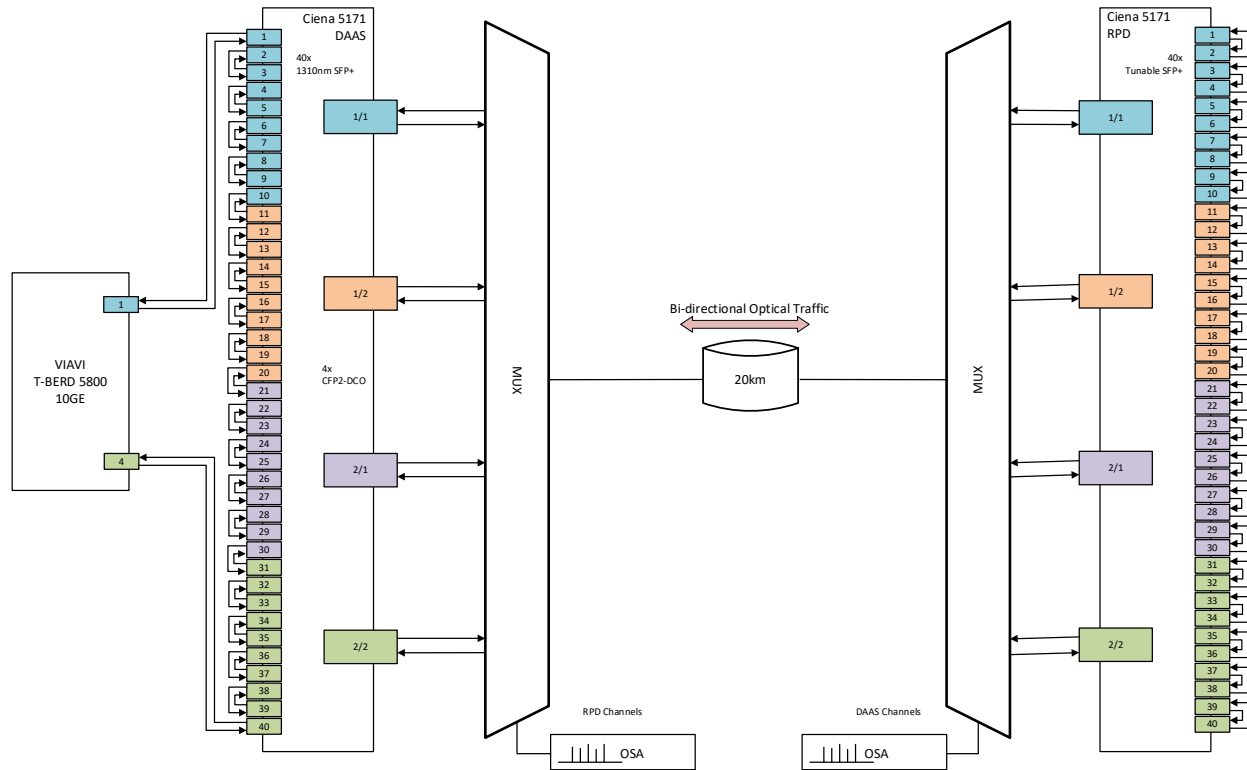

Figure 14 – The Hybrid Loop Test Illustrating Latency Reduction

Presented below is the test data collected and summarized. In it is seen that the latency on HCF is much lower than that on standard fiber. The 8972us delay on HCF compares to 11,330us delay in the SCF-SMF case. We also measured the latency of a link combining 20km of HFC and 10km of SCF-SMF, which led to 17,352us delay.

Figure 15 – Illustrating Latency improvement with HCF (top) over SCF-SMF (bottom)

6.2. Spider Diagram Grand Summary

Below in Figure 16, we present a Spider Diagram showing the key comparison points to summarize the main differences between the HCF and the SMF. The assumption here is to use the relative performance between the two fiber types. The key parameters used for the diagram vertices are purpose were latency, insertion loss, cross-talk (linear and non-linear), cost, and power consumption (green factor).

Figure 16 – Qualitative Comparison of Fiber Attributes

In addition to describing our test system and initial results, we also analyze some of the benefits in addition to latency reduction that are related to reduced optical non-linearities and other effects and the wider spectrum and the consequent Capacity enhancements possible. Practical deployment strategy of fibers is essential at Comcast, the ability to use a portfolio of fibers for some of the emerging low latency market while also driving fiber technology deeper into the network is of the essence of our approach towards the industry initiative of 10G.

7. Conclusion

In this paper we discuss the role of HCF in delivering different types of services over the access networks. We reviewed the history of HCF fibers and discussed some of the main attributes including a combination of minimum latency and non-linear impairments that help drive capacity and reach with continual improvements in HCF technology. We pointed out features that make HCF attractive not only in long haul networks, but also in access networks. While HCF can be a key tool for Comcast to provide low latency services in a cost-effective way. Its combination with traditional SMF provides the great flexibility to our designers to accomplish these goals.

Of particular note in this paper is our report for the first time in our knowledge of successful bi-directional transmission of optical signals across a hybrid HCF/SCF plant with a converging of multiple direct detect and coherent signals ranging from 10Gbps to 400Gbps on a single HCF fiber plant.

Abbreviations

AP	Access Point
Bps	Bits per second

1. Introduction

Today, critical communications facilities are largely managed manually. While some facilities (headends, primaries, data centers) may have fairly extensive monitoring, the data provided still tends to end up on a 2D “dashboard” for humans to interpret and act upon as necessary. Some facilities—especially remote hubs—may have very little telemetry at all.

This paper introduces big data then presents it as key to enabling advanced management of critical facilities (CF) in the future. The importance of collecting broad and deep data—starting today—is discussed along with extant and future sources of this data from facility infrastructure. Common challenges of contemporary facility management will also be discussed in the context of how big data can help reduce the human burden posed by those challenges. Several example use cases enabled by big data—when combined with modeling, visualization, and artificial intelligence—will be presented.

2. What is Big Data?

As is typical for contemporary jargon, a concrete definition for big data is elusive; you’ll find slightly differing definitions depending on what organization is using the term. In the simplest sense, big data refers to data sets too complex and/or large for traditional data processing methods to take advantage of.

An analogy might be the spiral-bound paper notebooks of every student in a school district (replete with chemistry lab notes, doodles, and phone numbers of the student at the adjacent desk). In contrast would be the perfectly alphabetized contacts list in your smartphone.

2.1. The Three Vs

While there are many characteristics of big data, it is chiefly defined by “The Three Vs”:

Volume - Lots of unstructured data

Velocity - Data delivered rapidly, real-time or near real-time with little or no pre-processing

Variety - Many kinds of data available that don’t readily fit traditional, ordered database schemes

More characteristics (also conveniently starting with the letter V) have augmented the definition over time, but for the purposes of this paper the original three will suffice.

Additionally, the term “broad” can be synonymous with Variety here. The term “deep” can be synonymous with Volume over time; that is, historical data.

2.2. A Dollar a Month

The primary driver enabling big data is the ever-decreasing cost of mass storage. In the early days of computers, five megabytes of storage occupied the space of a washing machine and cost perhaps quarter of a million dollars. The idea of storing even a byte of data with unknown importance—data which may never be accessed again—was unfathomable.

Today, however, vast amounts of both mass storage and compute resources are available at trivial cost relative to the potential benefit. For example, one terabyte of infrequent-access storage through a commercial cloud storage service such as Amazon S3 is a little over ten dollars a month. And at the

lowest-cost “Deep Archive” tier, a terabyte is less than one dollar a month and becoming cheaper every year.

Figure 1 - Historical Cost of Data Storage

2.3. Of Warehouses and Lakes

In order to take advantage of any data sets, there first has to be place to store the data. The storage method must be reliable, extensible, and allow for quick access to subsets of data of interest.

An evolution of traditional data processing concepts, a data warehouse stores well-structured data. The schema for the data is predefined and data is transformed to fit. A customer contact database is a simple example of structured data: first name, last name, city, country, etc.

Moving this into the Critical Facility (CF) management area with which we are concerned, consider a database of facility equipment. Expected fields would be manufacturer, model, serial number, install date, rack location, and so on.

But what if data is available that doesn't fit the structure?

Power Input Module B Inlet Air Temperature 56°C at 03:02:01 on 2022-07-03

Where does that go?

It goes into a data lake, a vastly scalable centralized repository for raw data of virtually any type be it structured or not.

A data lake takes a different approach to data storage that is better suited to massive amounts of diverse data available today and in the future. The idea behind a data lake is to store data in its elemental, uninterpreted state. The data is minimally processed before storage. A value (the data type is less important than with structured data—integers, floating point, strings, even image data are welcome in the pool) along with some context—a source identifier and a timestamp—are all that are needed.

3. Data Sources in Critical Facilities

Even in a critical facility built without an aim towards monitoring/telemetry, there are many sources available for useful data. We are primarily concerned with data from the facility infrastructure itself and will expand on that below. However, it's important to note that to fully take advantage of big data even the management channel data from the revenue-generating equipment itself is important to gather.

3.1. Power

Virtually every piece of power equipment you will find in a communications facility—from an Automatic Transfer Switch (ATS) to a Surge Protective Device to a DC Plant—is available today with a means to provide data in real time or near real time to a monitoring system via a network.

Early network-enabled power systems provided only coarse data—bus voltage, total current, alarm status, and other data at that level. Today, power systems are available with the ability to measure consumption down to the smallest branch circuit.

Figure 2 - “Smart” DC Fuse Panel With Individual Branch Circuit Current Monitoring

Stationary batteries, a key component of high-reliability power systems, have traditionally offered little in the way of data. Monitoring systems are often seen in facilities, but they typically only offer jar-to-jar voltages and perhaps a few temperature measurement points. However, the intelligence mandated by lithium batteries in consumer and automotive applications is making its way into reserve power batteries. Imagine a large critical facility with dozens of strings of backup batteries, each cell able to provide detailed metrics on its status. There could easily be ten thousand pieces of useful data gathered from a facility's batteries per minute.

3.2. Environmental

Many facilities have environmental monitoring capability either as separate systems or as part of the active Heating/Ventilation/Cooling (HVAC) systems. Computer Room Air Conditioners (CRAC) have been available with network connectivity for some time.

Again, like many power systems, the data from these HVAC systems is usually basic and local to the unit itself. Perhaps there would only be a dozen temperature readings directly from the HVAC systems in a facility. However, the number of temperature and airflow sensors present on all the equipment in a facility is likely in the hundreds if not thousands. The low cost of digital temperature sensors means that granular temperature readings should be available for intelligent thermal analysis of an equipment rack, row, or zone.

In addition, new low-cost infrared (IR) sensors could soon enable equipment to detect local hot spots without the need for quarterly site visit by a technician with an expensive IR camera (the data from which is quickly stale).

3.3. Security/Access

Today's advanced security systems provide data far beyond simple contact closures triggered by magnets on doors. Key card and Radio Frequency Identification (RFID) integration allows the tracking of not only access by personnel, but the presence of tools and even equipment assets. Visual and IR cameras add another.

Looking beyond the dedicated security and access control systems, however, many pieces of equipment have sensors that can detect when a physical change has been made: module insertion/removal, access door open, rack door open, etc.

4. Turning Data Into Information

In traditional CF telemetry, there is priority given to quickly turn elemental data into important (or seemingly important) information. Formulae and scripts are written to take near-term data and either present it to an operator as information, or cause some immediate action: put a rectifier module to sleep, open a low-voltage disconnect, turn on an economizer (or trigger the fire alarm!) as examples. All important things at the time, to be sure.

However, often the raw data is discarded after being processed into immediate information, and is no longer available for analysis months or even years later.

4.1. First, You Need the Data

Obviously to take advantage of big data you first need data. What may not be obvious is the importance of rich historical data, and the importance of capturing that data as soon as possible.

4.1.1. The Internet of Things (IoT)

The Internet of Things, or more commonly just IoT, is a popular buzzword covering all manner of intelligent, network-connected widgets that will magically and seamlessly talk with each other and work together. Any of us who've wasted an afternoon trying to get a Hi-Fi music streamer to stay connected to wireless speakers can attest, it's not quite there yet.

However, the idea of every *thing* being connected is fascinating: from the expected like discrete current transducers and humidity sensors, to the mundane such as light switches and fixtures. If a light fixture happens to also know the temperature, why should it not report that data to the building network?

Figure 3 - IoT Example Graphic

4.1.2. “Smart” Infrastructure

The decreasing cost of sensors, microcontrollers, and ubiquitous network connectivity has made it possible for almost every piece of building infrastructure to be some degree of “smart.” Today, even doorbells have microcontrollers and wireless network interfaces!

In critical facilities, however, most of the infrastructure today is still fairly dumb. That is, it is not able to provide data via a network connection. Or if the equipment is able, it is not connected, or nothing is done with the data. Indeed, some operators do not see the benefit of smart infrastructure, but they are making that choice from the perspective of the tools available to process the data today.

To take advantage of big data in the future, smart infrastructure is necessary today.

4.1.3. Retrofitting Telemetry

Operators large and small are faced with a chicken-and-egg question when it comes to smart infrastructure: “Why invest in network-enabled fuse panels and air conditioners when the majority of my existing equipment lacks the capability to tie in?”

Some may prefer the “sidewalk” solution: municipalities often require sidewalks be built whenever new construction is undertaken even if the surrounding neighborhood lacks sidewalks. While this results in a few “where the sidewalk ends” jokes on shorter timescales, longer term it results in neighborhoods with nearly contiguous walkways.

Unlike the relatively static central offices of landline heyday, today's critical facilities change, evolve, and grow quickly. When old HVAC systems and fuse panels won't meet the needs of the latest revenue-generating network gear, the new systems should be smart.

For installation conditions that don't readily permit the migration of old infrastructure to smart infrastructure, intelligence can often be retrofitted. Temperature sensors and clamp-on current sensors are readily available to augment smart infrastructure and instrument critical facilities.

Figure 4 - Traditional Dry Contact Telemetry

4.2. Hands Off! Reducing the Human Burden of Data Management & Analysis

The aim of big data in most industries is to *reduce* the amount of manpower required to evaluate, plan, and act to accomplish a business objective. Unfortunately, as more data is made available, operators often find it more difficult to digest and act upon.

4.2.1. Modeling

The first step in making big data useful for managing critical facilities is to move ahead from the "Mission Control" dashboard. Facilities can be surveyed and physically modeled in 3D and presented virtually. Then, with sufficient data sets, the electrical and thermal behaviors of the facility can be modeled as well.

Instead of sorting through out-of-date photos, looking at rack inventory spreadsheets, or sending crews to survey sites, it's conceivable to view a current *model* of the facility. Operators will be able to virtually walk down a rack row and see what equipment is installed, where floor space is available, and even where fiber trough and cable tray is ready for growth.

4.2.2. Data Visualization

Layered on top of modeling, big data allows the ability to overlay important data directly over the virtual facility. Today, most of us use similar capabilities in everyday life without realizing it: the satellite view overlay of a map application, per-zone temperature overlay on a smart home, and so forth.

Now imagine being able to view the inlet air temperature gradient across the entire front of a critical equipment rack. Or go back in time and see what that same gradient looked like when an air conditioner failed last summer.

Figure 5 - Process Temperature Overlay in a Factory

4.2.3. AI

Despite being misunderstood and maligned in countless science fiction books and screenplays, artificial intelligence is at work today helping businesses and improving the lives of people.

What AI can already do today is impressive—from creating striking images prompted by just a few words (DALL-E) to finding the most efficient paths for rovers to explore other planets. But far more exciting is what AI will be able to do five and ten years from now.

In the CF space, it is readily conceivable that AI will allow us to “see the future”. In our example above, instead of viewing the rack inlet temperatures from last summer, what if we could view the rack inlet temperatures for next summer? After adding another 10kW of revenue-generating equipment in the row! AI makes that possible and can do so better than the current “snapshot” predicting through the use of massive amounts of historical data.

5. Use Cases in Communications Facilities

With a sufficiently broad and deep set of data, what can big data do for critical facilities?

5.1. Outage Prevention

Operators spend significant time and money to ensure their networks are robust, resilient, and reliable. Redundant generators, dual DC plants, and diverse wiring are all aimed at preventing customer-affecting outages. Yet outages still occur all too frequently.

In many post-mortem investigations, sifting through logs reveals that data was available that indicated an outage was possible if not imminent. Often this data was not given enough importance to make it into any alarm logic or status dashboard. Ultimately, it’s often a human who would have to react to the condition to prevent the outage. Or, if some automatic action is taken it’s not granular enough and results in mitigation instead of prevention, which still results in something less than normal delivery of service.

Instead, why not allow computers to search for patterns in both current and historical data, run myriad “what if?” scenarios against the facility model, and identify where trouble may be brewing. Days, weeks, or months beforehand.

Figure 6 - Outage Postmortem

5.2. Operational Efficiency

Most operators would likely admit that their critical facilities do not operate at peak possible efficiency. Priority is understandably given to ensuring equipment is working, service is reliable, and just keeping up with customer demand. Analysis of power conversion loss, HVAC efficiency, and such is performed as time allows—usually when a major facility upgrade is planned. Such analysis is usually done on “snapshot” or coarse-grained historical data, and while the result may improve efficiency somewhat, it cannot continually *optimize* efficiency.

Big Data and advanced tools operating upon it, combined with smart infrastructure, will enable facilities to self-optimize in near real-time. Consider load-shedding, power source switching (utility to photovoltaic solar (PV), for example), economizer activation, etc.—all driven by machine learning working off broad, deep data sets.

5.3. Capacity Planning

As the worldwide demand for high-speed data grows unabated, the need to expand critical communications facilities keeps step. In these buildings exist leading-edge routers and switches and optical equipment yet planning for future growth remains largely a manual process. Obsolete equipment inventories, stale usage data, and myriad spreadsheets are used to determine whether new equipment can be added to a facility to meet growing service needs. Consider just a fraction of the simple questions that must be answered in order to add a significant new piece of equipment:

Physical: *Is there sufficient rack space available?*

Power: *Is there sufficient ampacity available at the BDCBB? At the DC plant? The service entrance? Is there even a feeder fuse or breaker position available?*

Cooling: *Can the proposed zone support the additional thermal load?*

Big data could answer these immediate questions, and much bigger ones without an operator ever needing to open a spreadsheet:

When will the utility service no longer support the rate of growth at this facility?

What would be the first point of failure during a prolonged utility outage?

Would it be cost-effective to add alternate energy sources to this facility?

Figure 7 - Old-Fashioned Planning?

5.4. Automatic Provisioning

Taking capacity planning even further, a comprehensive CF management system could analyze customer trends, predict required service growth, then cascade the infrastructure requirements to match those needs. Imagine a system that places a purchase order for a new distribution panel along with all the properly-sized cables, circuit breakers, and mounting accessories. The order is placed taking into account delivery time of the various necessary components, and an installation technician can even be scheduled as soon as the equipment is slated to arrive.

6. Conclusion

The question posed by the title of this paper is rhetorical; your critical facilities are not yet ready to be managed by big data today, nor are the advanced modeling and AI applications yet developed enough in this field to do so. However, many facilities already have a surprisingly rich set of data available that could be valuable in future decision-making. Now is the time to collect the data already available and augment infrastructure where that data is missing. The future of critical facility management will be driven by big data.

1. Introduction

Many books and articles have been written about artificial intelligence (AI) and machine learning (ML), in a variety of applications. ML is far from new, has an established theoretical foundation, and lots of different types of ML techniques have been introduced over the past decades. These techniques can be classified in different ways, but a full taxonomy is outside of the scope of this article. In this paper, we focus mostly on ML algorithms, as a subset of AI. Excellent introductions and overviews have been provided in e.g. [Goodfellow16, Bishop95].

Lots of successes have been claimed based on ML, and reports of AI intelligence are already the subject of ethical discussions [Google22]. Still, the powers of machine learning are not always a solution, and in many applications, even though they make for an interesting marketing statement, they do not lead to net gains or operational savings.

Machine learning has powerful applications in computer vision, image and video processing, and approaches using deep neural networks have become the center of academic and industry research. For example, residual neural networks have shown impressive results for image classification and recognition [Simonyan14, He16]. Still in most of these cases, very complex algorithms are needed, requiring e.g. deep neural networks containing dozens or hundreds of layers. While it's acceptable to have a very complex *training* stage (which needs to be executed once), it's primarily the complexity of the *inference* network (which needs to be repeated many times) that determines the feasibility of ML approaches¹. An important unit of expressing the complexity of ML inference networks is the number of *multiply-accumulate operations* (MACs). Some of the best-performing image recognition networks use millions of MACs per image.

Often, new approaches are deemed feasible when they can be run on state-of-the-art GPUs inside a server. In certain cases, this is acceptable, and the cost of a dedicated CPU or GPU is warranted. For real-time, cost-sensitive applications, however, this is not an option. In typical video encoding/transcoding set-ups, dozens or even hundreds of channels need to be processed on a single server, and the cost per channel is a crucial criterion. Furthermore, the latency of offloading decisions to accelerators (if they would be cost effective, which is not the case), would be prohibitive.

In this paper, we discuss the applicability of machine learning approaches in different areas of *real-time* video compression. We successively cover encoder complexity reduction, rate control, video quality improvements and video quality measurement. In each of these areas, we have studied ways to reduce the complexity of ML inference, to end up with algorithms that are applicable in real-time, cost-sensitive applications.

¹ While in this paper we're mostly concerned with the complexity of the inference stage (which needs to be run every time a decision is made), the cost of *training* these networks can still become prohibitive in some cases. Not only the impact on computation, but also on emissions needs to be considered. In the field of natural language processing, Transformer Networks such as GPT-3 have been developed, with 175 billion ML parameters, requiring tons of CO2e just for training.

2. Applying ML to video compression: from ML to TinyML

In contrast to what our marketing departments would like us to believe, applying ML to any problem is not a trivial task, and it doesn't work out-of-the-box. For any problem solved using ML, *domain knowledge* is required. In the case of video encoding, a lot of specialized knowledge about video compression and its components is essential.

When attempting to combine the difficulties of domain knowledge, ML knowledge and complexity aspects, it is easy to get stuck in the “trough of disillusionment”, where little or no net benefits of ML are reaped. In the end, product-grade encoders are usually mature, with smart human-designed algorithms. And indeed, in several areas, the gains are not immediately spectacular. Still, by pushing through, it is possible to obtain productivity and operational gains.

It is also tempting to assume that we can apply deep CNNs or similar computer-vision inspired techniques to video compression: detecting objects, humans, optical flow, or even apply a semantic meaning to each of these objects – after which we use that semantic information to help compression. While this is possible in theory, and a typical human reflex, such approaches are typically error-prone, inconsistent over time, and require a tremendous amount of computational resources.

In this paper, we focus on ML approaches that are feasible in real-time, with minimal impact on “channel density”, i.e., the number of video channels that can be processed on a single server. As a result, these are realistic techniques that lead to operational savings and efficiency increases.

As an analogy, the challenges encountered in ML-based video compression are similar to those in the research field of “Tiny ML” [Warden20] – even though we're working on servers with multi-core CPUs. But instead of running single tasks on a very low-power platform (in the mW range), we process hundreds of video streams on a single CPU, making millions of decisions per second. To continue the analogy with TinyML, every individual building block inside an encoder has only milliwatts of power available. This results in an exciting new combination of research on *low-complexity real-time ML inference for video compression*.

3. Video encoding complexity (reduction)

3.1. A high-level view on encoding

In this paper, we continue to focus on video encoding as application. Compressing and encoding video is an extremely complex process, comprising different steps including pre-analysis, mode decision, motion estimation, interpolation, intra/inter prediction, transform, quantization, entropy coding, in-loop deblocking etc. Executing each block is a time-consuming operation, but it's mostly search space exploration (i.e. evaluating the different encoding options such as partitions and motion vectors) that is expensive in encoders. A simplified version of a hybrid block-based encoder is shown in Figure 1.

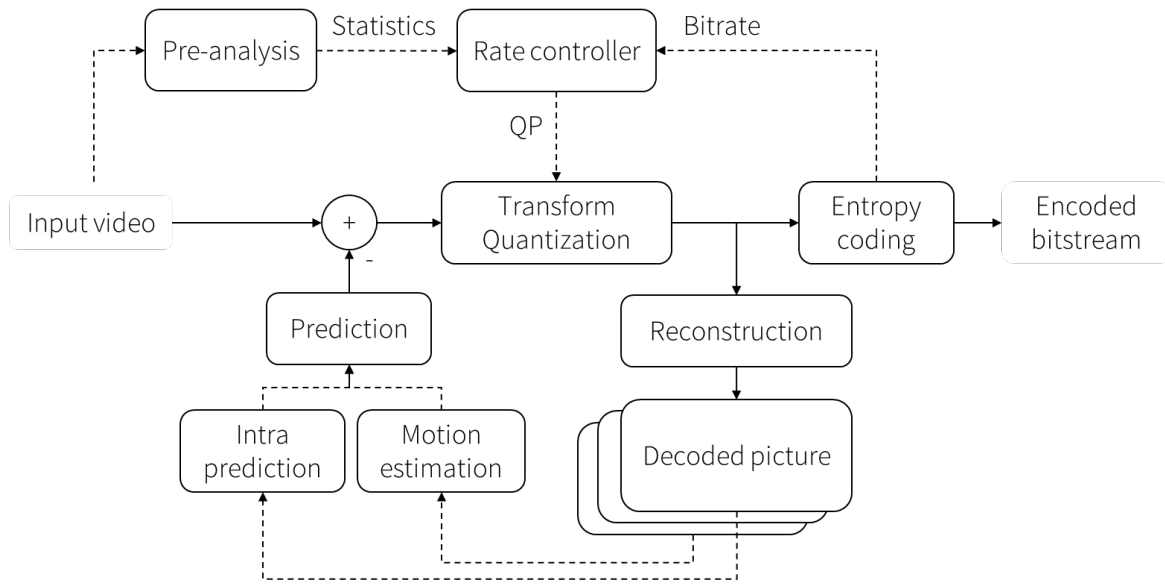

Figure 1. High-level overview of a hybrid block-based video encoder

Video encoding not only demands a lot of CPU power, but also memory (bandwidth). With higher resolutions (e.g. 8K) and higher frame rates (e.g. 120 fps), billions of pixels need to be processed every second. For lower-resolution streams, typically dozens to even hundreds of streams can be processed in parallel on a single server.

To cope with this complexity, lots of effort has been spent on developing hardware accelerators, FPGAs, ASICs and so forth. Still, encoding in software has many benefits, and brings maximum flexibility in deployment (on-prem, cloud-based etc), upgrades, and video quality improvements. For operational efficiency and flexibility, software encoding is often preferred, and will be the focus in this paper.

3.2. Encoder complexity reduction

To gain a competitive advantage, a low cost per channel is important. This is becoming increasingly challenging, as the complexity keeps increasing for newer compression formats. Each generation of video compression standards brings an increase in computational complexity (e.g. from MPEG-2 to AVC to HEVC), and newer standards are on the horizon (such as VVC). Typically, *decoder* complexity doubles with every generation, while jumps in *encoder* complexity can be even larger.

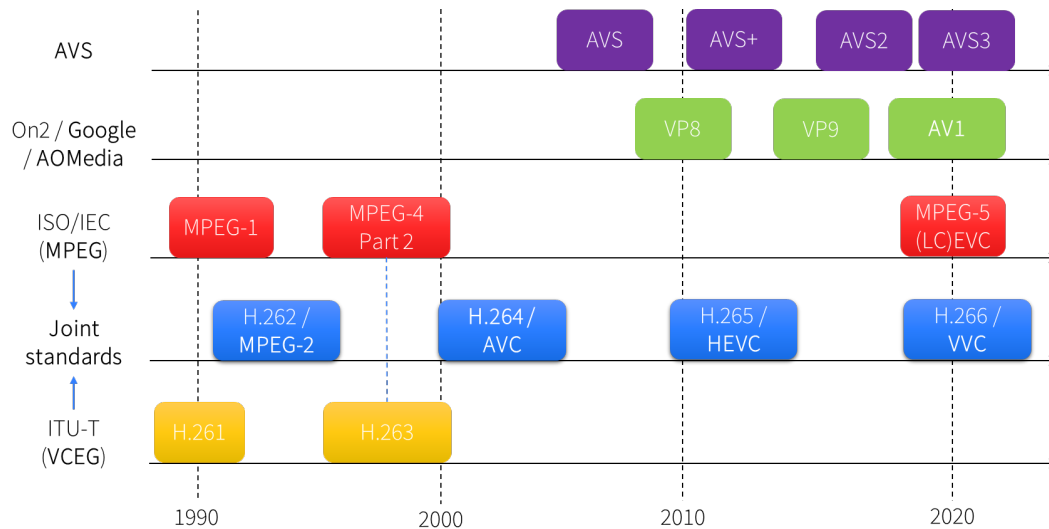

Figure 2. Evolution of video coding standards

Not only the resolutions are increasing, also the number of different ways to encode each individual frame or block is going up. While HEVC had about 80K different ways to partition a 64x64 block, the biggest coding units in VVC (128x128) can be partitioned in more ways than there are atoms in the universe².

128x128 coding unit in VVC

Figure 3. Example partitioning structure using VVC.

Given the potential for optimizations in this huge search space, finding efficient ways to make decisions inside the encoder is a popular research topic, and recent attention has shifted towards machine learning approaches. Plenty of references in this direction can be found in academic literature. Typically, however, the reference point in these papers is (extremely slow) reference software, and most of these gains cannot be transferred as such when applied to professional, real-time encoders.

Also, many publications on encoder complexity reduction focus on non-real-time (VOD-type) encoders. While this is useful as a starting point, those findings cannot be directly translated to *real-time* scenarios. Smart ‘production-grade’ encoders already make intelligent decisions, without exploring all options. In practical encoders, the promised complexity reductions are typically (way) lower.

² Every 128x128 coding unit can be split down to 4x4 coding units, with a recursive combination of binary, ternary or quaternary splits (or no split). I will leave the calculations up to the interested reader.

Still, interesting work in different directions has been performed resulting in ML networks with reasonable complexity, always while trying to limit the loss in compression efficiency:

- *Partitioning for HEVC and VVC.* [Liu16] presented a CNN-based CU partition size decision for HEVC with a reasonable complexity of 3,000 MACs, along with a hardware implementation. Among others, [Bhat21], [Wu21] and [Liu22] introduced CNN-based or SVM-based strategies for acceleration of VVC encoding, with a focus on the partitioning decisions, with encoding time reduction of roughly 30-80%, while limiting the impact on compression efficiency.
- *Intra prediction.* The work by [Santamaria20] presents NN-based intra prediction modes along with simplifications that lead to multiplications in the order of 100s up to 10,000s for 16x16 blocks. This builds on the work of [Pfaff18], and an interpretation analysis is run to come to simpler, explainable predictors that are easy to implement. The result is NN-based modes that are much closer to real-life usage.
- *Inter Prediction.* Although much of the recent work has focused on NNs, other ML techniques such as Decision Trees prove to be efficient ways to optimize encoder decisions, as in [Kim19], where inter prediction is accelerated for AV1.
- *Transform selection.* The transform search for AV1 is accelerated in [Su19], based on a neural network with one hidden layer. For transform kernel prediction, two shallow networks are used which are combined into a score for the 2D transform.

The message from these papers, along with our findings, are that fairly simple and shallow neural networks can produce accurate results, and at acceptable computational complexity.

3.3. Reducing the complexity of ML inference networks

Optimization techniques can help push the boundaries of what ML can achieve inside an encoder, and can help limit the cost of deeper networks. For example, *pruning* can be used to reduce the complexity of the networks, and to eliminate redundant MACs in the inference networks. Also, *quantization* allows to reduce the bit depth of operations, at the possible cost of some accuracy in calculations.

Specialized hardware *accelerators* can be tolerated in some applications, but might lead to a large overhead in latency, limiting their feasibility. Dedicated *instruction sets* (such as VNNI) provide a more convenient way to parallelize operations, and specialized matrix multiplication instructions are made available on the most recent CPU generations. Unfortunately, offloading ML inference to external accelerators or GPUs is usually not preferred, and would lead to unacceptable latency in the real-time applications we're discussing in this paper.

In all cases, a trade-off between accuracy and complexity needs to be found – again, domain knowledge is needed to find a good balance. That domain knowledge is also essential for the most important part, which is intelligent network design: shallow network and intelligent feature design.

4. Rate control

Rate control is another area where ML has proven to provide improvements. Video encoding can be considered as a resource allocation problem. Given a certain bit rate (=bit budget), the available bits need to be distributed in the best possible way across different frames and coding units, to reach the highest possible video quality. This is done by choosing the right quantizer (quantization parameter) for each block.

While this seems a fairly trivial task, it is actually an extremely difficult problem, given the multitude of options that every individual block can be encoded with. Furthermore, due to prediction, blocks are dependent on previously encoded blocks, further exploding the complexity of the problem. The power of its rate control algorithm is actually one of the biggest differentiators in the quality of an encoder.

In practical encoders, estimations are made to allocate quantizers to every block based on pre-analysis of the video content. Each block will be encoded with an estimated quantization parameter (QP), and the total bit rate for the frame needs to approximate the given bit budget as closely as possible. This pre-analysis and prediction stage is essential, and the prediction error needs to be as small as possible. The rate control process is depicted in Figure 4.

Figure 4. Simplified view on traditional rate-controlled encoding

Traditionally, prediction algorithms are based on human-designed heuristics, tweaking and testing. While this works well in general, there are cases where misprediction leads to fairly large bit estimation errors. This can lead to the rate controller over- or under-allocating bits for a number of frames. As a result, bits might be wasted, or quality might suddenly drop.

With machine learning, smart features can be calculated during the pre-analysis stage. With the resulting ML-based rate controller (Figure 5), we've noticed better resilience to a variety of content types, including sudden content or scene changes. As a result, we achieve better correlation between estimated and encoded bits, as illustrated in Figure 6.

Figure 5. ML-based rate control

Figure 6. Improvement in rate control prediction accuracy between traditional (left) and ML-based (right) rate control.

5. Subjective improvements

Reaching a high level of video quality is extremely important when offering premium video content. Over the past decades, major steps forward have been made, going from analog TV to HD digital TV, and now it is common to watch premium sports in UHD, with the first 8K channels becoming available. In any case, we’ve come a long way since analog or DVD-level quality, and viewers are getting used to high-quality and ultra-high-definition video, by watching popular VOD services.

Pushing the limits in video quality is important to offer a premium to viewers, and as a differentiator when selling video encoding services. When comparing encoders (in so-called shoot-outs), offering the best quality is one of the most important criteria. In the next section, we will discuss VQ measurement based on *objective* metrics (as calculated by algorithms). But in this section, the focus is on *subjective* quality, as perceived by the viewer.

Several elements are important to optimize the visual quality as perceived by viewer. In early videos circulating on the Internet, digital video was suffering heavily from blocking artifacts, blurring, mosquito noise, ringing etc. These are quality artifacts that should be avoided at all costs, and that are no longer acceptable (and fortunately, less common) in modern video distribution.

In recent years, per-title, content-aware (CA), or even shot-based encoding have become mainstream. Introduced by Netflix [Aaron15], CA encoding finds the best bitrate (or settings) for every segment or shot. Content-adaptive encoding can help boost the quality of every segment of a video sequence. In a “black-box” version, a wide range of settings can be determined and fed into an ML framework, e.g. as demonstrated by Facebook in [Coward16].

While these techniques were introduced for VOD-type encoders, and operating at a very high complexity (e.g. by evaluating multiple options before deciding on the final encoder settings), they can also be applied to real-time encoders. In this case, decisions need to be taken much faster, with low latency and limited lookahead, and before the entire shot is available.

Smart bit distribution inside encoders can make a substantial difference in video encoders, and is necessary to preserve detail in the right places (e.g. players on a football field, or the football itself), to reduce artifacts and preserve textures. ML is well-suited to make decisions in real-time, and with a high degree of content adaptivity. Coding tools such as adaptive quantization, sample adaptive offset (SAO) filtering in HEVC or VVC, ALF in VVC, are excellent candidates for smart decision making based on ML. Some examples of improvements that were obtained by moving from handcrafted algorithms to ML-based subjective decisions are shown in Figure 7.

Figure 7. Example quality improvement between traditional (left) and ML-based (right) texture preservation.

For detection of areas of importance, ML algorithms can be used for higher accuracy. For example logos, faces, football players etc can be better detected and protected in sports games.

Figure 8. ML-based logo detection

Also filtering and post-processing are excellent candidates for smart ML-based techniques. Several articles have been published in this direction, such as in [Yang17] and [Kuanar18]. Also deinterlacing can benefit from CNNs, as described in [Bernasconi20], by combining residual and dense neural networks.

6. Video quality measurement

To verify the effectiveness of VQ optimizations, a great deal of time needs to be spent on subjective quality assessment. This is a process in which viewers (experts and/or non-experts) provide feedback on the video quality. Subjective test methodologies have been designed and standardized to handle this process. And every codec development team will have a set of ‘golden eyes’ in house to guide this process.

In practice, it’s not feasible to verify the subjective quality of each and every video stream or channel, and subjective quality assessment is typically used only in specific occasions, e.g. during encoder comparisons, during the set-up or configuration of an encoder – or whenever an issue occurs. To reduce the high cost of human intervention, *objective* quality measurements have been introduced, to assist VQ measurement in an automated way, and as accurately as possible.

Objective VQ measurement is useful in applications such as encoder comparison and configuration, bitrate selection, ABR ladder (resolution, bitrate) optimization, real-time VQ measurement and monitoring, and in-loop quality control.

Different types of objective VQ measurement exist. In cases where the source video is available, a *Full-Reference* (FR) VQ comparison is possible (Figure 9). Examples of such metrics are MSE (mean squared error) or PSNR (peak signal-to-noise ratio), which calculate the difference between original and distorted pixels.

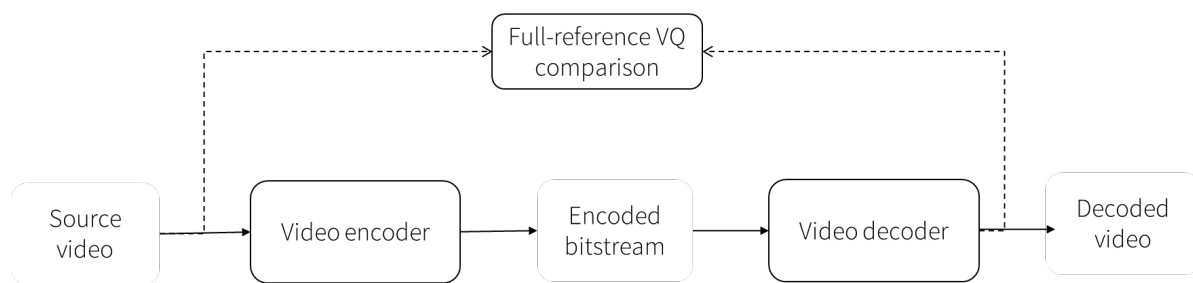

Figure 9. Full-reference video quality assessment

In other cases, a more difficult task is to evaluate the VQ without reference to the original (NR, no-reference). Here, indicators of e.g. the *naturalness* of images need to be calculated to get an impression of the overall quality. While NR metrics are extremely useful, the absence of a reference point makes NR scores less accurate. Inside the encoder, the encoded video can be compared to its input, and FR metrics can be used. We revisit NR metrics later on in the context of quality *monitoring*.

A multitude of FR metrics have been introduced over the past decades, including PSNR (peak signal-to-noise ratio), SSIM (structural similarity), MS-SSIM (multiscale SSIM), VMAF (video multimethod

assessment fusion) and others. The more complex metrics (such as MS-SSIM and VMAF) have shown to provide higher accuracy, while simple metrics like PSNR are not reliable enough for most purposes.

Machine learning has started to play a big role in VQ assessment and the creation of new metrics. An excellent example of an ML-trained metric is VMAF, which takes into account compression and scaling artifacts, and reaches a high accuracy on a variety of test sets. It is being used by many companies and is on its way to become a de facto industry standard. VMAF was trained on subjective data collected from human viewers, and uses a combination of underlying metrics as features. These features are weighted using SVM-based regression, resulting in a score between 0-100 to output the overall quality of the frames.

6.1. From offline to real-time VQ measurement: tracking video quality

A first obvious step to reach operational efficiency is to select the most efficient encoder and encoding configuration. Comparing encoders can be tedious, in particular when many different bitrates and parameters can be configured. Objective metrics can help identify the strengths and weaknesses of encoders, and can point to difference in encoder behavior over time or for different types of video content. Still, the question remains how the encoder will continue to perform, when an upgrade is applied, or when changes in configurations are made. Repeating extensive testing every time is an expensive and time-consuming task. Real-time VQ measurement is the preferred approach to track video quality over time.

As discussed above, ML metrics such as VMAF have been developed that work well for off-line measurement. For *real-time* measurement, however, we need metrics that are both accurate and affordable (meaning fast enough). VMAF's main downside is its computational complexity. Although efforts are ongoing to reduce the complexity of VMAF, its computational requirements remain high, especially when looking at the operational cost.

For operationally feasible VQ measurement, the cost of calculating VQ metrics needs to be reduced by several orders of magnitude compared to VMAF, and should be a fraction of the cost of the encoding itself. While simpler metrics like PSNR are often embedded inside encoders (as in Figure 10), they are not reliable enough for accurate VQ tracking.

Figure 10. Calculating VQ inside the encoder

Machine learning provides ways to calculate VQ metrics in a smarter way. Deep video quality metrics such as DeepVQA have been proposed [Kim18], or using dynamic receptive fields and CNNs [Kim20], which provide state-of-the-art correlation with subjective scores. Still, they require multiple convolutional layers to reach the final score, and as a result, a high computational cost. As an alternative, smart features can be

calculated inside the encoder (or even reused from the pre-analysis stage inside the encoder), as a more powerful input to ML networks. This process is illustrated in Figure 11.

Figure 11. ML-based VQ measurement inside the encoder, based on pre-analysis features.

Finding a balance between input features, network structure, network complexity and accuracy is a complicated process, which as mentioned before, requires a lot of domain knowledge. We have identified ML networks that have more than 90% correlation with subjective scores, and that provide a fast and reliable alternative to expensive VMAF calculation. Example ML networks are shown in Figure 12, where we started from the network on the left, but were able to reduce the number of MACs by 70% to reach the same accuracy with network on the right.

Figure 12. Example networks used for ML-based VQ prediction.

Once a VQ metric with acceptable accuracy and complexity is available in the encoder, it becomes possible to track video quality, and to verify 24/7 that a certain quality level is reached during encoding.

6.2. From rate control to quality control

Measuring video quality is one part of reaching efficient compression. An even bigger challenge is to actively *control* the VQ in real-time. In video compression, it is essential to reach a high video quality. But at the same time, for operational efficiency, you want to avoid overspending bits where they don't matter. At a certain point, bits can be added, but visual quality will no longer improve. This leads to waste, higher-than-necessary-bitrate, and delivery networks that are overloaded with redundant bits. Accurate video

quality metrics can help determine the saturation point and improve the intelligence of encoders. Figure 13 shows an example *rate-distortion* plot where the saturation effect is visible.

Figure 13. Above a certain bitrate, adding more bits will no longer (or hardly) improve quality

In the end, more important than constant bit rate, is to reach *consistent* quality. Note that *constant* quality is not feasible in practice. In all practical encoder systems, there is a maximum bitrate (cap rate) constraint, which will limit the allocation of bits. In case of very difficult scenes, quality might be limited because of that cap. Still, on average, in-loop quality steering will lead to less overspending (wasted bits) and less underspending (quality drops).

On top of VQ measurement, quality control poses an even more challenging problem, as VQ needs to be predicted before encoding. As a result, you end up with a chicken-and-egg problem. Fortunately, ML turns out to enable accurate prediction of encoded VQ, even before encoding. In this way, rate control can be turned into *quality* control. The result is a VBR stream which not only reaches a consistent quality, but also saves bits compared to traditional CBR rate control. Figure 14 shows how the different components fit together: ML-based rate control and VQ measurement, working alongside the ML-optimized video encoder.

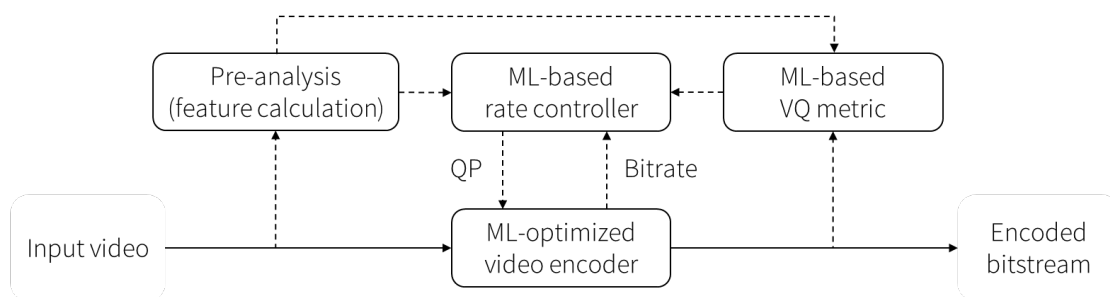

Figure 14. Quality-controlled compression

Figure 15 shows how quality-controlled compression can accurately reach a targeted quality value (in this case VMAF=90). Some variation is possible, and acceptable, when sudden changes in content occur, or when bitrate caps are reached.

Figure 15. Result of quality-controlled compression (target VMAF=90).

Quality-controlled compression can be extended across multiple streams, e.g. in *statistical multiplexing* scenarios. Even though statmuxed streams are inherently VBR in nature, traditionally they have not been optimized with a particular VQ in mind. By using quality control, target quality levels can be specified for each individual stream in a statmux bundle, while still satisfying the total constant bit rate.

Also, *adaptive bitrate (ABR)* encoding can benefit – not only while optimizing individual streams, but also across the whole ladder. Instead of statically defining an ABR ladder as fixed resolution/bitrate pairs, it becomes possible to define quality targets for bitrate ladders, avoiding the need to specify fixed bitrates or even resolutions.

7. Video quality monitoring

One step beyond video quality tracking is *VQ monitoring*. Automated monitoring reduces the need for human inspection to keep track of video quality, with the objective of detecting issues with input sources, transcoding, delivery, or unexpected quality loss. This is another area where machine learning can provide clear benefits.

While VQ measurement as described in the previous section can give a good view of the quality loss introduced by encoding or transcoding itself (by comparing output and input), it does not provide a view of the *absolute* quality of the signal, or whether a potential problem might have occurred. If a disrupted signal enters the transcoder, the FR metric might still report high output quality. Basically, garbage in leads to garbage out...

To allow more flexibility in monitoring, *no-reference (NR) metrics* are essential since they give an impression of the overall video quality. In recent years, NR VQ assessment has been a hot research topic, with successful introduction of new metrics, often using deep neural networks, such as:

- [You19] proposed 3D-CNN and LSTM networks to extract local spatiotemporal features from small cubic video clips.
- [Bosse17] presented a deep neural network approaches with 10 convolutional layers and 5 pooling layers, and 2 fully connected layers for regression, totaling 5.2 million trainable parameters.
- [Bianco18] discusses different design choices for CNN-based blind image quality assessment, where the best design reaches a correlation of 0.91 with subjective scores.

For a good overall impression of quality, a combination of metrics (or *indicators*) is recommended. In the Video Quality Experts Group, studies have been made of different NR metrics. One of the higher-accuracy metrics is Sawatch (v3) [vqeg22], which combines multiple underlying quality indicators to detect e.g. blurriness, blockiness, saturation levels etc.

Still, even the more complex NR metrics reach relatively low accuracies when compared to FR metrics. Also, when quality issues occur, they are more prone to false positives or false negatives when compared to full-reference comparison. For more reliable VQ monitoring, measurements can be taken in different places during delivery, and their results correlated in a central point (e.g. in a cloud service). This provides a reliable comparison point for VQ degradation, transcoding artifacts, or simply transmission errors. Whenever a problem occurs, captures taken from the devices can be uploaded for deeper inspection. Only in those cases, human intervention is needed.

By combining FR and NR metrics, different monitoring scenarios become possible, such as:

- Observing quality fluctuations at a *single point* in the delivery chain. For example, quality measurements can be taken inside an encoder or transcoder and monitored over time. For this use case, either FR metrics (comparing encoded output to its input, Figure 16(a)) or NR metrics (without comparison to a source, Figure 16(b)) can be used.
- Comparing measurements taken in *multiple points* in the video delivery chain (Figure 16(c)). For example in video transport cases, or in multiple processing steps, metrics can be calculated to track the evolution of quality in the delivery chain.

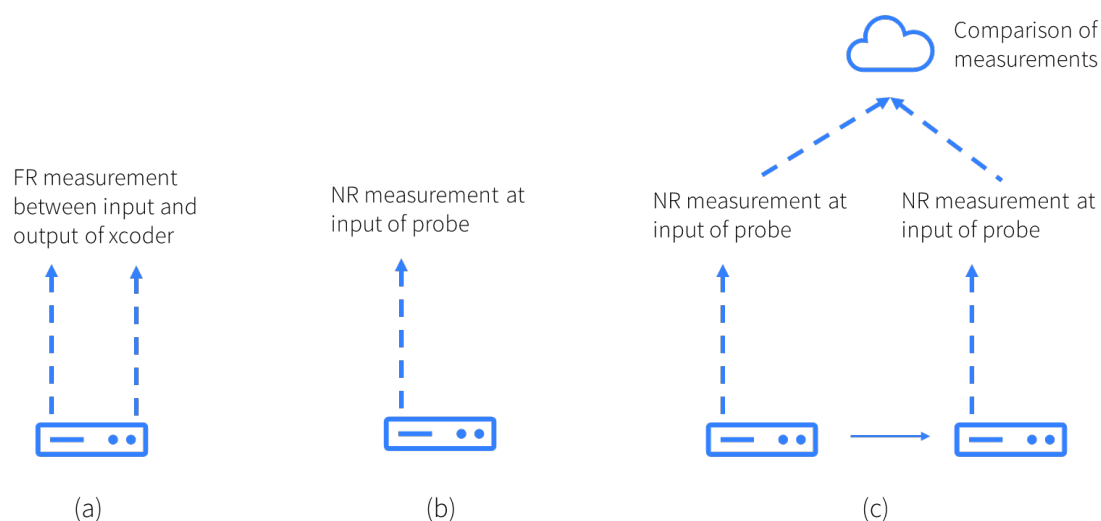

Figure 16. FR and NR quality measurement for VQ monitoring.

By combining these different measurement capabilities, monitoring across the whole delivery chain becomes possible, from contribution encoding to end delivery, as illustrated in Figure 17.

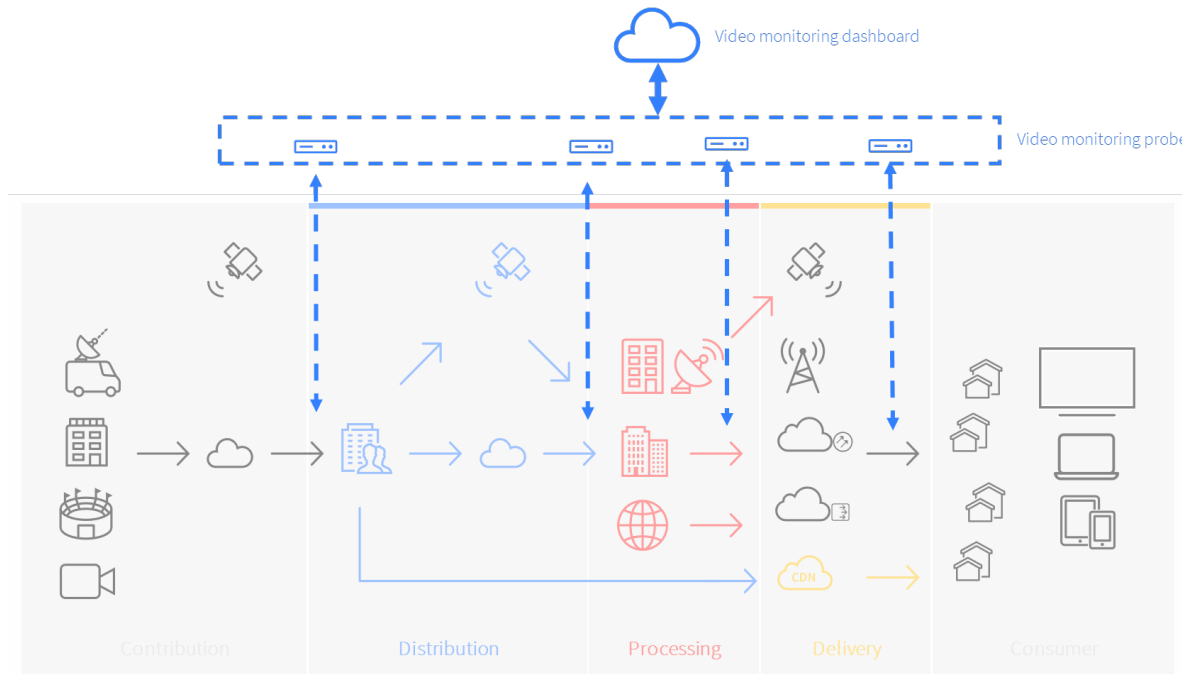

Figure 17. VQ monitoring at different points in the video delivery chain.

8. Conclusions

In this paper, we discussed several areas in video coding where machine learning has shown to provide benefits, including computational complexity reduction, rate control, and subjective video quality improvement. In contrast to popular deep neural networks for image recognition and classification tasks, less complex networks are needed in real-time scenarios, resembling the field of “TinyML”. Relatively shallow ML networks are both computationally acceptable and have been shown to lead to improvements.

The field of VQ measurement benefits from ML approaches, both for non-real-time (such as VMAF) and real-time metrics that can be embedded inside encoders. For VQ monitoring, the combination of FR and NR metrics can be used to analyze quality across the end-to-end delivery chain. By bringing together the ML optimizations for rate control, subjective improvements and VQ measurement, quality-controlled compression can be achieved.

1. Introduction

The fiber access market is largely dominated by passive optical networks (PON). A PON is a point-to-multipoint network supporting multi-service traffic across a single fiber that can be split up to 1:128 in the outside plant and run end-to-end passively (no amplifiers required). The passive splitting feature conserves trunk fiber and minimizes equipment in the central office, node, and headend.

The IEEE and ITU-T define standards for PON at multiple speeds. Ethernet PON (EPON) is specified by the IEEE 802.3 at 1 Gigabit per second (Gbps) in the upstream and downstream direction. The IEEE has also specified a 10 Gbps version called 10G-EPON deployed in Japan and with North American MSOs. The ITU-T defined the Gigabit PON (GPON) that provides 1 Gbps upstream and 2 Gbps downstream. Many operators in China deployed with GPON and selectively upgraded to a higher speed version called NGPON1 with 10 Gbps downstream and 2.5 Gbps upstream. The ITU-T later defined a 10 Gbps downstream and 10 Gbps upstream version of GPON called XGS-PON. Operators in Europe, North America, and other parts of the world started with GPON and upgraded to XGS. XGS has begun to dominate PON deployment and will be the favored solution for residential PON into the future.

Since user demand for bandwidth will continue to increase, it is inevitable that PON speeds beyond 10 Gbps will be needed. The IEEE most recently added a 25 Gbps version with the option of 50 Gbps by optically combining two 25 Gbps signals on the same fiber. Using the IEEE's 25 Gbps optical layer definition, a group of companies formed a Multi-Source Agreement (MSA) to create a 25 Gbps version of ITU-T's GPON. The ITU-T standard has been actively defining multiple versions of 50 Gbps PON. 50 Gbps downstream with 12.5 Gbps upstream or 25 Gbps upstream has been created. A 50 Gbps upstream is currently being defined by the ITU-T. Unlike the IEEE 50 Gbps, the ITU-T uses a single wavelength. Cable Labs has also started a 100 Gbps Coherent PON standard as well.

With multiple operators announcing field trials and devices becoming available, we wanted to write a paper on 25 Gbps PON to explore the bandwidth, latency, upgrade, and cost impacts. The three authors of this paper represent a component supplier, a system provider, and a major operator. From the component level, we want to understand the cost and technology differences between the 10 Gbps PON technologies, 25 Gbps PON technologies, and the future 50 Gbps/100 Gbps PON standards. From a system level, we will explain the coexistence and upgrade paths from lower PON speeds to 25 Gbps. From an operator perspective, we want to explore the use cases for a 25 Gbps symmetric PON solution. Finally, this paper explains the expected bandwidth and latency possibilities with a 25 Gbps PON system. PON has very significant overhead from forward error correction, framing, and burst overheads that will drop the 25 Gbps line rate. In the upstream direction, tradeoffs must be made between low latency and high bandwidth. This paper will present some simple models to explore those tradeoffs.

Since analyses of both the ITU-T and IEEE standards would be prohibitive for a single document, this paper focuses on the 25GS MSA standard that uses the ITU-T's XGS framework. (We believe that a significant amount of the analysis and conclusions would be the same for the IEEE's 25G EPON.) The 25GS MSA defines a downstream rate of 25 Gbps with upstream rates of either 10 Gbps or 25 Gbps. This paper will only consider the 25 Gbps symmetric system where both upstream and downstream are 25 Gbps.

The results in this paper are largely based on modeling of the XGS and 25GS PON systems with some spot checking of the model in XGS mode from lab tests. Since 25GS technology is still in development, large system testing results are not available.

2. Adding 25GS PON to the ODN

Migrating between PON technology can be implemented via two methods:

- New fiber and splitters for each technology
- Wavelength coexistence via a single feeder fiber

For areas where an operator is fiber-rich and has capacity for splitters at the distribution enclosure, they may elect to use additional feeder fiber and additional splitters. In cases where fiber is constrained, an operator may elect to deploy a wavelength coexistence strategy. There are two methods for supporting coexistence. One method, which is internal to the OLT optic, is via a multi-PON module, in which multiple PON technologies (GPON and XGS, or XGS and 25GS PON) are integrated into a single module. The other option is an external coexistence element that combines multiple PON modules.

Table 1 – Wavelength Definitions

Legend	Wavelength Name	Center Wavelength (nm)	Wavelength Range (nm)	Specification
	ITU GPON US	1310	± 20	GPON "Reduced", ITU-T G.984.5
	ITU GPON DS	1490	± 10	ITU-T G.984.2
	ITU XGS PON US	1270	± 10	ITU-T G.9807.1
	ITU XGS PON DS	1577	+3/-2	ITU-T G.9807.1
	25G (UW0) US (MSA & 25G EPON)	1270	± 10	IEEE Std 802.3ca
	25G (UW1) US (MSA & 25G EPON)	1300	± 10	IEEE Std 802.3ca
	25G PON (UW3) US 25GS MSA Only	1286	± 2	25GS-PON MSA
	25G (DW0) DS (MSA & 25G EPON)	1358	± 2	IEEE Std 802.3ca
	25G (UW2) US (50G EPON - 2nd 25G WL)	1320	± 2	IEEE Std 802.3ca
	25G (DW1) DS (50G EPON - 2nd 25G WL)	1342	± 2	IEEE Std 802.3ca
	ITU 50G PON (12.5G/25G/50G) (Option 1) US	1270	± 10	ITU-T G.9804.3
	ITU 50G PON (12.5G/25G/50G) (Option 2) US	1300	± 10	ITU-T G.9804.3
	ITU 50G PON DS	1342	± 2	ITU-T G.9804.3

Figure 1 – PON Wavelength Plan

As illustrated in Figure 1, GPON and XGS PON upstream(US) and downstream(DS) wavelengths are separated which allows for coexistence across a single feeder fiber. The simple figure below illustrates how a passive coexistence element (CE) can bring XGS-PON US/DS Wavelengths together with GPON US/DS wavelengths. This would not be possible if the wavelengths overlapped.

Figure 2 – GPON and XGS PON Coexistence

In conjunction with the use of a CE, two other key factors must be considered. First, the ONTs must be able to filter out or block the downstream wavelengths for the coexisting OLT. In the GPON-XGS coexistence example above, this means that the GPON ONT must block the downstream XGS wavelength and the XGS ONT must block the downstream GPON wavelength. Second, since both PON variants share the same ODN, the OLT and ONT optics for both PON variants should be compatible with the attenuation range of the shared ODN.

Table 2 below from ITU-T G.9807.1 gives the attenuation range classes (B+, N1, etc....) for the ODN. May want to pull in the attenuation range info as a reference of ODN Classes.

Table 2 – ITU-T Optical Class Definitions

PON TYPE	ODN Class	Attenuation Range (dB)
GPON	B+ class	13-28
GPON	C+ class	17-32
XGS/25GS	N1 class	14-29
XGS/25GS	N2 class	16-31

PON TYPE	ODN Class	Attenuation Range (dB)
XGS	E1 class	18-33
XGS	E2 class	20-35

As identified in Table 2, B+ and C+ are ODN classes that supports a maximum fiber plant loss of 28db and 32db respectively. In addition, N1 (29dB), N2 (31dB), E1 (33dB), and E2 (35dB) are defined in ITU-T, while N1 and N2 are defined in the 25GS PON MSA specification.

Figure 3 – XGS and 25GS (UW1) PON Coexistence

Figure 4 – GPON and 25GS (UW0) PON Coexistence

Figure 5 – GPON, XGS, and 25GS (UW3) PON Coexistence

As seen in Figure 3, Figure 4, and Figure 5, there are three paths to facilitating coexistence between 25GS with GPON, 25GS with XGS, or 25GS with both prior PON technologies. The IEEE 802.3 standard developed the options for UW0 (1290-1310 nm) or UW1 (1260-1280 nm) with DW0 (1356-1360 nm).

The 25GS-PON MSA incorporated these into their specification and added UW3 (1284-1288 nm) with DW0 (1346-1350 nm).

UW0 and UW1 are 20nm wide, supporting the use of a DML for an N1 class ODN. UW3, on the other hand, is 4nm wide and will require an EML for an N1 class ODN. UW3 allows for triple coexistence between GPON, XGS, and 25GS but there are additional cost considerations that need to be weighed by the operator. With UW0 or UW1, an operator achieves double coexistence (GPON and 25GS or XGS and 25GS) with less expensive optics but loses the ability to coexist across three PON technologies. The 3rd PON technology must be placed on a separate fiber and splitter.

While this paper focuses on 25GS PON it should be noted that 50G PON (EPON or ITU-T) can coexist across a single feeder fiber with a prior PON technology.

3. System Upgrade to 25GS PON

Whether an operator is introducing PON for the first time or evolving a PON network to services supported by a 25G solution, a general consideration is how the new deployment implementation will support introduction to or coexistence with 25GS. Historically, PON technology evolutions involve evaluating customer behavior, preferred network topology, platform MAC scale and implementation granularity. These evaluations typically revolve around how and where an OLT is implemented.

There are three OLT model types: the large chassis, the pizza box, and the MSA pluggable OLT. In the following sections, we review the implications of these options with regards to introduction and evolution to 25GS.

3.1. Large Chassis OLT

Figure 6 – Example of Chassis with XGS Cards and 25GS Cards

The large OLT platforms, as seen in Figure 6, offer from the twenties to hundreds of PON ports. They are typically made up of modular, dedicated functional cards integrated into mainframes that distribute signal back and forth via a high-speed backplane. The platforms are physically large in the range of 10 rack units or more, and require locations with dedicated HVAC systems. OLT platforms of this type are quite efficient when dedicated in scale to the particular function or technology they were created for very large contiguous deployments of a particular PON technology, servicing a large number of customers within 20 km of a central office or hub. Their drawbacks are the sunk investment of a large platform when not used in scale and their otherwise inflexibility to work beyond the technology they were designed for.

Figure 7 – Example of Chassis with Dual Speed XGS/25GS Line Cards

The evolution of large OLT platforms to 25GS is implemented in the context of line card scale capability, their modularity, i.e., processing capacity and backplane throughput, with the understanding that if a box was created for, as an example, 100 PON instances of GPON, transitioning through XGS then to 25GS would likely result in a continual reduction of port counts to the point where it is no longer an efficient large scale box. Similarly, although to a lesser extent, evolving from XGS will also result in the PON instance capability being reduced. In one example, 25GS is supported by a new line card with half the number of PON ports. In the other example, the dual speed line card can select the speed by using a different transceiver. Large platforms can also be equipped to function as broadband network gateways (BNG) and collocated for large scale deployments.

3.2. Pizza box OLT

The “pizza box” refers to integrated platforms of a reduced size, typically one rack unit and generally less than four. The attractive quality for pizza box OLTs is flexibility. They can be used to service less dense population areas, and because of their size (and if temperature hardened) they can be placed in remote cabinets to service customers at distances much greater than 20km. They can also act in unison as a large OLT when racked together, interconnected by a top or rack switch and facilitated by a centralized controller.

With regards to evolution to 25GS PON, the flexibility of pizza box platforms is lost. Boxes that are not preconditioned to support a 25GS solution must be replaced with a new box. This is certainly a service-affecting change. If a 25GS option is available, it is most likely at a lower density than for prior PON technologies.

3.3. Micro-OLT

Figure 8 – XGS/25GS MicroOLTs in a multi-rate Ethernet Switch

As seen in Figure 8, the MSA pluggable OLT solution is also known as a micro-OLT (μ OLT). (MSA pluggable refers to SFP+, SFP28, CFP2, etc.) These μ OLTs facilitate one PON instance at a time through a single port on an Ethernet switch. In contrast to the large chassis and pizza box solutions which combine the MAC domain chipsets with the switching fabric but isolate the optics, the μ OLT technology combines the MAC domain chipsets with the optical interface, leaving the switching fabric separate.

The scalability of these platforms is determined by the host switch, which also determines the geographic deployment. The μ OLT can service sparsely deployed regions, including being temperature hardened and deployed in remote cabinets, in the most granular manner—one PON instance at a time. The flexibility is nearly boundless when creating PON deployments with μ OLTs.

A previously unattainable dimension of flexibility is also available when using μ OLTs. Because the PON service is limited to a dedicated switch port per the pluggable, combining other services on the same Ethernet fabric is now possible. Studies in recent years have looked at the convergence of services over the same access network, and the μ OLT facilitates service integration at the layer 2 and layer 3 levels. The considerations for deterministic bandwidth assignments are beyond the scope of this paper, but there is a whole field of study that expects to leverage μ OLTs as an easy method to enable service convergence.

With regards to the evolution or introduction to 25GS, the flexibility follows the granularity of the μ OLT. Transitions to 25GS would be a straightforward port change; μ OLTs have been generally available since 10G PON implementations. Note that the technical challenge is for pluggable solutions to maintain the development necessary to include additional capabilities, such as thermal growth into continually small form factors. One particularly interesting dimension of pluggable solutions is their ability to support the coexistence of different PON technologies on the same bridging domain. For example, a single switch can be populated with a mix of both 10G and 25GS services. Such flexibility

could potentially support large usage end-line customers, gradually transitioning their services to 25GS. This collection of system design qualities makes the μ OLT a very attractive option for 25GS solutions.

4. Use cases for 25GS PON

There are several factors that will determine how 25GS is used:

- Coexistence can be used as a mechanism to move from one PON technology to the next (e.g., GPON to XGS or XGS to 25GS) without having to place additional feeder fiber and splitters.
- XGS is now in scale deployment with many operators either offering or preparing to offer a multi-gig broadband service.
- Most of the cost of fiber-to-the-premises (FTTP) is fiber placement. If fiber is abundant, then it may be more cost effective to use a feeder fiber and place a new splitter. If fiber is constrained, then a coexistence strategy may prove to be more cost effective.
- ONTs are normally dedicated per unit/household and thus component costs are important to constrain (i.e., DML vs EML).
- OLTs are a significant cost but can be shared among multiple subscribers:
 - Large chassis: 128-256 PONs x 1:64 split (8K to 16K subscribers)
 - Pizza box: 24-48 PONs x 1x1:64 split (1.5K to 3K subscribers)
 - μ OLT: Varies from 1-48 PONs based on the switch x 1:64 split (64 to 3K subscribers)

So, the question is, what do you do with 2.5 times more capacity than XGS?

As shown in Figure 9 the architecture proposal will support consumer, business, and mobility applications across a single feeder fiber and splitter. This design will allow a mix of best effort multi-gig broadband services with a maximum latency of 4ms through the OLT, as well as business and mobility applications with 10G+ multi-gig broadband services with a “protected” (guaranteed) amount of capacity and sub-ms latency across the OLT.

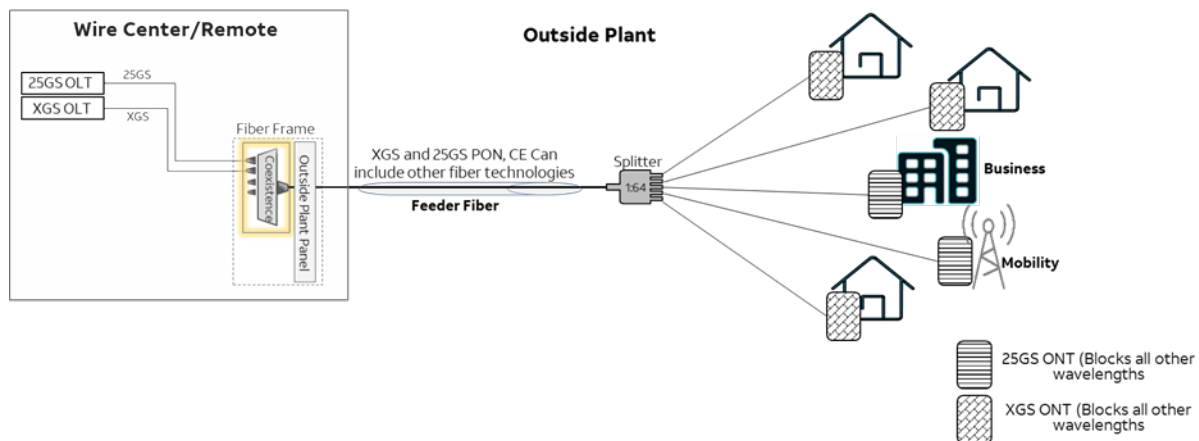

Figure 9 – XGS and 25GS Coexistence Architecture

XGS will continue to be a valuable technology, and currently supports consumer services through multi-gig broadband. Many users will continue to be supported over XGS for years to come. 25GS offers not only the ability to offer 10G+ broadband speed tiers, but also much more capacity at a small incremental increase in cost. 25GS could initially target business, work from home subscribers, mobility, and capacity failover for bandwidth intensive subscribers on XGS. Since consumer scale deployments on

25GS are assumed to be a future phase, a smaller percentage of the total is assigned to the splitter. For example, a splitter of 1:64 is usually capacity-managed to the total. In this design, however, two PON technologies are managed separately. XGS would have access to capacity of all 64 ports while 25GS would be set to capacity trigger at 25% (16 ports of a 1:64 splitter in this example). Placement of the XGS or 25GS ONT and assignment to the appropriate OLT PON port determine what is serviced on the splitter. An operator does not need to lock in specific ports of a passive splitter. Any port on the splitter can support XGS or 25GS as long as the capacity triggers are not exceeded. In this example, XGS can be deployed across more than 48 ports, and the capacity algorithm for 25GS would be decremented to maintain the total of 64.

The four initial use cases for 25GS mentioned above are described below:

- **Business:** 25GS has the capacity to support large numbers of customers behind a switch with an SFP28 25GS ONT or a purpose-built gateway. In this case, capacity, “protected” bandwidth, and sub-ms latency would benefit this market without driving significant cost.
- **Work from home:** an operator could use the additional capacity to offer consumer-grade broadband service-mapped interfaces (such as wireless SSID or physical LAN interfaces) while also supporting business services to other interfaces.
- **Mobility:** 25GS allows for more than 20Gbps x 20Gbps of usable bandwidth. “PON as a transport” for backhaul and mid-haul mobility services is possible with a sub-ms PON.
- **Capacity protection:** As new applications emerge that drive additional capacity requirements on XGS, 25GS offers a capacity failover from XGS and allows the operator to offer more tailored services to these high-end users. In addition, the XGS is managed for a better customer experience for the remaining subscribers. Note that with a coexistence strategy, the transition for an existing XGS subscriber to 25GS requires the shipment and customer installation of a new 25GS PON ONT or gateway.

Refer to the following Table 3 and Table 4 for details about PON capacity by splitter.

Table 3 - 1:16 Splitter, 25% 25GS PON, Decrementing 25GS

5. Cost Analysis of 25GS PON

5.1. OLT/ONU

The highest equipment cost in a PON deployment is the customer-side device, the Optical Network Unit (ONU), also known as the Optical Network Terminal (ONT). These devices connect to an Optical Line Terminal (OLT) at the operator side. Since the OLT is designed to split a single fiber to 64 ONUs at 20 kilometers, adding only \$1 to the cost of the ONU adds \$64 to the cost of operating the OLT port. For 25GS to succeed as the next evolution from XGS, it must support a cost-effective ONU. This goal is currently attainable in most cases.

In 2020, the *Journal of Optical Communications* presented a relative cost comparison between components of the various PON speeds beyond XGS. The article noted that 25GS requires the same components as XGS, with minor upgrades for the higher speed. As a result, there is only a small cost increase for the 2.5x data rate. At speeds higher than 25 Gbps, additional components and major technology changes are required, which increase both the expense and the power requirements of the corresponding ONUs, as shown in Figure 10.

Figure 10 – Relative PON Transceiver Cost in Volume

Note that the specification for 50G/50G was not finalized at the time of this article. While we believe that costs will be significantly higher than for lower speeds, they will likely be less than the 14x shown above.

5.2. Optical Budget

PON speed increases require more optical budget. Going to a 25 Gbps line rate from 10 Gbps causes a 4 dB penalty. Forward error correction, or FEC (which sends redundant data to assist the receiving device with assessing errors) provides a portion of the needed gain. A larger block size and a low-density parity check (LDPC) FEC in 25GS provides additional gain over the Reed Solomon (RS) FEC used in XGS. 25GS FEC requires significantly more logic area in the PON OLT or ONU ASIC. The LDPC makes it difficult or cost prohibitive to use FPGAs for the OLT PON MAC. In ASIC form, the cost difference is not very significant. The 25GS FEC provides roughly 1.5 dB of optical gain over the XGS FEC.

In addition to the gain from FEC, the transmit optical power and receiver sensitivity must recover 2.5dB of the 4dB penalty. The proposed values for transmit optical and receiver sensitivity are near the limits of unamplified optics. For speeds above 25 Gbps in the upstream or downstream, a silicon optical amplifier (SOA) will be required. Adding the SOA can double the cost of the optics and consume an extra one watt of power. While the N1 optical budget doesn't require the SOA at 25 Gbps, the N2 optical budget is still undecided. It is easy to achieve N2 level with the SOA but it also seems very possible to achieve it with proper process control.

5.2.1. Transmission Lasers

PON systems use one of two laser types to transmit data across the fiber line:

- Directly Modulated Laser (DML) creates wider wavelengths with more frequency distortion. They are used for lower speeds and shorter distances.
- Externally Modulated Laser (EML) are temperature controlled with less distortion and narrower wavelengths. They are used for higher speeds and longer distances.

The EML is often 2.5x the cost of the DML. EML also requires up to one watt of additional power for temperature control. For the OLT transmitter, the EML is normally used for all current versions of PON and will likely be the solution for 25GS. As a result, migrating from XGS to 25GS will not result in significant OLT transmitter cost increase if the SOA is not added.

For the ONU transmitter, the DML can be used for GPON and XGS. For 25GS, the requirement is determined by the wavelength. DML can generate the wider UW0 and UW1 wavelengths, but EML is required for the narrower UW3 wavelength. For 50Gbps, EML will be required for all wavelengths.

5.2.2. DSP, High Speed ADC, Coherent

XGS and 25GS don't require a high-speed analog to digital converter and DSP to process the receive signal. Going to 50 Gbps and beyond will require these functions. These functions add significant cost, complexity, and power to the ONU receiver. In some estimates, 2 to 5 watts of additional power will be required to support these functions. Adding Coherent optics allows for higher split ratio, longer reach, and speeds beyond 100 Gbps. Unfortunately, Coherent optics will also increase the cost and power significantly over 25GS.

5.2.3. Cost Summary

With all things considered, 25GS has been estimated to be 1.5 times the cost of XGS in volume. Since the XGS ONU and 25GS ONU don't require an EML transmitter, SOA, or DSP, the increment in cost is reasonable for a 2.5 times speed increase. The 25GS ONU optics could be significantly higher cost if the SOA is required to reach the N2 optical budget and/or the EML transmitter is required to use the UW3 wavelength.

6. Bandwidth Analysis of 25GS

A 25GS delivers less than a full 25 Gbps worth of Ethernet bandwidth across the PON. Framing, forward error correction (FEC), and physical layer management eat into the total bandwidth, see Figure 11

6.1. Downstream Bandwidth Calculation

Figure 11 – XGS and 25GS Downstream Framing

To determine the actual downstream bandwidth, overhead costs will be removed, and variable overhead costs will be estimated. These overhead costs are described below and listed in Table 5:

- Like XGS, 25GS uses non-return-to-zero (NRZ) data without additional bits for line encoding. At a line rate of 24.8832Gbps, 25GS PON is exactly 2.5x the XGS line rate of 9.95328Gbps; no additional bandwidth loss is incurred by the higher rate alone. These starting rates are shown in the first row of the table.
- In both XGS and 25GS, the downstream contains a 24-byte physical synchronization block (PSBd) every 125μs. This block allows for downstream byte alignment, FEC block alignment, and frame alignment (these bytes are not covered by FEC). The PSBd impact is shown in the second row in the table.
- The most significant difference between XGS and 25GS is the new FEC (mentioned in the previous section). In XGS, a FEC block of 248 bytes contains 216 bytes of payload and 32 bytes of parity, reducing the data rate to 8.667648Gbps (efficiency ≈ 87%). In 25GS, a FEC block of 2144 bytes contains 1824 bytes of payload and 320 bytes of parity, reducing the data rate to 21.154304Gbps (efficiency ≈ 85%). The resulting data rates are shown in the third row in the table.
- After the PSBd, the 125μs downstream frame contains the framing sublayer (FS) header and FS trailer. For both XGS and 25GS, the FS trailer is a 32-bit interleaved parity over the FS data excluding FEC parity. The FS header has a minimum size of 4 bytes and a variable size for the physical layer OAM (PLOAM) and the bandwidth map (BWmap) carrying the upstream grants. The resulting data rates are shown in the fourth row in the table.
 - Each PLOAM message is 48 bytes long. For the bandwidth calculations, we assume one PLOAM every 125μs for both XGS and 25GS.

- Each upstream allocation in a BWmap is 8 bytes long. The number of allocations required by the upstream is determined by the polling and maximum burst size configuration.
- ITU-T-based ONUs are managed by ONU management control interface (OMCI) frames. These frames allow for setting up the ONU data path and monitoring the performance. The amount of OMCI required for XGS and 25GS should be the same, averaging two frames per second for each ONU; for a 64-ONU system, this is 128 frames per second. OMCI includes a baseline frame of 48 bytes and a variable extended frame size. Since many ONUs support only the baseline size, we will use this value in the calculations below. Finally, every OMCI frame includes an 8-byte XGEM header, bringing the total size to 56 bytes. The resulting data rates are shown in the 5th row in Table 5.

Table 5 – Downstream Overhead

	XGS (10G/10G)		25GS (25G/25G)	
	Deduction (bps)	Available BW (Gbps)	Deduction (bps)	Available BW (Gbps)
Initial Line Rate	-	9.953280000	-	24.883200000
<i>minus:</i> PSBd, FS Header/Trailer	2,560,000	9.950720000	2,560,000	24.880640000
<i>minus:</i> FEC Parity	1,284,096,000	8.666624000	3,727,360,000	21.153280000
<i>minus:</i> OMCI	57,344	8.666566656	57,344	21.153222656
<i>minus:</i> PLOAM	768	8.666565888	768	21.153221888
<i>minus:</i> BW Map	1,677,517	8.664888371	227,253,073	20.925968815
% User XGEM Data		87%		84%

The ITU-T-based PON system uses XGEM framing to carry Ethernet. The XGEM frame is an 8-byte XGEM header that encapsulates each Ethernet frame from the destination address to the CRC-32. XGEM frames do not include the 12-byte interpacket gap (IPG) or the 8-byte preamble found in the Ethernet frame. XGEM framing allows for segmentation of the Ethernet frames, but only at the 125μs frame boundary in the downstream direction. When comparing the XGEM bandwidth (BW) with the Ethernet Layer 1 BW, the per-packet overhead is 20 bytes (preamble + IPG) for Ethernet and 8 bytes for XGEM. This difference allows for a higher BW to be carried on the PON than on the Ethernet side of the network. The difference can be significant with small frames and less significant with large frames.

Finally, our calculations must include the application layer bandwidth available to customers running speed tests, FTP, etc. To calculate these values, we assume a layer 2 (DA/SA/TYPE/CRC-32) of 18 bytes, an IPv4 header of 20 bytes, and a TCP header of 20 bytes. Despite a drop in data rates from the table above, applications on XGS can still operate at download speeds above 8Gbps while 25GS can still operate at download speeds above 20 Gbps, as shown in Table 6.

Table 6 – Downstream Bandwidth Available

	XGS (10G/10G)	25GS (25G/25G)
XGEM Frame BW	8.659910 Gbps	21.146566 Gbps
L1 Ethernet BW (64B)	10.103228 Gbps	24.670994 Gbps
L1 Ethernet BW (1500B)	8.728822 Gbps	21.314841 Gbps
L7 Application BW (1500B)	8.280895 Gbps	20.381963 Gbps

6.2. Upstream Bandwidth Calculation

The upstream for 25GS uses the same 24.8832Gbps line rate (2.5 times the XGS line rate) as the downstream. The calculation of the possible upstream bandwidth is more complicated than for the downstream because the amount of bandwidth lost is determined by the variable size of the upstream burst. We will start by assuming 64 ONUs on the PON and a simple static granting to see the maximum possible performance. We will then add the overhead required to make the upstream a dynamic operation, so it can be shared on demand. Finally, although the PON can support multiple services in multiple upstream traffic containers or prioritized traffic in a single container, we will assume a single service and the same priority level for each ONU for both our bandwidth and efficiency analyses.

For these analyses, we will consider the three primary impacts on upstream bandwidth: burst overhead, static (fixed) BW allocation, and dynamic BW allocation (DBA).

6.2.1. Burst Overhead

Figure 12 – Upstream Burst Overhead

The upstream burst can be split into 3 parts, (as seen in Figure 12 and Figure 13): dead time between bursts, a preamble at the start of the burst, and the block of data. For ITU-T PON, the dead time and preamble are determined by the configurable parameters of guard time and preamble time. The guard time includes the ONU Laser ON time, the ONU Laser OFF time, and the dead time for any jitter in the upstream slot time. The preamble time includes the time required for the OLTs to perform gain control and clock recovery. The preamble is shown as the physical layer synchronization block for upstream (PSBu). Optical components for 25GS are still in development and they will certainly improve over time. For this analysis, we will assume the same time duration values as XGS. For XGS, a value of 256 bytes will be used for guard time and preamble time combined. For 25GS PON, we will multiply the XGS's 256 bytes by 2.5 to get 640 bytes for both values combined.

Figure 13 – Upstream Framing Overhead

After the PSBu, the FS burst is the FEC protected data. The FS burst starts with the FS header that is 4 bytes long without a physical Layer OAM (PLOAM) or 52 bytes with a PLOAM. The grant in the Bwmap from the OLT selects the inclusion of PLOAM, inclusion of bandwidth request (BWR), and the size of XGEM blocks within the FS burst. Bursts that only carry PLOAM and/or BWR can have a length of 0. The FS burst can contain grants to one or more allocation IDs on the ONU. For our analysis, we will assume a single allocation per burst. The standard allows for a maximum grant size of 9719 upstream slot times. In the case of XGS, upstream slots are defined as 128 bits or 16 bytes. In 25GS, the upstream slots are 2.5 times greater, so they are 320 bits or 40 bytes. In that case, the maximum grant of 9719 upstream slots equals 155,504 bytes in XGS and 388,760 bytes in 25GS. The FS burst ends with the 4-byte FS trailer that contains a parity for checking the data.

6.2.2. Static (Fixed) BW Allocation

With static allocation, the OLT sends a fixed-size grant to each ONU in a simple round robin. This is often called unsolicited granting in DOCSIS. In this analysis, we will assume that all ONUs receive the same fixed allocation.

Physical layer OAM (PLOAM) provides the initial configuration of the PON physical layer and key exchange for encryption. PLOAM in the upstream is infrequent after registration, so required bandwidth consideration is negligible. ONU management control interface (OMCI) is the management traffic from the OLT to the ONU. Data path configuration, firmware download, and statistic gathering are the primary tasks using OMCI. For OMCI frame bandwidth in the upstream, a fixed payload of 56 bytes is granted every 8ms. Discovery slots are 250μs of deadtime for ONUs to register (assuming a 20km PON). In this analysis, a discovery slot is granted every 3 seconds. With the maximum allocation of 9719 upstream slots and the overhead described above, we can calculate the maximum upstream bandwidth for both XGS and 25GS:

- For XGS, a grant of 9719 upstream slots would carry 155,504 bytes of payload data, 8 bytes of FS header/trailer, and 23,040 bytes of FEC parity.
- For 25GS, a grant of 9719 upstream slots would carry 388,760 bytes of payload data, 8 bytes of FS header/trailer, and 68,480 bytes of FEC parity.

It should be noted that while these grants are possible, they are not practical for a 64-ONU system, since the delay between grants would be very long. As an alternative, a static allocation of 20,000 bytes is included in the following table as an example of a viable lower latency configuration.

Table 7 – Static Allocation Analysis for 20km, 64 ONU PON

	XGS (10G/10G)		25GS (25G/25G)	
Line Rate	9.953280 Gbps		24.883200 Gbps	
Static Payload Size	20,000 Bytes	155504 Bytes	20,000 Bytes	388760 Bytes
Minus Preamble, Guard time, FS H/T	(-222,852,025 bps) 9,730,427,975 bps	(-29,233,025 bps) 9,924,046,975 bps	(-1,291,341,739 bps) 23,591,858,264 bps	(-69,785,265 bps) 24,813,414,735 bps
Minus FEC	(-1,256,075,050 bps) 8,474,352,925 bps	(-1,275,622,869 bps) 8,648,424,106 bps	(-3,507,347,934 bps) 20,084,510,330 bps	(-3,687,418,908 bps) 21,125,995,827 bps
Minus OMCI	(-38,912,000 bps) 8,435,440,925 bps	(-38,912,000 bps) 8,609,512,106	(-106,496,000 bps) 19,978,014,330 bps	(-106,496,000 bps) 21,019,499,827 bps
Minus Discovery	(-829,440 bps) 8,434,611,485 bps	(-829,440 bps) 8,608,682,666	(-2,073,600 bps) 19,975,940,730 bps	(-2,073,600 bps) 21,017,426,227 bps
L1 Ethernet BW (1518B packet)	8.507744902 Gbps	8.677271545 Gbps	20.08482188 Gbps	21.09803954 Gbps
L7 Application BW (1518B packet)	8.076272794 Gbps	8.237201857 Gbps	19.066215828 Gbps	20.028047937 Gbps
Latency	1.46 ms	9.46 ms	.762 ms	9.72 ms

The static allocation in Table 7, shows both a very high possible bandwidth (the second column for each rate) and the ability to achieve a lower latency with a smaller burst size consuming lower bandwidth (the first column for each rate). Note that using smaller burst sizes increases the amount of bandwidth required for the combined per-burst overhead (preamble, guard time, FS header and trailer), since smaller bursts require more bursts to be sent, and each burst contains its own overhead.

While static granting is helpful for a simplified overhead analysis, it is impractical for most PONs. For a 64-ONU system with the maximum burst size, the upstream Ethernet bandwidth per ONU is only 135Mbps in XGS and 329Mbps in 25GS. Since operators expect PON networks to meet their requirements for statistical gain, fewer ONUs and different allocations should be used in real-world scenarios to allow for grant sizes to be adjusted accordingly. The static BW analysis above shows the maximum possible upstream bandwidth and cost of the PON overheads.

6.2.3. Dynamic BW Allocation (DBA)

Figure 14 – DBA Upstream Bursts

Adjusting the upstream slot according to subscriber needs is facilitated with DBA in a request/grant methodology. The OLT sends a dynamic bandwidth resource unit (DBRu) in the upstream slot. The returning DBRu consumes 4 bytes in the upstream burst and indicates the amount of packet data remaining in the queue. If the ONU returns the DBRu with a value of 0 (indicating no data in the queue),

no grant will be sent from the OLT. Instead, the OLT will send another DBRu to the ONU after a fixed time interval. This process is known as polling.

If the ONU returns the DBRu with a non-zero value, the OLT then sends a variable-size grant to the ONU based on the reported data payload need. The data payload sent upstream from the ONU includes a DBRu reporting additional payload waiting. The granting of a follow-up DBRu with the data payload burst is known as piggyback granting. When a grant is piggybacked, polling is not needed.

Calculating the available upstream bandwidth for a DBA system is more complicated than for a static allocation system since there are endless possible burst sizes from different traffic scenarios and different SLAs. For this analysis, we will establish some basic parameters to model the most complex scenario, as follows:

- We will consider request/grant or status-reporting DBAs only, and not non-status reporting or predictive grants.
- All ONUs will be assigned the same SLA, with the goals of low latency and higher bandwidth for the entire PON.
- The status reporting methodologies used will be polling and piggybacking.

In a DBA PON system, the amount of overhead is determined by the number and size of the bursts. We will examine the extreme conditions to calculate the bandwidth and latency of the PON upstream in a PON of 64 ONUs, considering two scenarios:

- When a single ONU is requesting the maximum rate, it will use piggybacking, while the other 63 ONUs will use polling. The bandwidth for polling the 63 ONUs will decrease the amount of bandwidth available for the single piggybacking ONU. In this scenario, the key factor is the polling interval: a shorter polling interval will have lower latency for the 63 polling ONUs but consume more upstream bandwidth from the single piggybacking ONU, while a longer polling interval will increase latency for the 63 polling ONUs but save upstream bandwidth for the single piggybacking ONU.
- When all 64 ONUs are actively sending payload data and requesting the maximum rate, they will all use piggybacking exclusively. Since all ONUs are treated equally, the DBA will schedule the ONUs in a round robin based on the last time data was granted. The size of the round robin is the number of active ONUs times the maximum size of the burst. In this scenario, the key factor is the maximum size of the burst: a larger burst will be more efficient for the ONU that is sending its payload, but it will create a longer delay for the other ONUs.

Table 8 – Dynamic Bandwidth Allocation Analysis for 20km, 64 ONU PON

	XGS (10G/10G)		25GS (25G/25G)	
Line Rate	9.953280Gbps		24.883200Gbps	
Polling Interval	3.5 ms		3.5 ms	
Max PON Burst Size	60,000 Bytes		140,000 Bytes	
ONU Activity	1 active and 63 idle	64 active	1 active and 63 idle	64 active
Payload Burst Overhead	75,319,749 bps	75,920,301 bps	191,775,180 bps	193,589,029 bps
Payload FEC Overhead	1,259,482,114 bps	1,269,524,418 bps	3,634,877,255 bps	3,669,256,667 bps
Polling Overhead	80,064,000 bps	0 bps	232,128,000 bps	0 bps
L1 Ethernet BW (1500B packet)	8,539,654,048 bps	8,607,743,778 bps	20,761,985,282 bps	20,958,356,379 bps
L7 Application BW (1500B packet)	8,122,924,176 bps	8,187,691,169 bps	19,748,813,154 bps	19,935,601,462 bps
Latency	4.125 ms	3.95 ms	4.125 ms	3.80 ms

Table 8 above shows a practical configuration for XGS applied to 25GS. This configuration allows an XGS system to have a ~4ms maximum upstream latency. In both XGS and 25GS, polling inactive ONUs becomes significant when fewer ONUs need to use the upstream. The polling waste is reduced to 0 when all ONUs are active. XGS shows 8.5 Gbps of Ethernet bandwidth 8.1 Gbps of application bandwidth while 25GS achieves 20 Gbps of Ethernet bandwidth and just under 20 Gbps of application bandwidth. While the goal of 2.5 times the speed of XGS is not reached, the results are very close.

Main Port Traffic Statistics										
Name	TX L1 (%)	TX L1 (bit/s)	TX L2 (bit/s)	TX (pps)	TX (bytes)	TX (packets)	RX L1 (%)	RX L1 (bit/s)	RX L2 (bit/s)	RX (pps)
P-0-0-0	89.600	8,959,986,780	8,842,092,220	736,841	39,254,169,000	26,169,446	86.120	8,612,033,640	8,498,717,480	708,226

Figure 15 – DBA Lab Results for 64 active ONUs

Name	TX L1 (%)	TX L1 (bit/s)	TX L2 (bit/s)	TX (pps)	TX (bytes)	TX (packets)	RX L1 (%)	RX L1 (bit/s)	RX L2 (bit/s)
P-0-0-0	90.000	8,999,997,660	8,881,576,700	740,131	23,786,878,500	15,857,919	85.059	8,505,864,680	8,393,945,480
P-0-0-1	90.000	8,999,990,280	8,881,569,320	740,131	23,848,053,000	15,898,702	87.329	8,732,881,510	8,617,672,070

Figure 16 – DBA Lab Results for 1 active ONU on 64 ONU system

A lab test of a 64-ONU system in XGS with the sample configuration shown in the table able was performed to validate the model. With 64 ONUs transmitting 9 Gbps upstream, the “RX L1” of 8.612 Gbps received is very close to model’s prediction of 8.607 Gbps, as seen in Figure 15,. With a single ONU transmitting, the 8.505 Gbps “RX L1” on P-0-0-0 closely matches the model’s prediction of 8.539 Gbps, as seen in Figure 16. The downstream performance from the lab is also available on P-0-0-1 “RX L1”. The lab shows 8.733 Gbps which is very close to the downstream Ethernet L1 model’s predication of 8.729 Gbps.

7. Latency Analysis of 25GS

Latency has become a hot topic in the industry. Residential subscribers are looking for low latency for gaming and interactive experiences such as the metaverse. In this paper, we will look at the one-way packet latency between the OLT NNI port and ONU Ethernet UNI port. These delays assume layer 2 switching at the OLT and ONU. Routing devices, Wi-Fi interfaces, etc. will add more latency. This analysis focuses on worst case scenarios with a fully loaded PON. In most cases, the customers will see much better latencies due to a lower take rate or activity.

7.1. Downstream Latency

The downstream latency for PON is very low, and largely based on the functional characteristics of the network switches and the length of the PON fiber. On a 20km fiber, the flight delay is 100μs for both XGS and 25GS. The FEC block for 25GS is 2144 bytes versus 248 bytes for XGS, so the 25GS decoder will require more time for processing. However, the FEC decoder time is still minimal for 25GS, at approximately 1μs. This is a small value compared to the store and forward delays in the OLT and ONU switching. Finally, equipment delays are normally less than 50μs, so the worst-case delay on a 20km fiber is 150μs. This calculation also applies to both XGS and 25GS.

7.2. Upstream Latency

If operators don't have demand for the 20 Gbps of upstream traffic possible in 25GS, they can trade off the upstream bandwidth for a lower latency upstream. Since TCP/IP traffic downstream requires an upstream acknowledge, a lower latency upstream can also improve downstream throughput. By decreasing the interval for polling and reducing the maximum burst size, the latency for all ONUs in a 64-ONU PON could be reduced significantly. The inaccuracy of predictive granting, inflexibility of fixed granting, and other less predictable techniques can be avoided. The ability to lower the latency provides an opportunity to increase the downstream performance and throughput. Since the large downstream TCP/IP bursts require acknowledging in the upstream direction, minimizing the latency for these frames increases the downstream throughput and overall latency. Upstream latency on a PON can be broken down into 3 areas: start latency, continuation latency, and queue delay.

7.2.1. Start Latency

Whenever the upstream packet stream gives a DBRu of 0 to the DBA, it is considered idle and won't be granted until the next polling cycle. Since data arrives randomly compared to the polling cycle, the maximum wait time to be sampled is the polling interval. After the polling interval, the DBRu must be sent to the OLT/DBA to be granted. This transmit time can be 0μs for a 0 km distance ONU and 100μs for an ONU at the end of the fiber. An idle ONU should be at the front of the round robin so it will be granted quickly. The DBA will have a delay to issue the grant. This delay can be 125μs waiting for the start of the downstream framing or additional delay for software processing. In a software DBA, the cycle time is often used to define this time interval. In the example below, a hardware DBA is assumed that only waits for the 125μs downstream frame boundary. After the DBA issues the grant, the grant must travel to the ONU and back up the PON. This time is often referred to as the PON round trip time. On a 20km PON fiber system, it is 250μs. Because ranging an ONU delays the transmitter for closer ONUs, this delay is constant regardless of the ONUs position. The PON round trip time also sets the size of a discovery window to the same 250μs. If the polling or data grant to the ONU is needed after a discovery window has been requested, an additional 250μs of delay/jitter is possible. A small delay for the ONU and OLT hardware should be included as well. While not always the case, it will be considered a fixed delay in this analysis. When testing in the lab, the fixed delay will show up as the min delay on a long test and variable delay can be determined by subtracting the max delay from the min delay.

$$\text{Start_Up_Fixed_Delay} = \text{Upstream_Flight_Time} + \text{PON_Round_Trip_Time} + \text{ONU_HW_Delay} + \text{OLT_HW_Delay}$$

$$\text{Start_Up_Variable_Delay} = \text{Polling_Interval} + \text{DBA_Delay} + \text{Discovery_Window}$$

$$\text{Start_Up_Max_Delay} = \text{Start_Up_Fixed_Delay} + \text{Start_Up_Variable_Delay}$$

The start latency is a big factor in downstream TCP/IP performance. The upstream acknowledge frames are often spread further apart than the polling interval so they will see the start latency as the dominant

factor. Large bursts upstream will hit the start latency for the first packets but the delay for the tail of the burst determines the true latency of the transaction, so the start latency might not be the key factor in large upstream bursts.

Figure 17 – Upstream Start Latency vs Polling

The polling interval is the only factor in the start latency that can be easily modified. The fiber length, number of ONUs, and hardware delays are fixed inputs. Based on 20km fiber and estimates for the hardware delay, the start delay is $625\mu\text{s}$ plus the polling interval. Figure 17 shows the direct relationship between the maximum start latency and the polling interval. Both XGS and 25GS have the same start latency equation since the data rate is not a factor.

Figure 18 – Polling and the Single Transmitting ONU

Decreasing the polling interval can significantly reduce the bandwidth. Figure 18 shows the scenario with the largest polling penalty. 63 ONUs are idle and 1 ONU is requiring the full bandwidth. In this case, the polling grants are non-traffic carrying blocks of time that limit the bandwidth to the single ONU transmitting. A shorter interval limits the bandwidth. When more ONUs are transmitting, the bandwidth lost to polling idle ONUs decreases but it is minimal until a large percentage of ONUs are active.

Figure 19 – XGS Upstream Bandwidth versus Polling Interval

Figure 20 – 25GS Upstream Bandwidth versus Polling Interval

7.2.2. Continuation Latency

Figure 21 – Piggybacking and 64 ONUs transmitting

After an ONU has received the first grant of a burst, piggybacking will allow the OLT to accurately grant the remaining packets, see Figure 21. In this case, the latency is determined by the number of ONUs actively in the round robin at that time. In the best case, it is a single ONU. In the worst case, it is all ONUs requesting maximum burst sizes at the same time. In this case, the maximum latency is dominated by the number of ONUs and the maximum burst size allowed. Small bursts have a higher percentage of overhead to data (less efficient) with lower latency while large bursts have a lower percentage of overhead to data (more efficient) with greater latency. The continuation latency has similar equations as the start latency. The DBRu must travel upstream and the grant must traverse the entire PON. The big difference is the Round_Robin_Time that replaces the Polling_Interval and DBA_Delay. The DBA_Delay is often absorbed since the grant is known well before the Round_Robin_Time is available.

$$Cont_Fixed_Delay = Upstream_Flight_Time + PON_Round_Trip_Time + ONU_HW_Delay + OLT_HW_Delay$$

$$Cont_Variable_Delay = Round_Robin_Time + Discovery_Window$$

Figure 22 – 64 Active ONU Latency

Figure 23 – 64 Active ONU Bandwidth

7.2.3. *Queuing Delay*

Queuing delay occurs when the input bandwidth exceeds the upstream bandwidth available. In the PON upstream case, it can occur when the subscriber exceeds their SLA or congestion limits the bandwidth available to a smaller number. Queuing delay performs an important function in TCP/IP networks. The delay on the acknowledge frame causes the next block of data to be delayed and thus slowed to a lower rate. Alternatively, a queue that overflows will cause a timeout and retransmit of a data block. Dropping frames has a much more significant impact to the user than the queuing delay. The queues in the ONUs should be sized to absorb large bursts of data and avoid drops. Priority queues can be used to allow higher priority traffic to avoid congestion. It is important to downstream performance to have a stable and low latency upstream. Variable upstream delays can cause the downstream bursts to be delayed and thus lower the throughput. By configuring a priority queue in the upstream for small acknowledge frames, it is possible to minimize the latency jitter to the downstream bursts. Queuing delay can be calculated by determining the difference in data rate between the input and output. If the difference in data rate is multiplied by the queue size, the maximum queuing delay before discard can be determined. The latency in this paper focuses on flows that have adjusted to the data rate and thus are below the maximum capacity of the SLA or total capacity. Since the queuing delay is a short-term factor required for bandwidth adjustment, it isn't something that could or should be removed from the system. A low max delay and low jitter delay when the subscriber is below the maximum capacity is the focal point of this analysis.

7.2.4. *Balanced Delay*

If the maximum start latency and the continuation latency are roughly the same, a single maximum latency covers both traffic conditions. Balancing the two delays to a common value allows for a

consistent performance without wasting efficiency. For upstream traffic, the balancing of start latency and continuation latency is a good goal. To achieve a balanced maximum latency under 1ms in XGS or 25GS, the polling rate and maximum burst must be adjusted to smaller values. The amount of upstream bandwidth available is variable based on the number of ONUs bursting upstream. The table shows the lower of the two values for comparison.

Table 9 – Sub Millisecond Delay for 20km, 64 ONU PON

	XGS	25GS
Up Max Burst Size	9500 Bytes	22000 Bytes
Polling Interval	300 us	300 us
Start Latency	0.925 ms	0.925 ms
Continuation Latency	0.975 ms	0.975 ms
L1 Ethernet BW (1518B packet)	7.346 Gbps	16.739 Gbps
L7 Application BW (1518B packet)	6.992 Gbps	15.932 Gbps

Table 9 shows that reaching sub millisecond max latency for 64 ONUs is possible in both XGS and 25GS. In both cases, a significant amount of upstream data is used to guarantee the lower latency. In XGS, almost 7 Gbps of application bandwidth remains while 25GS has almost 16 Gbps of upstream application data. The 25GS can still provide a 10Gbps symmetric commercial service along with the more asymmetric residential service.

7.2.5. XGS and 25GS Sharing the Fiber

In the earlier scenarios, a PON was either 64 XGS ONUs or 64 25GS ONUs. In many deployment scenarios, XGS and 25GS will exist side by side on the same fiber. In this case, it is possible for an operator to selectively move subscribers to a higher speed PON. If subscribers purchasing 5 Gbps, 10 Gbps, or higher SLAs were moved from XGS to 25GS, the number of subscribers on 25GS would be limited and the need for very high upstream bandwidth on XGS would be lessened. For example, the number of high bandwidth SLAs on the PON could be limited to 8 or 16 subscribers. Therefore, the maximum number of 25GS ONUs would be 8 or 16. In this case, the penalty for achieving the sub 1 millisecond latency on 25GS is much less. Table 10 shows an example of up to 8 25GS ONUs on a PON. In this case, the burst size can be significantly increased since the round robin will be only 8 ONUs. Additionally, the number of idle ONUs polling at 300µs is limited to 8 on the 25GS PON. With these two factors, the 25GS can achieve a 20 Gbps upstream Ethernet bandwidth with a sub millisecond worst case delay. With a total upstream bandwidth of 28 Gbps, the combination of XGS and 25GS could have a long-term future in the market. If the number of 25GS ONUs is increased to 16, the upstream drops by 400 Mbps but still stays above 20 Gbps of Ethernet BW, as shown in Table 11.

Table 10 – Shared PON with XGS (up to 64 ONUs) and 25GS (up to 8 ONUs)

	XGS	25GS	Total
Up Max PON Burst Size	9500 Bytes	180000 Bytes	
Polling Interval	300 µs	300 µs	
Start Latency	0.925 ms	0.925 ms	
Continuation Latency	0.975 ms	0.924 ms	

	XGS	25GS	Total
L1 Ethernet BW (1518B packet)	7.347 Gbps	20.818 Gbps	28.165 Gbps
L7 Application BW (1518B packet)	6.992 Gbps	19.802 Gbps	26.794 Gbps

Table 11 – Shared PON with XGS (up to 64 ONUs) and 25GS (up to 16 ONUs)

	XGS	25GS	Total
Up Max PON Burst Size	9500 Bytes	100000 Bytes	
Polling Interval	300 μ s	300 μ s	
Start Latency	0.925 ms	0.925 ms	
Continuation Latency	0.975 ms	0.988 ms	
L1 Ethernet BW (1518B packet)	7.347 Gbps	20.417 Gbps	27.764 Gbps
L7 Application BW (1518B packet)	6.992 Gbps	19.421 Gbps	26.413 Gbps

8. Conclusion

The IEEE 802.3 and a 25GS MSA group of 50+ companies standardized a 25 Gbps symmetric speed for PON access. 25 Gbps is the last PON speed that doesn't require a DSP, SOA, or EML at the ONU so it can be cost effective and low power. 25 Gbps is a useful speed for that reason. 50 Gbps and 100 Gbps will be available in the future at a higher cost and power. The 25GS standard is essentially 2.5 times the speed of the ITU-T XGS standard with the LDPC FEC defined by the IEEE 802.3. 25GS can be mixed with GPON or XGS on the same fiber plant allowing for a simple upgrade path. Equipment vendors offer simple upgrade paths for 25GS and a way to co-exist in the same box. 25GS allows operators to offer 5 Gbps and 10 Gbps symmetric services to customers. With all overhead considered, operators can expect to get approximately 20 Gbps in the downstream or upstream application bandwidth with 25GS. In addition to higher speed tiers, operators may choose to use the additional upstream bandwidth to lower the upstream latency. It is possible to achieve sub millisecond worst-case latency for 64 subscribers on the PON. By mixing XGS and 25GS on the PON, it is possible to achieve sub millisecond latency and 28 Gbps of upstream bandwidth. Based on the cost, ease of upgrade, simplicity, and additional bandwidth, 25 Gbps PON will provide value to operators looking for higher bandwidth and lower latency.

1. Introduction

Software obfuscation techniques have become increasingly popular in recent decades due to their broad applicability toward malware threats and intellectual property protection. Reverse engineering and tampering attacks are prominent means for software piracy and exploitation. Obfuscation is a collection of techniques for securing software and protecting applications from harmful malware. The goal of these techniques is to increase the cost and feasibility for attackers to exploit security vulnerabilities and carry out successful attacks against software implementations.

Bitcode obfuscation is a form of obfuscation that operates on an intermediate code representation rather than the original source code or native binary. This technique is based on sound and proven mathematical principles that retain the security characteristics of native binary while also maintaining the portability and platform independence of source code. Obfuscating at the bitcode level enables developers to utilize obfuscation-as-a-service without exposing their source code or proprietary libraries, while achieving levels of protection not possible with source-code obfuscation. As such, bitcode obfuscation is a promising field for developing the next generation of software protection services in the cloud.

In this paper, we offer technical details of control-flow and data-flow obfuscation techniques based on the idea that no source code or other dependencies are required to apply strong obfuscation directly to the intermediate bitcode representation rather than the original source code or the native binaries. We conclude by providing insights into the usage of obfuscation in relation to the security requirements of connected and cloud software systems.

2. Introduction to Software Obfuscation

In software development, obfuscation is the act of generating source or machine code that is difficult for humans and automated tools to reverse engineer. The goal is to achieve maximally unintelligible code without introducing unacceptable levels of overhead. Many techniques have been described in the literature that have both heuristic and tractable security basis. A combination of techniques can provide synergy in terms of the work factor required to reverse engineer the resulting binary code.

Programs often use high-level programming language constructs, common design patterns, and reusable components. These software engineering practices make code easier to reverse engineer and exploit (Wikipedia, 2022). It is therefore not appropriate (nor sufficient) for programmers to deliberately obfuscate their code to attempt conceal its purpose (security through obscurity), since many advanced tools exist to deobfuscate code that has not been sufficiently protected (OWASP, 2016).

Obfuscation is not the same as encryption. There is a common misconception to think of obfuscated data or code being the same as encrypted ones. While they both manipulate the original data/code to a different form, they are fundamentally different processes. Encryption requires a key and deploys a well-known cipher algorithm such as AES to convert the data or code to an unreadable form; where a decryption process is needed to perform reverse operation and get back the original data/code. Obfuscation on the other hand utilizes algorithms which often do not require a key. The obfuscated data and code can be used as-is without a need to de-obfuscate them. In-fact the goal is to make the code hard to de-obfuscate while retaining the original purpose and minimizing overhead as much as possible.

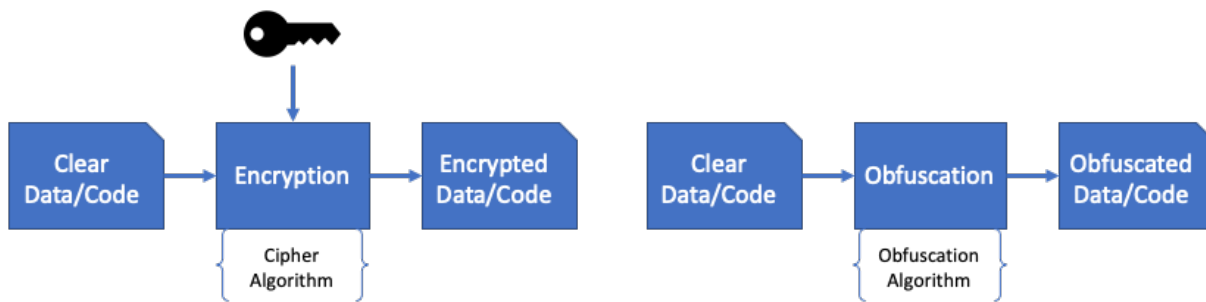

Figure 1 - Encryption vs Obfuscation

When it comes to source code or binary object encryption versus obfuscation, the encrypted object must be decrypted prior to execution rather the obfuscated object can be executed while remaining in the obscured form. It is possible for obfuscated elements to be captured and de-obfuscated, but the obfuscation presents a barrier to understanding and analysis (Arini Balakrishnan, 2005).

Several notions of obfuscation were shown in (Barak, et al., 2001) and (Balakrishnan & Schulze, 2005). The main result is that a strong notion of obfuscation cannot always be achieved. Over a decade later, Garg, Gentry, and Halevi (Garg, Gentry, & Halevi, 2013) gave the first candidate construction of an efficient general-purpose indistinguishability obfuscator, called multilinear jigsaw puzzles. While indistinguishability obfuscation promises secure general-purpose obfuscation, it remains an open question as to whether any practical real-world indistinguishability obfuscators can be implemented under this new model.

There are many mature obfuscation techniques offering a wide range of protections based on heuristic approaches to manipulate source code and even binary without altering the logic or the purpose of the code. The strength and weakness of obfuscation approaches can only be determined by effectiveness of the attacking and exploitation mechanism. Tools such as disassemblers and decompilers are often deployed to perform reverse engineering attacks by extracting sensitive information, adding malicious code and application cloning (Barak, et al., 2001). Although code obfuscation can thwart many attacks, given enough time and effort any of these techniques can be eventually overcome by reverse engineering process. Regardless, programs are obfuscated every day in the real world without any provable security guarantee. Nevertheless, obfuscation and diversification remain viable protection tools from the practical perspective (Garg, Gentry, & Halevi, 2013) (Goldwasser & Rothblum, 2007).

While obfuscation can be applied to programs written in any language, they are more effective for programs that are compiled to binary without the need for a virtual machine (VM). There are limited techniques that can be considered to obscure high level languages (i.e. Java and C#) instructions and control flow such that are heavily relying on their underlying VMs. Unlike C/C++, decompilation of Java programs is a much simpler task and therefore may be fully automated by attackers. Class hierarchy, high-level statements, names of classes, methods and fields can be retrieved from class files emitted by the standard javac compiler. Every current obfuscation product is easily circumvented by off-the-shelf de-obfuscation tools for java. The challenge gets even worse when trying to obfuscate a Python program. For Python, it basically comes down to renaming and hiding some of the instructions that can even be easily de-obfuscated (OWASP, 2016).

3. Control-flow and Data-flow Obfuscation

Obfuscation protects an application from reverse engineering, protecting proprietary source code, intellectual property and to increase the difficulty of exploitation. Obfuscation can be split into two main types: Control-flow and data-flow obfuscation. Together, these can provide a synergy that is similar in nature to how individually weak confusion and diffusion components when used together in cryptography lead to strong ciphers like AES (Anderson L. , 2015) (Worldwide Patent No. WO2018106439A1, 2018).

3.1. Control Flow Obfuscation

The aim of control-flow obfuscation is to make a program's execution difficult for an attacker to understand and hence reverse-engineer. Typical control-flow obfuscation methods include:

- **Instruction substitution** replaces assembly-level operations with randomly chosen code blocks that perform the same operation in different ways. The aim is to add resilience against both static analysis and dynamic analysis of the program code as well as automated attacks that look for code fingerprints.
- **Bogus-control-flow** obfuscation modifies a program's control-flow by adding entry points that evaluate complex expressions to determine the outcome of conditional jumps: either to jump to valid program code or to randomly altered "junk" code blocks.
- **Control-flow-flattening** rearranges a program's basic blocks in a randomized manner to give a program a uniformly random structure, where the original program's control-flow is only able to be re-established by the runtime computation of a control variable representing the state of the program.
- **Virtual-machine interpreter obfuscation** incorporates known hard mathematical problems in the computation of the control-flow to further increase the cost of reverse-engineering attacks.

3.2. Data Flow Obfuscation

Data-flow obfuscation is about randomizing the instructions that compute logical and arithmetic operations in a program (Worldwide Patent No. WO2018106439A1, 2018). Data-flow obfuscation methods include:

- **Randomized branch encoding** involves representing data-related logical and mathematical operations as a branching program composed of a sequence of permutations. Sequences of these branching programs are then concatenated together. When these programs are converted back to machine code, the result is uniformly randomized and unintelligible code that bears no resemblance to the original algorithm.
- **Randomized input, output encodings** can be used to make the obfuscated code even harder to reverse-engineer, as well as protecting constants and allowing seamless secure chaining to and from the obfuscate application.

4. Bitcode obfuscation techniques

Obfuscation (and other protection methods) can be applied directly to bitcode files. This enables application protection to be applied via a third-party service, and as such reduces the need for in-house tools and expertise in application security.

4.1. What is bitcode?

Bitcode is a platform-independent, universal low-level intermediate representation (IR) used by LLVM compilers and tools, such as Clang, XCode, Microsoft Clang-CL, Objective C/C++ Swift, GO, EM-Scripten, Rust, and many others. **Bitcode is the file format for LLVM IR** (LLVM Documents, 2003).

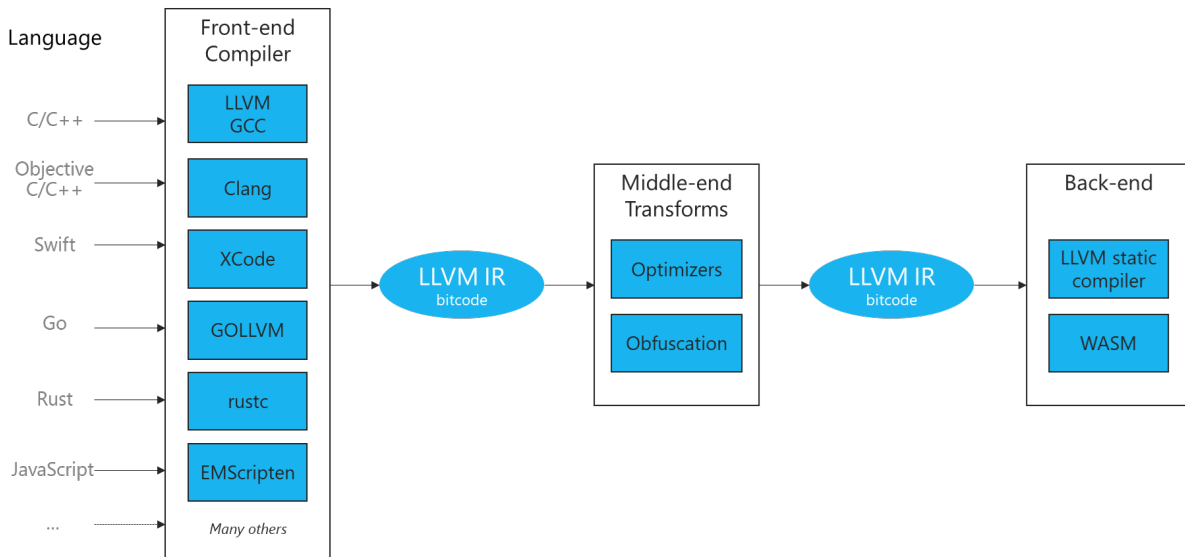

Figure 2 - LLVM Architecture

- Front-end compilers compile source languages to LLVM intermediate representation.
- The LLVM IR can then be optimized and transformed by middle-end tools that are front-end and source language agnostic. In addition to optimization, these transformations can include obfuscation and other protection techniques.
- Finally, back-end tools convert the LLVM IR to native machine language for any of the many supported platforms and architectures. These back-end tools are agnostic to both the front-end and the middle-end layer, thus facilitating broad platform and language independence of the LLVM architecture.

4.2. Why bitcode protection?

Developers are naturally focused on developing and delivering their features and services to their customers. As a result, security is often neglected to varying degrees at both management and operational levels. Security policies may be insufficient to identify unprotected, weak, or otherwise exploitable code, and under-tuned security parameters. Even if good policies are in place, expertise and resources required to manage and implement security may be insufficient to ensure adequate security protections are in place.

A well-designed cloud-based bitcode obfuscation solution can incorporate security policies and parameters to bridge the gap between in-house expertise and practices and robust security implementations.

- The cloud-based service would allow the definition of security policies and would then verify that these policies are correctly implemented during the application of bitcode obfuscation.

- Audit reporting of security coverage and any identified weaknesses can be provided to appropriate parties in the organization.
- Since the compilation of source code is done prior to the application of bitcode protection; and linking is done afterwards, confidential source code and proprietary libraries do not need to be exposed to the middle-end when applying bitcode protection to an application.
- Bitcode is platform and target agnostic, therefore protection can be applied across all LLVM supported source languages and target architectures. This will allow developers to set global security goals or customize security per target platform.
- Alternatives, such as source-code obfuscation methods can be quickly broken and circumvented with readily available de-obfuscation tools (GitHub, 2022). Bitcode obfuscation is not vulnerable to these same attacks.

4.3. How does it work?

Obfuscation is applied directly to bitcode files via a LLVM middle-end according to a set of protection parameters. No source code, header files, libraries or other dependencies are required in order to obfuscate the bitcode. In addition to the protected bitcode, the middle-end can generate audit reports and logs to assist with the monitoring, implementation, and management of the protected code.

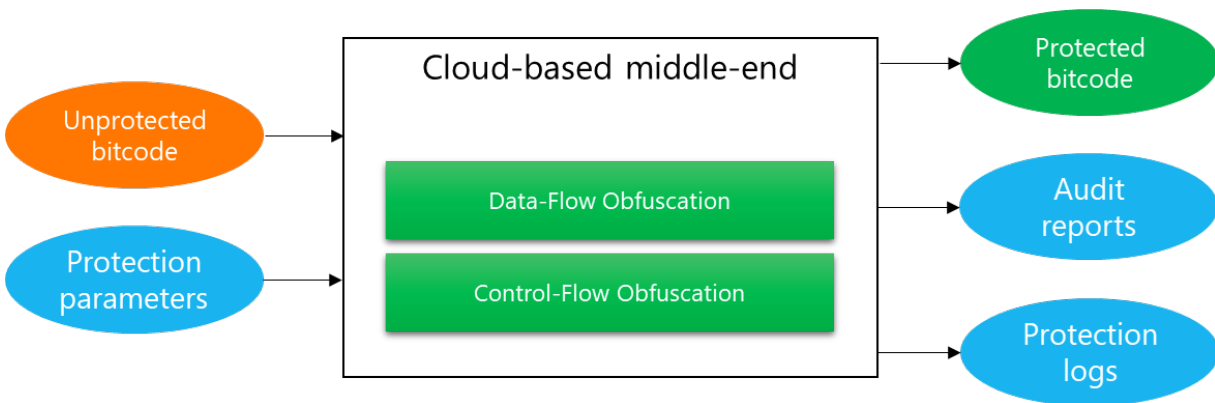

Figure 3 - Cloud-based bitcode obfuscation use-case.

- Unprotected bitcode is sent to a cloud-based middle-end that can apply dataflow and control-flow obfuscation to the bitcode according to a set of supplied protection parameters.
- The middle-end pass manager executes a series of passes to apply the control and dataflow obfuscating transforms. These passes are interleaved with each other and with optimization passes to ensure that the obfuscation complexity matches the tuning requirements specified in the protection parameters.
- The higher the complexity, the higher the runtime overhead, thus the importance of enabling developers to tune the amount of obfuscation applied by the middle-end. Further tuning is possible via LLVM function and inline attributes (LLVM Project, 2022), which can be embedded in the source code and remain readable from the bitcode by the middle-end transform passes.

5. Exploring the usage of bitcode obfuscation

Bitcode obfuscation offers strong protection against tampering and reverse-engineering attacks for software programs running in non-secure environments. These techniques allow tunability to achieve a balance between security and performance; and can be applied to a wide range of applications targeted to

various platforms and devices. In this chapter we explore how obfuscation can be utilized to protect specific types of applications in different industries.

5.1. Mobile applications

Mobile applications (running on iOS or Android devices) often process customer credentials and other sensitive data, while containing differentiated business logic. With stiff competition in the mobile application space as well as an increasing background security of exploits and attacks, it is crucial to protect applications against reverse-engineering by adversaries seeking to gain proprietary knowledge of the app. It is additionally important to prevent adversaries seeking to circumvent authorization and authentication, and to protect against the extraction of sensitive and confidential information.

Secret business logic embedded in the app's source code is considered intellectual property of the app owner and should not be exposed. Generally, all mobile code is susceptible to reverse engineering according to OWASP (OWASP, 2016). Even though security of iOS and Android mobile platforms has always been improving, access to low-level security components is not always available to apps. An attacker will typically download the targeted app from an app store and analyze it within their own local environment using a suite of different tools to statically analyze the code/binary and perform reverse engineering attack.

Let's take an iOS app for example and examine its structure to understand how obfuscation can protect it. The language of choice to develop an app for iOS devices is either Objective C or Swift. They are both compiled into LLVM bitcode binary suitable for Apple App Store submission. The following picture shows the application framework and underlying components of iOS platform (Lucideus, 2019).

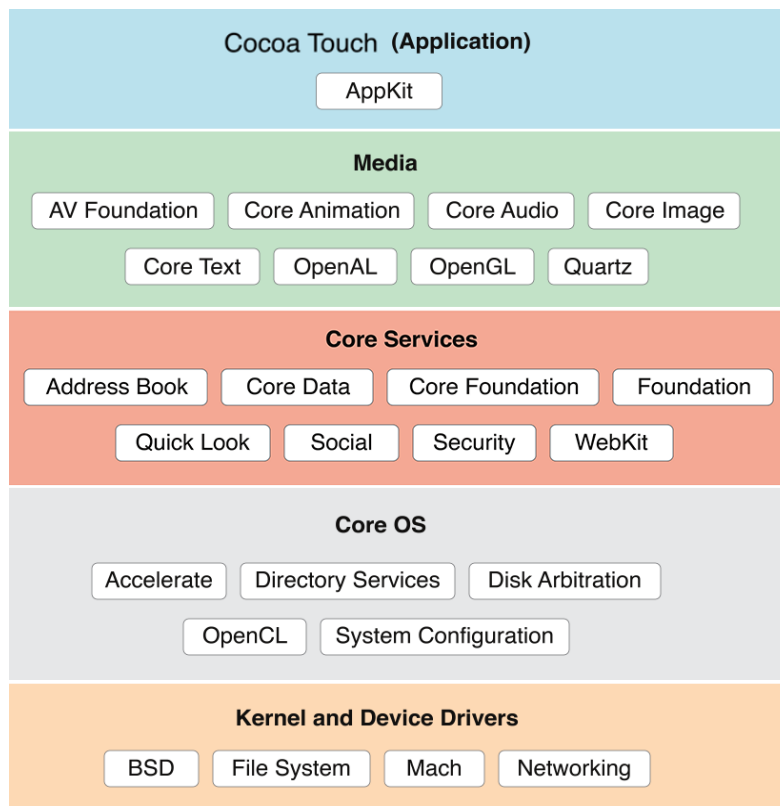

Figure 4 - iOS Mobile App Framework

The app utilizes iOS SDK APIs to access certain functionalities performed by low level libraries while containing a series of business logic and confidential codes within the app layer. App developers are essentially creating complicated puzzles of these APIs glued together with their app's specific codes to build a unique experience to serve the purpose of the app. While there is no secret about the usage of the iOS SDK APIs, the very experience created by the app becomes the intellectual property and requires proper protection. Furthermore, Apple App Store recommends iOS app developers to submit a bitcode version of their app for Apple to perform post-processing on the submitted app for thinning or optimizing purposes. Including the bitcode version of the app will allow Apple to re-optimize the app binary in the future without the need to submit a new version of the app to the Apple App Store (Apple Help, 2020).

An effective obfuscation should be at the bitcode layer to preserve protection against reverse engineering of the binary while still being compliant to Apple App Store. The final iOS app will be placed in a sandbox to create isolation from other apps running on the same device providing some level of security and protection. However, the app is still susceptible to reverse engineering attacks using static analysis offline. Applying obfuscation in the application layer and entry calls to iOS SDK APIs makes it hard for the advisories to identify and follow the app logic. Of course, any software obfuscation comes with an overhead associated with making control flow unpredictable. A bitcode obfuscation level can then be tuned to an acceptable level to balance desire app performance and protection.

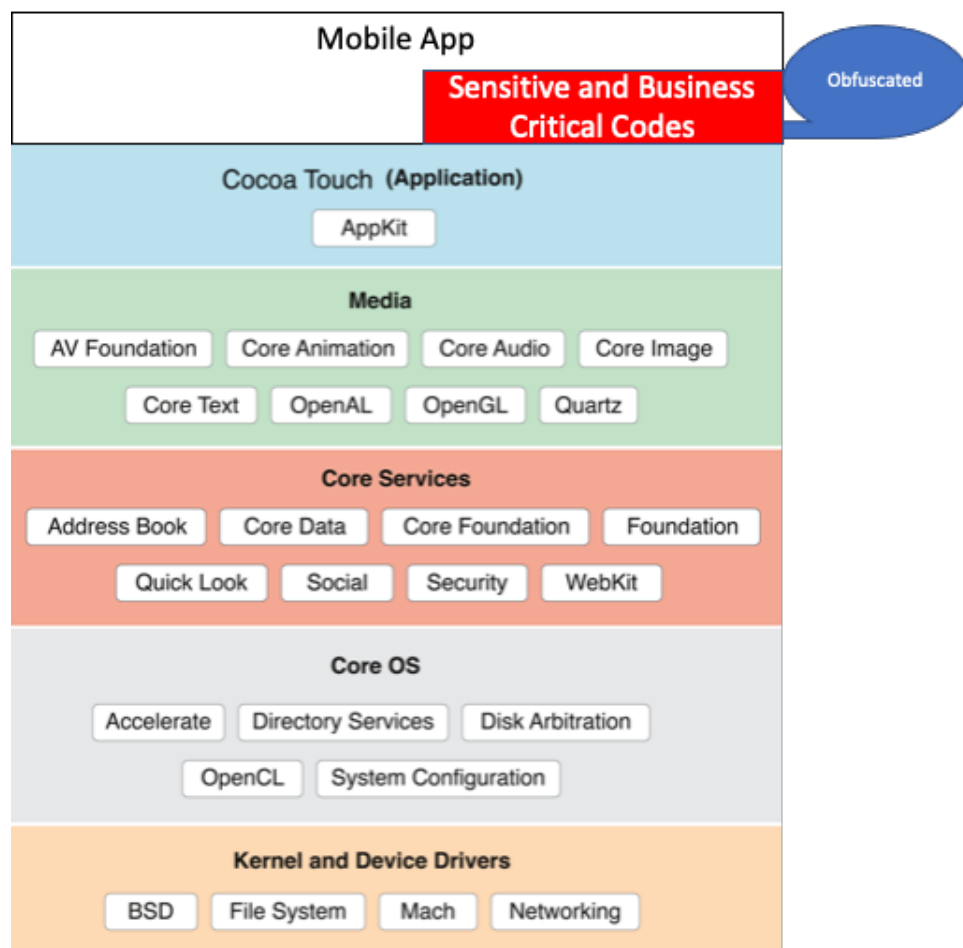

Figure 5 - iOS Mobile App Framework with App Obfuscation

The bitcode obfuscation provides a protection mechanism at the app layer that does not depend on underlying mobile platform security while conforming with Apple App Store requirements. It makes static analysis of the mobile app more complicated even with sophisticated tools.

5.2. Cloud Server Applications and Web Services

With the advent of cloud virtualization, more and more companies are pushing their server applications and web services to public cloud environments where they can clearly benefit from the scale, reliability, and availability of such services. This process requires a comprehensive analysis of cloud readiness of such applications. Companies typically rush to virtualize their server app to cloud without performing much needed due diligence evaluations. As a result, these server apps are posed to attacks when deployed in the cloud. Relying on cloud provider security alone is not an option when it comes to securing an app running in the cloud. Even though cloud providers typically come with a certain level of industry accepted secure environment, the security of data and application remains the ultimate responsibility of the cloud customers in every cloud model.

With exploitation of server apps using reverse engineering methods, an attacker can reveal information about back-end processes, steal intellectual property and gain intelligence needed to perform subsequent code modification (Dolan, Ray, & Majumdar, 2020). Web services are not exempt from these types of attacks either. A viable protection solution would require independence of the app protection from the underlying cloud platform. The notion of In-App protection means that the app is self-contained in terms of protecting its code and data within its binary regardless of its deployed environment.

Modern server applications and web services are typically written in high languages such as Java, JavaScript and GO. As discussed in the introduction, protecting such apps with obfuscation is not effective. Therefore, it's recommended to move all business critical and secret sauces in the app source code to native languages such as C/C++ for the obfuscation to be more appropriate. For example, if the cloud application is written in Java, there should be a Java Native Interface (JNI) layer to access C/C++ native code that are obfuscated as shown in the following diagram.

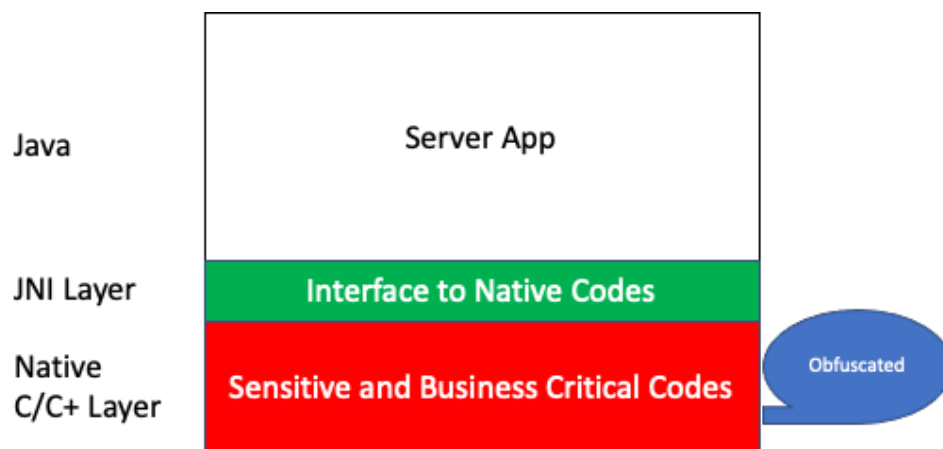

Figure 6 - Sample Cloud App with Obfuscation

5.3. IoT Applications

The rapid expansion of IoT devices creates opportunities for companies to be more innovative with the purpose and scope of their IoT applications. This large ecosystem comprises a variety of devices that are being used in diverse environments including healthcare, industrial control, and homes (Dolan, Ray, &

Majumdar, 2020). From SmartCity to SmartHome to Wearables, IoT devices are entering our world and the list of IoT apps will grow as technology evolves in the years ahead (Placeholder9) These IoT apps are edge devices collecting and processing sensitive data on end users' behavior, the user's devices, habits and their actions in addition to managing Personally identified information (PII).

Naturally the security of IoT apps remains the focus of various standard and industry bodies to regulate and advise. Limited security capabilities along with time-to-market pressure leaves IoT application developers with little or no provisions on securing the app. IoT devices typically come with no hardware security module, making them vulnerable to various attacks. These sophisticated apps analyze the collected data with rich business algorithms all within the IoT device. Even though most attack surfaces are runtime in nature and occur when the IoT app is in action, there is potentially a lot that can be discovered with statically analyzing and reverse engineering these apps.

As a result, the root of trust, device identity, keys and crypto operations conducted by IoT applications are exposed. Bitcode obfuscation can potentially reduce and even eliminate such concerns with IoT applications independent of the IoT device security.

6. Conclusion

In this paper, we introduced bitcode obfuscation as a very effective and powerful tool in protecting software application against reverse engineering attack. We explored different obfuscation techniques such as control flow and data flow obfuscation without accessing the original source code. The idea of operating on the intermediate binary without the need for the source code makes the bitcode obfuscation more practical to be offered as a cloud service (obfuscation-as-service). We also offered a few examples of how this protection can be applied to different software application domains and industries.

1. Abstract

Cable operators are actively addressing upstream capacity with their most powerful tool – new spectrum. Mid-Split and High Split architectures satisfy long-term capacity and speed requirements, and are further empowered by DOCSIS 3.1 OFDMA. While capacity gains and speeds are straightforward to predict, the “how” of upstream spectrum migration requires careful planning.

At the 2021 SCTE Expo, in a paper entitled Executing the Upstream Makeover without Leaving Scars, a newly developed, remotely automated, in-Home Assessment Tool (iHAT) was unveiled. This tool was designed to manage large-scale activation of new Mid-Split spectrum while ensuring minimal customer disruption.

That was then! One year later, iHAT is fully integrated into production and technical operations workflows. The new spectrum is delivering up to 5 times more capacity. Technical training has been developed and deployed, and new care processes have been created and implemented. The iHAT tool itself has evolved – the production code is now ‘iHATv3’ – to make activation more efficient, automated, and less disruptive.

It is now timely to share the learnings along the path from tool development to production in scale. In this paper we will describe that journey. Technology, tools and processes for execution of large scale Mid-Split activation have been developed, launched, and scaled. Attendees will understand the spectrum activation journey from start-to-finish – system engineering, technical solutioning, operationalizing, and best practices – from the experts that made it happen.

2. The What and Why of iHAT

2.1. Background

Network upgrades of spectrum have historically targeted extending the Downstream from, say 550 MHz, to 750 MHz, 860 MHz, 1 GHz, or even 1.2 GHz. The outcome was fresh new fields of Bandwidth to seed with new and/or expanded video and data services. For the upstream, the spectrum has changed significantly less, based on consistently lower upstream demand and upgrades addressing upstream needs consisted primarily of adding additional DOCSIS channels and splitting nodes to prevent them from being congested.

Over the years, the spectrum has become fully occupied – albeit there is still capacity upgrade levers available by moving from DOCSIS 3.0 to DOCSIS 3.1. Furthermore, with the spectrum fully occupied, upstream traffic growth continuing, and mass CPE device swaps difficult and costly for modest capacity gains in the available upstream spectrum, node splits have become the primary tool of managing upstream, and as a result have been accelerating. The time to add more spectrum to the upstream has arrived, and Comcast, along with other MSOs, have made the decision to migrate to the 85 MHz Mid-Split architecture.

2.2. Purpose

Unfortunately, unlike the downstream, however, the “how-to” of spectrum migration gets more complicated in the upstream. The 42/54 MHz split has been in place for decades, and devices that adhere solely to it, particularly set-top boxes (STBs), are in many millions of homes. These devices support services that will remain active, and large scale swap outs of devices in homes, or

processes that require large scale physical visits to homes, should be avoided in order to cost effectively and efficiently deploy Mid-Split spectrum at scale.

Therefore, production-scale tools, techniques, and processes must be developed to ensure that a new, wider upstream path can be efficiently operationalized, while being transparent to customers. This the purpose of the iHAT tool. It is the foundational kernel of the Mid-Split activation process, allowing remote diagnosis of the drop-home environment necessary to activate seamlessly and create processes to activated ubiquitously and harmlessly to customers.

2.3. Theory of Operation

The problem statement for Mid-Split activation, highlighted in Figure 1, is to develop a way to unobtrusively discover the state of a home with respect to these two criteria:

- Potential for video interference
- Ability to support DOCSIS upstream pass-through in the Mid-Split band

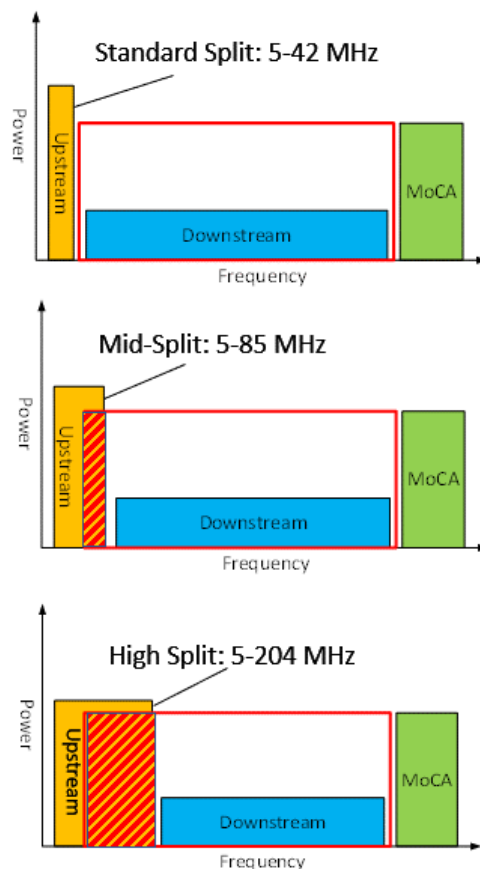

Figure 1 – New Spectrum Split vs Standard Split Deployed Equipment

To enable this home-by-home assessment in scale, an automated in-Home Assessment Test – aka iHAT – was developed to enable a seamless migration of capable CMs to utilize Mid-Split when conditions 1 and 2 above are satisfied, as shown in Figure 2

Figure 2 – The Two Basic RF Assessments Evaluated by iHAT

2.3.1. Video Interference Risk

With the decades of spectrum split in North America being set at 42 MHz/54 MHz, all QAM video STBs deployed are configured this way. They were built to receive video channels beginning at 54 MHz. When the network is NOT configured this way, and instead is upgraded to enable the duplex split to expand the upstream and activate new spectrum above 42 MHz, the QAM STB's point of view for Mid-Split or High-Split changes. This is shown in Figure 1.

The red cross-hatched areas in Figure 1 represent the spectral overlap imposed on a QAM STB by a Mid-Split capable cable modem when utilizing that band. Any signal energy that appears above 54 MHz can be seen by the STB downstream receiver, because it is built expecting to operate on downstream signals that begin at 54 MHz. Unfortunately for the STB, in a home that also contains a Mid-Split capable cable modem (CM), the CM sees that band as “eligible” for placing carriers when the CMTS is configured to allow CMs to use it.

Note that the STB is not acting on any specific signal type – it is simply adapting its Automatic Gain Control (AGC) function to deliver the ideal level to the A/D converter. AGC measures the total energy in the downstream band and doesn't care about its origin. Thus, if new Mid-Split upstream energy on the STB receiver is very high, the STB receiver will add attenuation. When this happens, the *desired* video channels will inadvertently be pushed lower through a phenomenon called “Adjacent Channel Interference” or ACI. If it attenuates too much, then the QAM video signals can be low enough to cause low SNR in these channels, and video pixelization could ensue.

Note the above description is a “static” or time-fixed snapshot view of upstream energy and spectral overlap with signals moving downstream to a STB. Actual upstream traffic is “bursty.” This is important because the AGC function has dynamic characteristics, but they tend to be slow acting. As a result, the duty cycle (off/on ratio) and burst duration is a factor that can impact the AGC implementations differently in different STBs.

As represented in Figure 1, the nature of the levels is not favorable – the downstream receive level is low (DS Rx), while the upstream transmit level (US Tx) is high. Until now, there was a diplex filter to separate them, but now, between 54-85 MHz, this is no longer the case. Fortunately, between a CM and a QAM STB there will be an RF splitter, the design of which will inherently isolate the port of a CM from the port of a STB by some amount. This scenario is illustrated in Figure 3, showing just one isolation path between modem (MTA) and a STB's RF inputs.

Figure 3 – Mid-Split Band Energy Isolation Path Across RF Splitter

How much energy leaks through to the STB? That question depends directly on the splitter and home wiring shown in Figure 3. Home wiring has a very predictable dB/loss per foot and is easily modeled. The most important factor with respect to the ACI phenomenon is the splitter(s) used to distribute RF to devices for video and data services.

2.3.2. Drop Amplifiers

In addition to OSP and traditional CPE devices that provide residential services that only know the 5-42MHz split, many homes also use drop amplifiers. These are also built with a Low-Split diplexer.

These devices must come out...eventually.... but because they may or may not be customer-impacting, they do not *necessarily* have to be tackled coincident with the activation of Mid-Split spectrum. From a capacity perspective, every drop amplifier that can be removed is good for capacity. The operations perspective depends on the percentage of homes that include a drop amplifier – estimated at 15-20% but can cluster depending on geography and practices. Methodically removing in-home drop amps over a period of time may make more sense than dealing with amplifiers transactionally as part of a service call or product upgrade. A proactive plan to address drop amps will eliminate the perpetual limbo state that is mixed-mode devices working in mixed-mode spectrum.

With capacity and product in mind, we can itemize home amplifier management into two buckets:

- Capacity-driven – All DOCSIS 3.1 CMs at Comcast are Mid-Split-capable, and all DOCSIS 3.0-only CMs are not. CMs are migrating to DOCSIS 3.1 steadily, so in time the majority will be installed and capable of Mid-Split upstream connectivity. However, even if a Mid-Split-capable CM is present, any home that cannot allow the spectrum to pass out of the home reduces capacity gain and upstream lifespan is compromised. Over time, these amplifiers must be removed to deliver on the full capacity promise. How quickly this must be done is a mathematical analysis of utilization vs penetration trajectory.
- Product-driven – One of the key benefits of the Mid-Split is the ability to deliver HSD speeds in the upstream such as 100 Mbps, 200 Mbps, 300 Mbps, and higher. Once such products are made available, customers with home amplifiers will be (self)-blocked from receiving them. Interest in speeds that require Mid-Split would trigger immediate action, to remove the blocking amplifier. The challenge is how to manage this efficiently and, more importantly, in a way that minimally impacts the customer. The good news is these blocking devices (amplifiers or any filtering within the band that may have been installed inline) can be discovered remotely and in real-time. While the customer cannot get the new upstream speed immediately, a rapid and transaction-based process can serve to notify the customer that additional steps are required to support the speed upgrade.

2.3.3. Issues with Legacy Systems

Some of the lessons learned from production deployments are that we now have the ability to uncover modifications made on the network over time to keep it operating and delivering services, but that have not been historically documented, or at least well-documented. Drop amplifiers are of course a case where documentation has been limited, but other scenarios exist:

- Noise and/or trap filters
- Frequency selective in-line equalizers
- RF Amplifiers added for plant extensions after initial build

Filters installed, such as for ingress, that impact upstream transmission bandwidth are somewhat obvious candidates to be found. AS scale is built, we are able to begin putting numbers around the likelihood of these types of devices effecting the ability to fully activate Mid-Split. The percentage is low, but not negligibly so. Incorporating processes to detect and locate these devices during the upgrade and activation will be incorporated. Not all cases need immediate remediation, but all cases where a customer is looking to achieve higher upstream speeds that only Mid-Split can provide, will. However, this can be a transactional process on product order.

The last category – RF Amplifier – may be less obvious. Over time, single amplifiers may have been added to a complex HFC network cascade to capture, for example, a new development at the end of a block. If these were not properly documented and put into the spatial database, then they could be missed in the upgrade process when existing amplifiers are swapped out for Mid-Split capable devices. The result is a Mid-Split blocker in a sea of newly upgraded Mid-Split capable actives. Fortunately, manifests itself as a cluster of localized iHAT failures that indicate more of a systemic issue than a home-by-home situation. Additional tools are then able to pinpoint the most likely ancestor device – which will be identified as a device close to the “missing” amplifier, a from which the actual location can quickly identified for remediation.

2.4. Evolution

A “Black Box” view of iHAT that includes the core functions of the initial design core is shown in Figure 4.

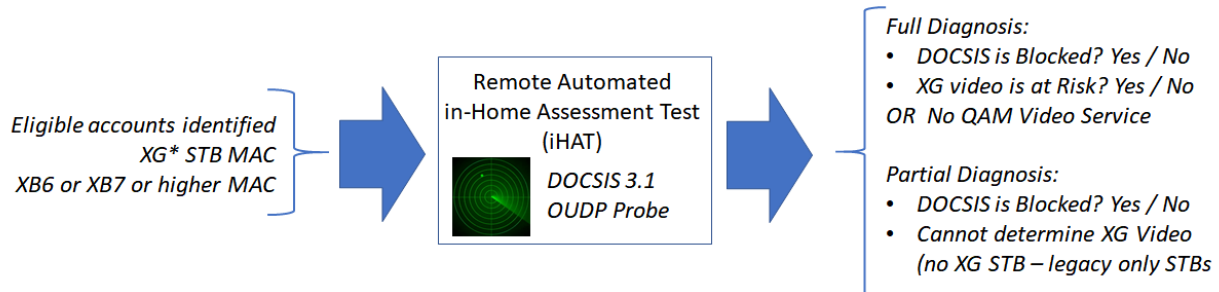

Figure 4 – The iHAT “Black Box” Method and I/O

2.4.1. iHATv1 – Proof of Concept and Functional Validation

With the introduction of the “N+0” architecture [Howald fiber frontier/2016, surf conditions/2018], Comcast began the upgrading of its HFC plant to an 85 MHz upstream. This has continued unabated, and is now on an accelerated path to cover more footprint, faster, by also upgrading in-place N+x HFC footprint to be Mid-Split capable. The system engineering and development of operational practices began at this time, and the mathematical basis for the potential for ACI due to Mid-Split quantified theoretically. Further lab testing was performed to assess the sensitivity of different STB models to ACI as a function of RF level and On/Off duty cycle of US traffic. The next step was to observe performance in the field against these projected impacts.

The first version of iHAT (iHATv1) was very much a trial-worthy, proof-of-concept (PoC) approach to facilitate learning about the drop amplifier and video interference deployment challenges. The approach used had high customer impact – multiple reboots to switch the CM diplexer between Low Split and Mid-Split, and a proprietary MIB managed. Fortunately today we have standardized MIBs via DOCSIS 3.1.

The method to evaluate readiness of a home for Mid-Split was to increase the upstream burst rate – i.e. change the speed tier to be higher to exercise the full Mid-Split spectrum and ensure the CM upstream signal would overlap with STB receivers, so the effect on the receiver could be observed when it did. Speed tests were then used to simulate utilization, while simultaneously measuring the effect on STB fidelity by observing modulation error ratio (MER) and uncorrected codeword error rate (UCER).

FEC-free range of operation for 256-QAM is $MER \geq 34$ dB and $BER \leq 1E-8$. Through lab measurements, we observed that video experience degrades – visible pixelization occurs – for 256-QAM when $ACI \leq -20$ dBc for the most sensitive of STB makes and models. By reading the MER and UCER during a speed test, a home could be identified as being at risk for video interference or not. Furthermore, the ability to demodulate the Mid-Split signals at the CMTS would identify that the bandwidth was not being blocked by a drop amplifier.

While this tool was a significant simplification of the in-home measurements that preceded it, where technician had to go to a home and take measurements and make a visual and RF diagnosis, it was still too limiting as a tool for use in scale:

- It could only be run during maintenance windows, at times when customers would be minimally impacted
- Test duration in a single home was long, due to multiple device reboots. For large node this would translate to several hours of MW down time for each node.
- Multiple APIs were required to orchestrate configuration, speed testing, and data collection

All the above led to a semi-automated engineering tool suitable for trial learning with 10s to 100s of customer assessments during a given maintenance window.

2.4.2. iHATv2 – Ecosystem Automation and Transition to D3.1 OUDP Test Probe

The iHATv1 tool validated the general premise that devices in the home and the tools available to activate and monitor them could be programmed for new functionality that would enable home-by-home diagnosis of Mid-Split activation readiness. The evolution to iHATv2 was driven by the need to become less disruptive to customers, less burdensome for the operations teams, more efficient in test duration and results availability, and more scalable for a production environment. Automation of the manual processes of pre-selecting customers and of launching iHAT itself. As shown in Figure 4, iHAT retrieves a list of devices, by account, on a particular Mid-Split-enabled RemotePHY Device (RPD) node, after the node is cutover, activated, and services restored. When an account is identified as having a Mid-Split-capable CM – for Comcast, this includes the DOCSIS3.1 gateway family of XB6, XB7, and XB8 – it is deemed eligible for an iHAT test. With one of those devices present, it will be possible to place the CM in Mid-Split mode to determine whether its upstream transmissions in the Mid-Split band are able to be seen and received by a Mid-Split enabled vCMTS and DAA node, or if they are blocked.

When an account also includes the “XG” class of QAM STB, the iHAT evaluation will look both for DOCSIS Mid-Split pass-through and the potential for video interference. This XG family, the majority of QAM STBs in the Comcast network, supports the proactive network maintenance (PNM) and SpectraCM functionality needed to capture RF measurements that are the basis for iHAT scoring of video interference potential. Older QAM STBs do not support this capability. In a home that includes an XG class STB, that measurement is a reasonable proxy for the expectation for other non-XG STBs with respect to their isolation from Mid-Split spectrum energy. If there is no XG-class STB present at all, but “legacy” QAM STBs are present, then no iHAT assessment can be made with respect to the potential for video degradation. At the outset, these homes default to Mid-Split activation. This policy will be revisited as production scale assessment can be made. This risk is low – single digit percentage [Howald MUSL 2021 paper]. By NOT defaulting to activating, the alternative is to roll a truck to each of these homes and take “iHAT” style isolation measurements manually.

2.4.2.1. OUDP Test Probe

The method iHAT uses to make its determination is based on the DOCSIS 3.1 OFDMA Upstream Data Profile (OUDP) feature, which allows a pre-defined “probe” signal to be scheduled by a CMTS and generated as a test signal. The probe can be defined by center frequency, bandwidth, and duration. When iHAT runs, it schedules this probe signal, home by home, to be burst into a portion of the Mid-Split spectrum.

Figure 5 shows the probe signal centered at about 80 MHz. It is 1.6 MHz wide (a common reference bandwidth for OFDMA bandwidth used in the DOCSIS 3.1 requirements), has a PSD at the ranged OFDMA power, and lasts 3-5 seconds. These are empirically-derived values through trial-and-error testing and optimization in the lab.

Figure 5 – Probe Signal Used in iHAT via DOCSIS 3.1 OUDP Feature

When the probe is fired, the time stamp is used to instruct the XG STB when to execute a Full Band Capture (FBC), and with that capture, samples are returned to that include levels of the OUDP probe and the first few downstream QAM channels. By determining the relative levels of these components and comparing them to an interference threshold value, making offset adjustments that account for the test probe not occupying the Mid-Split band completely, the home can be classified as to whether it needs remediation.

The OUDP method provides three major advantages:

- 1) It is part of the DOCSIS 3.1 specification, so a required feature to be compliant to the specification (when asked for!)
- 2) It can be a scheduled event within a system's normal operation, and therefore is very non-intrusive, happening without a customer's awareness or service interruption
- 3) As a scaled down (in total power) representation of an actual upstream signal, it does not actually create enough interference to impact video. Instead, it emulates what a small portion of the filled spectrum would look like and extrapolates mathematically to draw the proper pass/fail conclusion.

Iterative optimization of the parameters yielded a repeatable, reliable result that correlates well as a mathematical extrapolation with the video threshold testing that forms the foundation of ACI analysis.

The probe signal can also be used to evaluate blocking of the Mid-Split upstream by a drop amplifier, because if this is so, the CMTS will not be able to observe the probe. However, as part of the iHAT test, Mid-Split becomes active on a modem prior to an OUDP probe being launched, once the CMTS has a configuration that supports it. Ranging information of the OFDMA band (DOCSIS 3.1 ranging) is available to determine if the upstream was successfully sounded. If not, this is typically sufficient cause to identify a home with a drop amp issue, at which point the CM

can remain in partial service or reverted to Low Split mode. In either case, the home state is logged as “remediation required.”

An further benefit of the OUDP approach, looking to the future, is that it has a lot in common with the Sounding function that is part of DOCSIS 4.0 FDX.

2.4.3. iHATv3 – “Hitless” Implementation and Operation

While iHAT v2 provided significant improvements in the implementation of the test itself, in particular with respect to the execution of the core RF function itself, it still represented significant disruption because of the direct management of filters in the CM to be switched into one position or another. Modem resets that were required and device implementation differences for going back between filter settings, and onsite remediation challenges were among the obstacles. These ideas begat iHATv3, which was focused on “hitless” – or a substantially less intrusive iHAT operation sequence. A key change made to move in this direction was the use of the DOCSIS-standardized (and thus enforceable for all manufacturers) MAC Domain Descriptor (MDD) broadcasts to configure switchable duplex filters. Two major advantages to this approach are

- MAC re-initialization to Mid-Split is owned by configuration of the vCMTS and RPD, and not an iHAT function itself
- Dedicated boot files for the purpose of switching duplexers to assess Mid-Split serviceability is eliminated, removing a major disruptive step and minimizing boot file redundancy

An important element introduced by the integration of the vCMTS into iHAT’s functionality is the powerful role the vCMTS has in managing the broadband network. It puts much more capability at iHAT’s disposal, far above and beyond the initial simple iHAT functionality originally defined. iHAT is able to take advantage of this but moving away from duplex filter-based split configuration to manage whether a device is in Low Split or Mid-Split. With the vCMTS now an API away from iHAT, it is called upon instead to configure the bonding group of the modem to Low-Split or Mid-Split utilization, rather than move a switch in a CM. Referring to Figure 4, if iHAT finds that the device should remain in MS mode for either failure case it will dynamically adjust the bonding channel configuration (DBC) to Low Split so that there is no energy in the Mid-Split band, avoiding a drop amp blockage that could result in partial services flags at the vCMTS, or protecting a STB in the home.

2.4.4. Future Roadmap of iHAT

The iHAT tool has been launched, but as with any new launch and particularly in an agile SW-based environment, the road does not end at initial launch, it is just the beginning. Lessons learned will be rolled into future patches and releases, but also new use cases discovered and features needed to support those use cases developed, tested, and integrated into the production code.

Some of the use cases known at this time and part of the iHAT development backlog include;

- Low-Split amplifier, OFDMA blocker scenarios that extend beyond the home drop amp:
 - Use for outside plant amplifier cascades

- Cases of “missed” plant amplifier upgrades
- Hidden multiple dwelling units (MDUs) riser amplifiers
- In-line frequency-selective (and low-split) equalizers
- Enhanced orchestration between device APIs to minimize CM/STB communication failures
- Periodic iHAT results home health and maintenance checks
- Event-driven iHAT re-tests (for example, triggered by metrics in home or a new device in the home)
- Systemic failure results detection and automation
- Various iHAT dashboard filters and optimizations
- Extension to “nHAT” – detection of potential neighbor interference issues due to split changes, supporting expected phenomenon in both High Split and DOCSIS 4.0 FDX system

The features and capabilities will be addressed and rolled out in future software sprints.

3. From Lab to the Field

The mission statement for the original definition of iHAT in 2020 was to remotely go into a home with a test that would determine its readiness to be activate the home immediately with Mid-Split spectrum, and if it was not able to, diagnose why not. Now, two years hence, its fundamental technology has improved, it has been hardened, its capabilities and role expanded, and, more importantly, its APIs built out to turn it into a system that can be part of a large scale production operational step.

3.1. Completing the Ecosystem

Consider Figure 6 below, where iHAT is depicted at the heart of a broader upgrade workflow.

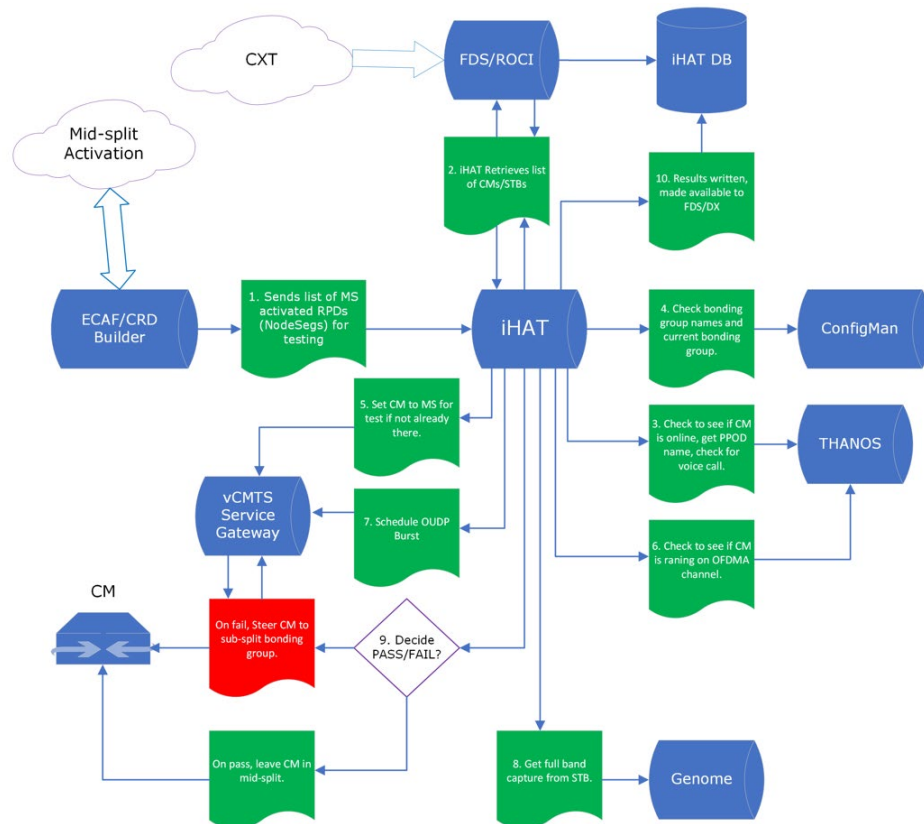

Figure 6 – iHAT as Part of a Production Upgrade Workflow

With a commitment to upgrade millions of HHP per year to mid-split capability, the tool cannot be operated in isolation, or be part of a workflow that has a “Stop” sign until human intervention to push a button. Automation is required to meet the pace required to cover the footprint target. Figure 6 contains a lot of homegrown names and acronyms associated with Comcast operations. The decoder ring is below, along with a description of their functionality as it pertains to Figure 6:

CXT = Customer Experience Technologies, the name of an organization within Comcast focused on systems and tools built for, and to maintain and support, the customer experience

FDS = Federated Data System. For iHAT purposes, it acts as an attribute and information sharing database for reading of essential information from the home and publishing out iHAT outcomes for subsequent disposition, processing and to other APIs. For example, what devices exist at this address? What type of device is it? What is the MAC address? What was the result of the iHAT test? The **iHAT DB** next too FDS/ROCI is where the output is pushed for other applications to use, in particular technician tools.

ROCI = An ML-based spatial tool that maps logical connectivity of devices to physical network architecture to the level of an individual Tap in the field. What modems are connected to which RF amplifier? Which node leg? Which RPD?

ECAF = A tool within the automated workflow managing construction projects. For iHAT purposes, ECAF signals when a Mid-Split RPD and HFC network upgrade project has been

completed in the field, triggering that the spectrum activation via iHAT can begin (there are some timing nuances to exactly when but the functional trigger is closure of ECAF ticket)

CRD = Configuration of an RPD is determined by the CRD it is programmed with. Its function in the iHAT workflow is to prepare the vCMTS to accept OFDMA upstream carriers for the iHAT testing and for data carriage itself after successfully passing the test.

ConfigMan = Configuration Manager. As described, this tool keeps track of the channel bonding configurations deployed and their state in the devices. Its role in iHAT is associated with the disposition of an iHAT result, whereby a “Pass” results in bonding if US SC-QAM and OFDMA carriers across the Mid-Split band for that home or business, and a “Fail” bonds only the 4 SC-QAM channels.

THANOS = A popular Marvel character, but for iHAT purposes it is an information store of vCMTS DOCSIS information of status, state, and logical connectivity.

Genome = A application that obtains metrics and data from devices and subsequently used to build dashboards and views in tools that maintain and support the RF network. Its role here in iHAT is to get the snapshot of the STB spectrum during the iHAT test to measure the isolation in the home.

vCMTS Service Gateway – An external application that in the iHAT application drives the vCMTS operation and the functions required to execute during the period that iHAT is running. It is apparent from Figure 6 that, while iHAT is at the heart of this flow, it is dependent upon a range of ecosystem software components to scale Mid-Split activation rapidly through the footprint. As part of the qualification of iHAT, a disciplined Integration and Test (I&T) process was developed to bring this full system to maturity and harden it for production. This process included phases of pairwise testing of relevant components to verify the APIs were communicating properly, exchanging the proper information, acting as expected on the information - reporting results, creating notifications or alarms, kicking off additional processes, etc., and executing cleanly and consistently before moving to the next phase of integration as the system was brought online component-by-component.

4. Integration with Production Ecosystems

While advancements in our network are necessary and important we have to be mindful about customer service interruptions. Minimizing the times we interrupt the customer’s service is crucial to limiting customer frustration, churn and sentiment. With the customer experience top of mind, we developed a roadmap for a customer’s journey and the touchpoints along their journey. We broke out the customer journey in three parts, as shown in Figure 7: Preparation, construction and appreciation.

PROCESSES: CUSTOMER COMMUNICATIONS

In an effort to convey reliability and to deliver a seamless customer experience, we're looking holistically across the customer lifecycle.

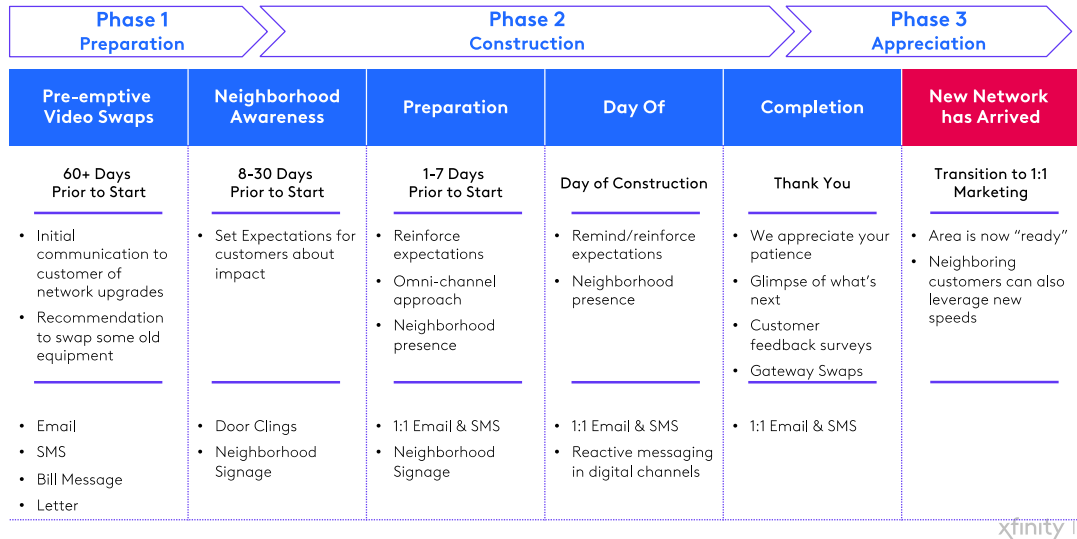

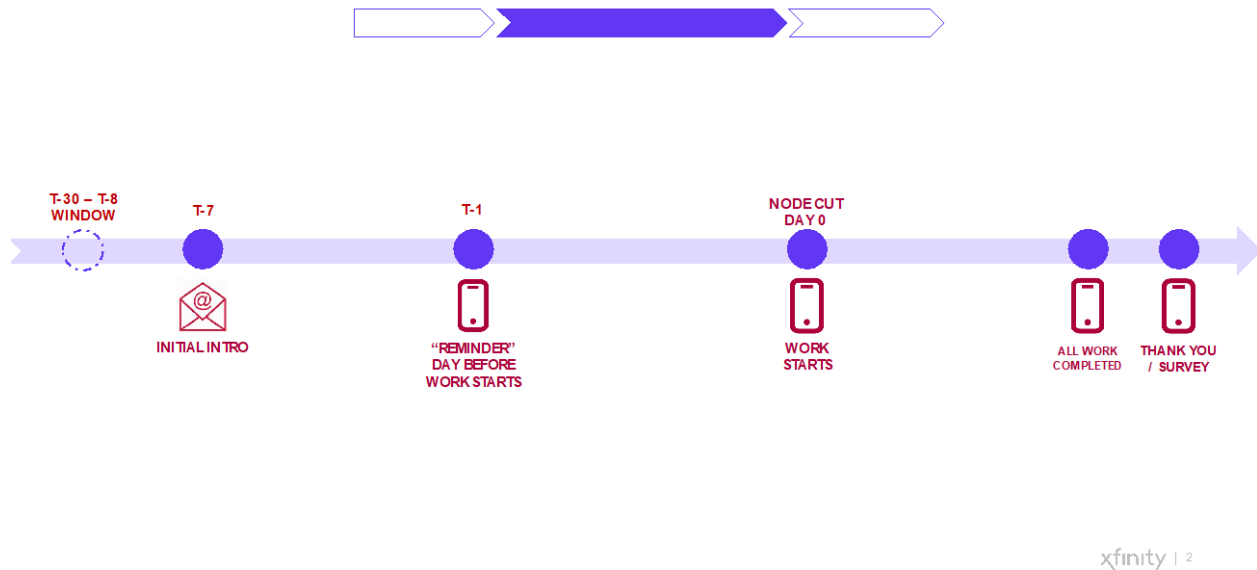

Figure 7 – Customer Journey During Upgrade

Along the customer journey we make it a point to notify them of upcoming service interruptions at least sixty days in advance. We reach out through multiple methods both physical and digital to ensure they are aware and have alternative options for connectivity during the times of interruption. During the construction phase our goal is to not have a customer hard down more than 180 minutes on average. Should we exceed 180 minutes hard down then credits and other forms of acknowledgment will be offered to the customer. When their journey is complete, we thank them and share our appreciation for their patience. We also share with them the new opportunities and capabilities offered to them with the upgraded network. This process is summarized in Figure 8.

PROCESSES: CUSTOMER COMMUNICATIONS

Proactive Communications journey – happy path of comms indicated by purple touchpoints

xfinity | 2

Figure 8 – Communications Strategy During Upgrade Cycle

From a CARE perspective we have also built-in the automatic detection of Mid-Split customers so that the moment they call us we know and meet their unique wants and needs. Furthermore, we integrate the intelligence of iHAT within our interactive troubleshooting guide to determine whether a truck roll is necessary to remediate an issue specifically caused by the enablement of the OFDMA spectrum. With both Mid-Split identification when a customer reaches out and quick diagnosis as to whether their issue is Mid-Split related will set us up for success in the future. This flow is shown in Figure 9.

PROCESSES

Example: Mid-Split Spectrum Activation – SIK+ Drop Amp Remediation (XB6/7 Only)

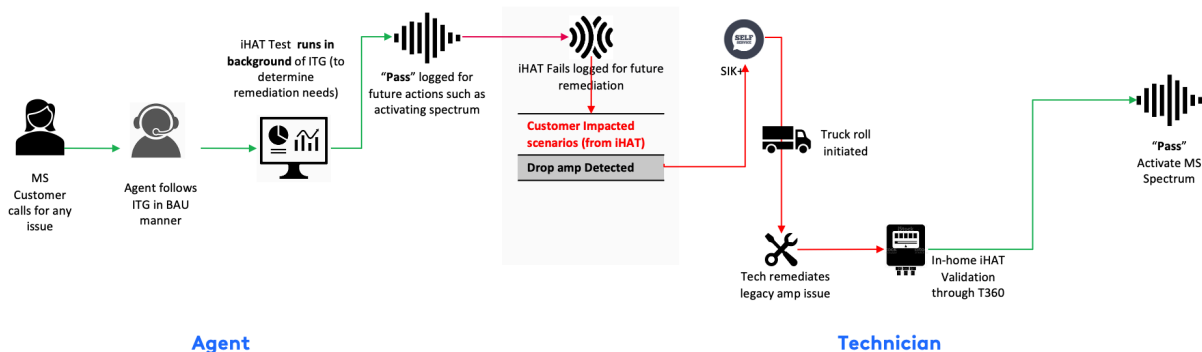

Figure 9 – Customer Care Workflow

5. Technical Operations Best Practices

Cross-functional teams across all Divisions and HQ are involved in executing the Mid-Split architecture at scale while caring for the end-to-end customer experience. A major advantage of our network architecture is that we can quickly and continuously evolve it with minimal disruption to customers — without digging up their yards and neighborhoods, as laying fiber to their homes would require. In most cases, customers should only be down for a few hours while our teams cut over to the enhanced technology on a neighborhood-by-neighborhood schedule.

Through neighborhood signage, SMS, email, and more, we will proactively and fully communicate to customers throughout the journey – well before work begins, during down time, and after the job is done.

In Field Operations, technicians will need to understand the importance of the work we’re doing to prepare our network for the future. They will also be responsible for:

- Preparing homes and businesses to use the new Mid-Split frequency range
- Identifying and removing hindrances preventing modems from leveraging the new frequencies

Due to the dynamic nature of Mid-Split deployment we’ve had to be very strategic about how, when and where we communicate. While technicians in a popular and competitive metro area would likely see activity in their market first it is equally important, we also communicate to their peers in more rural areas in a timely manner. **Table 1** is an example of the recommended communications timeline and tactics from both a national perspective to a small, localized trial.

Table 1 – Communications Timelines and Tactics

	Item	Audience	Key Message	Delivered By	Approximate Timing
	Final Comms Package and Templates	Division Communicators	Ensure the messaging is aligned and consistent across the enterprise with peer review	National Communications	
	Training Materials	Division Teams	Ensure the training is aligned and consistent across the enterprise with peer review	National Communications	
1	Leader Update	Supervisors+	Awareness to leaders that customers may start seeing advanced comms, program introduction & awareness	Launch Area Specific	Launch minus 3 weeks (or as determined by division)
2	Team Deck	Supervisors to use in team meetings	High level overview of Path to 10G	Launch Area Specific	Launch minus 2 weeks (or as determined by division)
3	Tech Awareness	All Technicians, Supervisors	High level overview of Path to 10G	Launch Area Specific	As Determined by local leadership
4	Tech Awareness	All Technicians, Supervisors	High level refresher of Path to 10G	Launch Area Specific	As Determined by local leadership

5.1. Hardware

Our network has evolved over the last few years to require less QAM set-top boxes in favor of QAM-less IP set-top boxes. The benefit of having less QAM set-top boxes in the premise means there is less of a need for in-home amplifiers in the home. For this reason we have been on a journey to bring field awareness about keeping the premise as passive as possible. Doing so sets us up for success and cost savings by not needing to return to the premise to remove a Mid-Split

amplifier when we move to High-Split or any unforeseen challenges when we go to DOCSIS 4.0.

An additional hardware consideration is the field meter necessary to support troubleshooting both OFDM and OFDMA in the field. Most of us are very familiar with how quickly technology can evolve so being prudent about which meter we deploy and when is crucial to our success. Furthermore, knowing the make and model technicians have with them is crucial to effectively route the ones with fully capable meters to a home that is leveraging the Mid-Split architecture. Lastly, the speed testing capabilities of the meter are very important for customer speed validation.

Training materials to onboard technicians for these challenges are shown in Figure 10 and Table 2.

TOOLS OF THE TRADE: HARDWARE

Keep homes as passive as possible and only use an amplifier when absolutely necessary

5.2. Software

Software is equally as important as the hardware because in many instances it can save a technician time by calling out impairments and opportunities ahead of their arrival. The software also serves as a be a second point of validation by confirming what the meter reads as opposed to a gateway. We've integrated tools like iHAT to help technicians be aware of previous conditions or impairments with a premise. The context enables them to know what they're likely going to a premise to remediate. Once they've remediated the issue we provide them the ability to force the gateway to start leveraging the OFDMA carrier.

Understanding enough about iHAT is important for technician to efficiently support the roll-out of Mid-Split and OFDMA. Figure 11 is a slide from the training material associated with this new software tool.

TOOLS OF THE TRADE: SOFTWARE

What is iHAT?

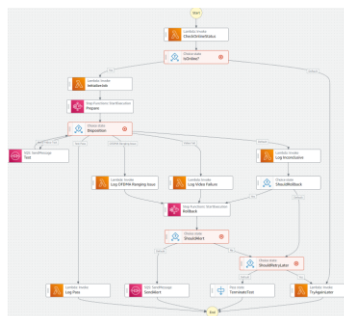

iHAT is a NGAN tool developed to help us determine whether a premise can support Mid-Split

How does it work?

When a node has been converted to Mid-Split, iHAT will be run by NGAN to determine which homes can activate MS spectrum without interruption and which homes may need remediation

What is iHATv3?

iHATv3 is an updated version of iHAT that will not require a device reset to perform a test

Identified Issue	Definition	Solution
OFDMA Ranging Issue/ Blocked Carrier	iHAT is unable to reach DOCSIS Device	Most likely cause is a drop amplifier in the way and will require a TC to remove or replace with Mid-Split Drop Amplifier
Video Interference	iHAT identified Video interference from one of the XG devices in the home	This is caused by low port-to-port isolation in the soft drop system TC will be required to ensure passive drop network meet Comcast specifications. (other solutions available depending on market availability)
No XG Devices		iHAT can perform a test but will not be able to provide video interference information
XB3/ BWG or older model		Customer does not meet minimum requirements to perform test

xfinity | [®]

Figure 11 – iHAT Definitions

6. The Terabyte Factory is Online

Comcast has been installing digital Mid-Split capable nodes for over 5 years as part of our “Fiber Deep” DAA network upgrade strategy using Remote PHY nodes (RPDs). Up until recently these deployments were exclusively in areas upgraded to “N+0,” which eliminates all RF amplifiers in the plant between the DAA node and customer homes. As we continue to build out our DAA network, deployments now include RPDs in typical “N+X” (X = number of RF amplifiers) using Mid-Split amplifiers swapped into existing amplifier locations to minimize plant rework. The entire DAA footprint is Mid-Split ready, and the process of activating the Mid-Split spectrum has begun, configured using both DOCSIS 3.0 SC-QAM channels and DOCSIS 3.1 OFDMA channels up to 85 MHz.

One of the advantages of using the vCMTS and DAA is the ability to perform extensive monitoring of the network and easily build custom tools and dashboards. These dashboards are critical during deployment to ensure we have visibility into the devices and network as the spectrum and upstream OFDMA are being activated.

We look at these aspects in more detail below.

6.1. Mid-Split Activation

Activating the Mid-Split spectrum is a multi-stage effort including planning, construction, spectrum activation, in-home health assessment, remediation and monitoring. Through June 2022, Comcast has over 30,000 DAA nodes built and activate, and the Mid-Split migration process has begun. The engineering effort, testing and planning for deployment is paying off and the monitoring tools and dashboards developed have been invaluable.

Spectrum activation consists of two stages:

- 1) Updating the system to use the OFDMA spectrum. This includes pushing an updated configuration to the RPD which has a 5 channel bonding group (4 SC-QAM channels + one OFDMA channel to 85 MHz). Figure 12 is illustrative of this configuration.

Figure 12 – Mid-Split Channel Configuration of 4x SC-QAM + OFDMA

2) Running iHAT

- a) Measures video interference on accounts with STB boxes and moves devices which are determined to have video interference to the standard 4 SC-QAM channel bonding group via Dynamic Bonding Change request.
- b) Moves devices which have OFDMA blocked and cannot use the OFDMA channel back to the 4 channel bonding group using Dynamic Bonding Change request.
- c) Steering the devices which cannot use OFDMA to the 4 channel SC-QAM bonding group prevents these from showing as in “partial” state in the monitoring tools.

During the spectrum activation and iHAT process, devices are monitored to ensure they are online and using the appropriate channel bonding group based on the device capability and iHAT analysis.

Upon initial spectrum activation, devices which have the spectrum between 42 and 85 MHz impaired will not bond to the Mid-Split OFDMA channel. These devices will initially show as upstream partial until iHAT is run. Once iHAT is run, these will be moved to the 4-channel bonding group and show as fully online.

As of June 2022, Comcast has over 35,000 DOCSIS 3.1 devices activated with Mid-Split and OFDMA across approximately 1,800 RPDs. The rate of activation will accelerate in the 2nd half of 2022 and through 2023 as new products enabled by Mid-Split are brought to market.

6.2. New Tools and Automation

Achieving the scale noted above would not be possible without monitoring dashboards. One of the main dashboards used during activation is the iHAT dashboard. This dashboard monitors the progress of checking for OFDMA partials and testing for video interference. In-home video interference, which caused by adjacent channel interference, is measured by having the cable modem send out a 1.6 MHz wide OUDP burst. This burst is sent out at the same spectral density as the OFDMA channel. The level of interference from this burst is measured at the adjacent STB in the home. If this burst exceeds a pre-determined threshold vs the downstream QAM signals at the STB, the cable modem is steered back to the 4 SC-QAM 4 channel bonding via DBC and will not use the OFDMA. This account is noted for remediation to be able to activate the OFDMA spectrum.

iHAT also checks the OFDMA channel and if it is registered and bonded. If the OFDMA channel is bonded and the account passes the video interference on the accounts with STBs, the CM remains in the 5 channel bonding group with OFDMA active.

If the OFDMA channel is not registered and bonded, iHAT steers the CM to the 4 SC-QAM bonding group via DBC. This removes the status of partial and shows the device online. The account is targeted for remediation to determine why the OFDMA channel is not bonded. The iHAT dashboard can look at the entire network, specific PPODs, and specific RPDs to see the number of devices with OFDMA blocked and video interference. Figure 13 is a sample of the iHAT dashboard after spectrum activation for a single PPOD which includes 154 RPDs.

This Dashboard shows the following:

- **RPD Count:** This is the total number of RPDs tested for the specific PPOD and timeframe selected.
- **Total number of tests:** This is the total number of tests performed which include testing for OFDMA Blocked, Video Interference
- **Pass:** Number of devices which can connect to the OFDMA channel and which pass the video interference test
- **OFDMA Blocked:** Number of devices which cannot connect to the OFDMA channel. This is caused by standard split in-home drop amps, or other in-home or plant issues affecting the Mid-Split OFDMA spectrum
- **Video Interference:** Number of devices which STB boxes on the same account, which connect to OFDMA, but where the OUDP burst received at the STB box is higher than the downstream QAM by the pre-determined threshold

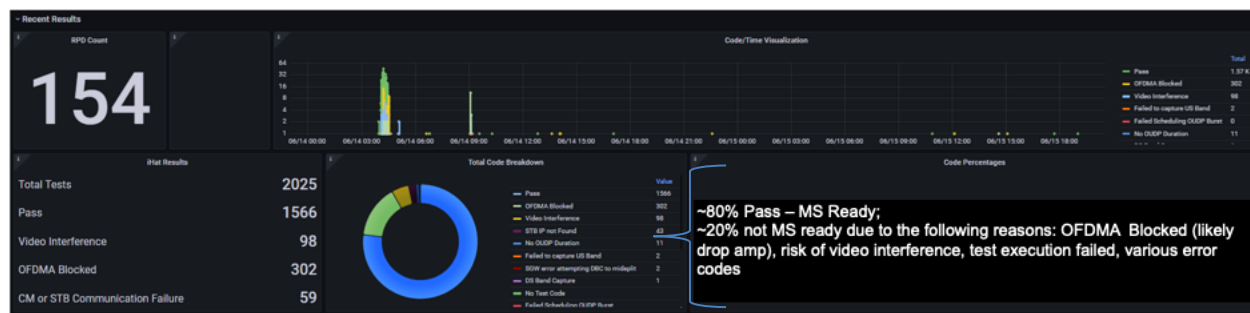

Figure 13 – Test Sample of an iHAT Dashboard

Additional tools and dashboards have been built to monitor the OFDMA health across the network. The dashboard in Figure 14 shows the OFDMA health for a specific PPOD. This dashboard can show the performance of critical OFDMA physical layer parameters of the whole network or down to a specific RPD.

Figure 14 – OFDMA Health Statistics

The dashboard in **Figure 15** shows the state of OFDMA cable modems and the percentage of OFDMA partials in a PPOD and the overall change in OFDMA partial count before and after running iHAT. Partial count is reduced significantly post iHAT.

Figure 15 – iHAT Execution Statistics

Standard existing tools are also used when activating the OFDMA spectrum. Yeti, which is an upstream spectrum analysis tool, has been updated to support Mid-Split can be used to verify the health of the upstream OFDMA spectrum. Figure 16 shows the upstream spectrum with the full 5-channel bonding group including OFDMA. In the Figure 17, the Yeti capture shows the 4 SC-QAM channels prior to adding OFDMA. Noise can be seen in the OFDMA band at 44-60 MHz and at 83 MHz. This is off air ingress from channels 2,3 and 5 which will have some effect on the total upstream capacity, but with PMA will be minimized.

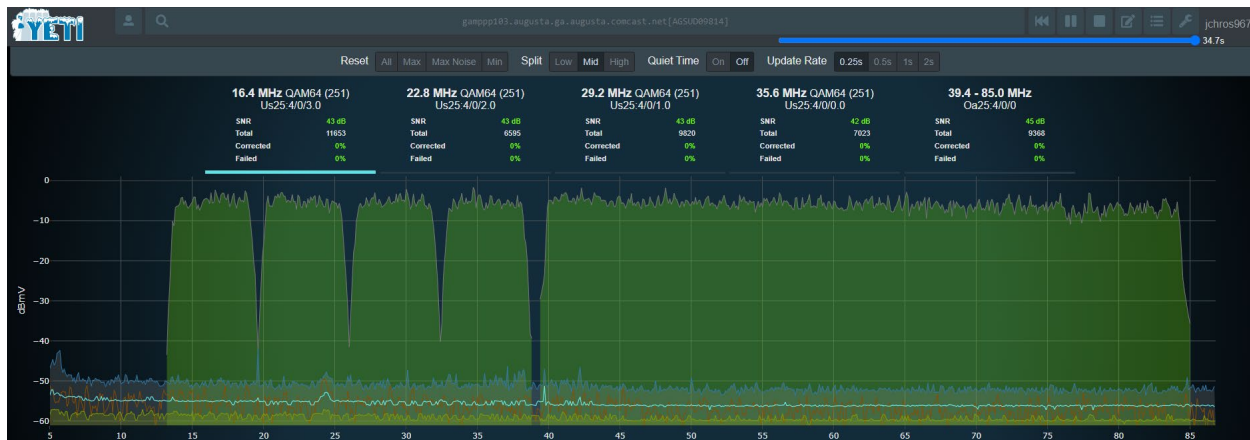

Figure 16 – Mid-Split Full Channel Configuration of SC-QAM + OFDMA

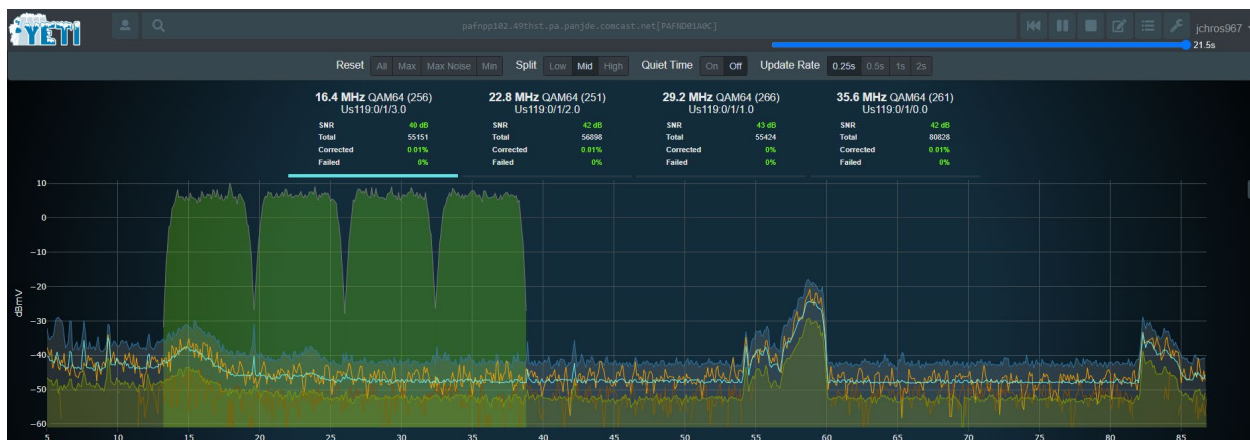

Figure 17 – Mid-Split Upstream Spectrum Capture Prior to Adding OFDMA

Numerous other tools and dashboards are available for scale deployment of mid-split and the ones above provide a look into the detail needed for this deployment.

Among the most important of these is the capacity impact of Mid-Split. Referring to Figure 16, a standard 4x SC-QAM plus an OFDMA channel from 39.4 MHz to 85 MHz offers a bonded total capacity of approximately 450 Mbps, with some variation around that depending mostly upon network fidelity variables. Of course, only the DOCSIS 3.1 devices can avail themselves to this bonded capacity. The DOCSIS 3.0 devices have their traffic contained completely within the SC-QAM allocation.

While only, roughly, doubling the upstream spectrum, we can calculate that the mid-split spectrum powered by DOCSIS 3.1 increases capacity > 4X compared to the standard 4-channel SC-QAM low-split upstream allocation. During the COVID outbreak, where an urgent need for capacity was felt everywhere and DOCSIS 3.1 had not yet been enabled (and still is not in the low-split spectrum), Comcast deployed 6 SC-QAM upstream channels to relieve congestion. This 6-channel capability represents effectively the “maximum” D3.0 only capacity in a low-split system by which to compare the Mid-Split allocation with the OFDMA augmentation.

Because of the interplay of device penetrations, capacity available to devices classes, and the variations of the network's ability to support QAM profiles, Comcast made an investment in capacity analytics to quantify how the introduction of OFDMA would impact network capacity in order to make good business decisions around device upgrades, network upgrades, and regional priorities.

For a complete analysis of the capacity impacts of Mid-Split with OFDMA, the reader is referred to [1].

6.3. Implications to Traffic Growth, Plant Upgrades, and Service Speeds

Mid-Split expansion takes the available upstream bandwidth from 37 MHz to a limit of 80 MHz. It was defined in DOCSIS 3.0, with the upper limit selected in part to fall just below the FM radio band in the US, while preserving the important downstream video out-of-band (OOB) signals widely used by legacy QAM set-top boxes (STBs). In recent history, it has been the upstream bandwidth limitation in the face of continued traffic growth that drove network upgrade activity.

The average per-user peak-busy-hour (pbh) upstream is still in the hundreds of kbps range – 400-500 kbps going into 2022. The downstream, by contrast, is about 10x that or more. As a general rule, the upstream payload has on average grown more slowly than downstream, although it has tended to more volatility year-over-year as different “killer apps” arose such as peer-to-peer file sharing (i.e. Napster) and home security video cameras. However, where DS was racing ahead at 50% per year for many years, driven by streaming video most recently, upstream averaged 20-30% - and less or flat in some years. An additional bonus of Mid-Split is that this new upstream spectrum is typically cleaner. As a result, when combined with use of much more spectrally efficient DOCSIS 3.1 OFDMA, the Mid-Split impact on network lifespan is extremely powerful. Roughly twice the total upstream spectrum converts to 3-4 times the available capacity.

Figure 18 shows the time runway generated by three options – node split, node split plus upgrade to Mid-Split, and finally N+0 with Mid-Split. While N+0, with smaller service group size, offers the longest runway of the three, an N+x migration tied to a node split is also a very effective way to extend HFC lifespan to nearly 7 years.

A key benefit of N+x with spectrum migration is its ability to add capacity quickly when compared to N+0. When the Covid-19 traffic spike eliminated months of CAGR lifespan, N+x upgrades brought more US bandwidth to the network quickly to reset the lifespan timeline. With a year of capacity growth runway erased by the pandemic – perhaps it flattens as the effect recedes and a new normal established – alternatives such as drop-in HFC upgrades that are both fast and effective make a sensible augmentation step.

Figure 18 – Mid-Split Upstream Spectrum Capture Prior to Adding OFDMA

The 7 years of lifespan offers a comfortable window of time to assess HSD trends (is CAGR changing), technology availability options (i.e. DOCSIS 4.0, R-OLT FTTH), and assess emerging applications and the speed, utilization, latency, and jitter requirements that they entail and adjust accordingly if necessary.

Lastly, while the “big story” for upgrading to Mid-Split is been its ability to deliver a long-term life span for the HFC plant without a major compromise of downstream bandwidth, there are significant upstream service speed opportunities as well. The Low-Split upstream payload data capacity using D3.0 SC-QAM with 64-QAM carriers is about 100 Mbps, and residential upstream service speeds limited to 35-50 Mbps today.

By contrast, the available capacity for a DOCSIS 3.1 CM in a Mid-Split network using the configuration shown previously in Figure 16, and as noted on the figure and observed in the prior section, is about 450 Mbps. This will enable upstream speeds of 100 Mbps, 200 Mbps, and up to 300 Mbps – under an empirical set of guidelines for penetration, utilization, service group size, etc. The field trial activity previously described validated speeds in scale up to 200 Mbps in preparation for market launches of these speeds in the future.

As DOCSIS 3.1 device penetration continues to increase, the DOCSIS 3.0 QAM carriers can be exchanged for more bandwidth efficient DOCSIS 3.1 OFDMA, which will make this bandwidth approximately 60-80% more efficient on average, resulting in the 450 Mbps of capacity increasing to over 600 Mbps if fully converted to DOCSIS 3.1, which would take practical speeds up to at least 400 Mbps.

So, the Mid-Split upgrade represents a strategy that addresses both effective capacity growth management and higher speed product offerings for residential and business customers.

7. Conclusion

Consumer usage trends continue to fluctuate as new applications and societal shifts take place. The year 2020, inclusive of the global pandemic, accelerated and altered some of the usage trends. Many companies sent employees to work from home at the onset of the pandemic while some schools went completely virtual. Online gaming has become less of a leisure hobby and adopted by many professional teams inspiring a young generation of one day having the opportunity to participate and potentially create and monetize for themselves. One thing is clear, all usage, including upstream, is likely to continue increasing. As we enter the last quarter of 2022 one would be hard pressed to believe we will ever see ourselves in a pre-pandemic state of usage trends. If anything, we should accept what we know today as the new normal and tactically plan to continue bolstering and augmenting our networks.

Mid-Split scratches the surface for the potential of our networks, but it is a realization of what was once only a vision not many years ago. We've built the tools, processes, training, technology and end-to-end systems to develop, launch, scale, support, and maintain a DOCSIS 3.1 OFDMA Mid-Split activate network, and Comcast and our customers are reaping the rewards of this effort through a healthier, smarter, more capable network that provides a better, high availability Internet experience for our customers with higher upstream speeds to deliver on these emerging trends and application

Looking ahead, the advent of High-Split and DOCSIS 4.0 FDX present their own new challenges that, much like Mid-Split, appear daunting at the outset. However, much like we've done in the past, we will use the collective wisdom of the industry to take on these new challenges. The learnings we have gained and will continue to gain building out DAA Mid-Split will make the path that much easier for the generations to follow.

1. Introduction

Internet consumption grew exponentially last decade, doubling every other year. Several years ago, the growth rate began slowing, but COVID turned the world on its head with everyone living, working, and playing from home. This created a bandwidth (BW) bubble, especially upstream. Will this bubble continue, signaling a new paradigm, or return to our previous path?

ARRIS/CommScope has the most extensive broadband capacity monitoring history in the industry. Data collection started in 2010; done every year since; and covers 10's of millions of modems from numerous multiple system operators (MSOs). The 2022 data is in: this paper analyzes the new normal, quantifies the '21 COVID bump, and shows our recent consumption or average bandwidth per sub (Tavg) growth rates.

The real multi-billion-dollar question is what's the BW growth for coming decades? This drives our network investment strategies. Has Tavg growth slowed to a lower rate (e.g., doubling every 3-4 years) or is it no longer exponential? Some folks claim exponential growth is dead, and that BW growth is linear or following the Adoption S-curve. [S-curves have exponential growth in early years, linear growth during middle years, and flattens out in later years.] E.g., will Tavg reach a limit of 2½ ultra high-definition (UHD) streams per home (~25Mbps) and stay there? Or will another S-curve, potentially driven by virtual reality (VR) / augmented reality (AR), start a new era of high growth?

The paper highlights research on all alternatives; creates trendlines for each; and measures how accurately it matches last decade's data. These BW growth trajectories are mapped out for 5/10/15 years. The resultant spaghetti plots show a cone of uncertainty that grows over time, roughly doubling every 5 yrs.

The 2nd half of the paper plugs various Tavg growth trendlines into the CommScope network capacity modeling tool to analyze 1218/204 megahertz (MHz) & Data Over Cable Service Interface Specifications (DOCSIS[®]) 4.0 plant. It shows their useful lifetime using various growth models and explores whether low growth might eliminate the need for 4.0, or just delay it, giving precious time to transition.

Our wrap up recommends some migration strategies to minimize up front investments while maintaining flexibility to increase network capacity and manage uncertainty risks.

2. Network Capacity Planning Overview

Determining the capacity requirements for a service group (SG) is critical for providing customers with the appropriate quality of experience (QoE). Figure 1 shows an example of a SG upstream (US) capacity usage over a 16-minute window sampled at 1-second intervals. If an operator samples the BW usage once every 16-minutes, then it determines the average BW over that interval as shown by the purple line. This is a very useful datapoint but insufficient to determine the required capacity for the SG.

Sampling at 1-minute intervals would capture some of the variations, or ripples in the system but would still miss the many spikes which are individual modems bursting on top of the average BW. The gray line in the figure shows the high-water mark from 1-minute samples.

If an operator could sample at 1-second intervals or faster, then they could more closely determine the required SG capacity. The 1-second high-water mark is shown by the orange line. But sampling at these rates is not feasible in real systems, so another method is needed.

Figure 1 – Example of Upstream Capacity Usage

2.1. The “Basic” Traffic Engineering Formula

The CommScope (formerly ARRIS) team has provided industry leading traffic engineering research for over a decade. Originally, [CLO_2014] introduced QoE for broadband networks and developed a relatively simple SG traffic engineering formula that’s easy to understand and useful for demonstrating basic network capacity components. Over time, this evolved and a network capacity analysis [ULM_2019] gave an updated insight into calculating the SG capacity requirements. Some additional references of note include [EMM_2014], [ULM_2014], [CLO_2016], [ULM_2016], [CLO_2017], [ULM_2017] and [HOWALD_2022].

The “Basic” formula shown below is a simple two-term equation. The first term ($N_{sub} * T_{avg}$) allocates bandwidth capacity to ensure that the aggregate average bandwidth consumption generated by the number of subscribers (N_{sub}) can be adequately carried by the service group’s bandwidth capacity. The first term is viewed as the “Direct Current (DC) component” of traffic that tends to exist as a continuous flow of traffic during the peak busy period. The growth rate of T_{avg} has seen much research.

“COMMSCOPE/CLOONAN’S CAPACITY EQUATION” Traffic Engineering Formula:

$$C \geq (N_{sub} * T_{avg}) + (K * T_{max_max}) \quad (1)$$

where:

C is the required bandwidth capacity for the service group

N_{sub} is the total number of subscribers within the service group

T_{avg} is the average bandwidth consumed by a subscriber during the busy period

K is the QoE constant (larger values of K yield higher QoE levels)...

where $0 \leq K \leq \text{infinity}$, but typically $1.0 \leq K \leq 1.2$

T_{max_max} is the highest Service Tier (i.e., T_{max}) offered by the MSO

Figure 1 shows there are obviously fluctuations that occur (i.e., the “alternating current (AC) component” of traffic) which can force the instantaneous traffic levels to both fall below and rise above the DC traffic level. The second term ($K * T_{max_max}$) is added to increase the probability that all subscribers experience good QoE levels for most of the fluctuations that go above the DC traffic level.

The second term in the formula ($K * T_{max_max}$) has an adjustable parameter defined by the K value. This parameter allows MSOs to increase the K value and add bandwidth capacity headroom that provides better QoE to their subscribers within a service group. In addition, the entire second term is scaled to be proportional to the T_{max_max} value, which is the maximum service tier being offered to subscribers.

In previous papers [CLOONAN_2013, CLOONAN_2014, EMM_2014], found that a K value between 1.0 to 1.2 provides good QoE results for a 250 subscriber SG. Larger SGs need even larger values of K while very small SGs might use a K value ≤ 1.0 .

2.2. The “Modified” Traffic Engineering Formula

Over time, it was discovered that the optimum K value varies based on all the inputs: N_{sub} , T_{avg} and T_{max_max} . [ULM_2017] noted some of these limitations along with some refinements to the basic formula above. This resulted in the following which is still algebraically equivalent to the basic formula:

Modified “COMMSCOPE/CLOONAN’S CAPACITY EQUATION” Traffic Eng Formula:

$$C \geq (N_{sub} * T_{avg}) + (K-1) * T_{max_max} + T_{max_max} \quad (2)$$

The subtle change is that there are now three main components to the traffic engineering formula:

1. Peak Busy Period Average Consumption (i.e., $N_{sub} * T_{avg}$)
2. Peak Busy Period Ripple for managing QoE (i.e. $(K-1) * T_{max_max}$)
3. Headroom for maximum Service Tier Burst (i.e., $1 * T_{max_max}$)

Figure 2 shows how the modified formula maps to the US capacity usage example given in Figure 1. The basic formula might have used a value of $K=1.2$ in this example. This is now broken into a burst component equal to $Tmax_max$ plus a ripple component that is estimated by $20\% * Tmax_max$.

Figure 2 – Mapping Traffic Eng Formula to US Capacity Usage Example

Figure 3 shows a network capacity example for a 1 Gbps downstream (DS) service tier; 150 subs in the SG; and $Tavg = 3$ Mbps/sub. This requires SG capacity ≥ 1500 Mbps. This includes a ripple component of $5\% * Tmax_max = 50$ Mbps. Note that in this example, the ripple component as a function of $Tmax_max$ is much smaller than the initial $K=1.2$ values because $Tmax_max$ is significantly higher.

Figure 3 – Network Capacity Example for 1G Service Tier

2.3. Max Service Tiers in 10G Era

So, what kind of service tiers will subscribers enjoy in this new 10G bandwidth era? These tend to be marketing driven. The T_{max} value from the traffic engineering formula helps define the Service Level Agreement (SLA) that the operator can potentially offer to their customers.

First, 10G passive optical network (PON) provides a net downstream capacity of ~8.5 gigabits (Gbps) to the consumer. Using the traffic engineering formula, this capacity might support a downstream SLA of 7.5 Gbps. The SG utilization (i.e., $N_{sub} * T_{avg}$) for a 64 subscriber PON might grow to a 1+ Gbps over the next decade. That means a consumer with a 7.5 Gbps SLA will have a QoE coefficient of $K = \sim 1.0$ which is reasonable for this relatively small SG size.

The 7.5 Gbps SLA from 10G PON sets a bar that Hybrid Fiber Coax (HFC) systems must match with their DOCSIS 4.0 upgrades. Some network capacity modeling results are shown in a later section to show how many subscribers the HFC can support per SG at this SLA.

HFC does have an advantage because it can incrementally add capacity with additional spectrum to achieve a true 10 Gbps SLA that is equivalent to 10G Ethernet. Getting to a true 10 Gbps downstream SLA will mean providing greater than 10 Gbps network capacity. This will push the PON networks into next generation PON technology (e.g., 20+ Gbps). Some future technologies such as 1.8 and 3.0 GHz HFC plants are discussed further in [CLO_2019].

Choosing the upstream SLA is more complicated. As will be seen later in Figure 7 with the DS:US consumption ratio, there might be a 12:1 ratio between the two. However, in the new 10G era, a gigabit US SLA tier with high burst rates may be needed, even if the US consumption is much lower than downstream.

Looking at PON systems, they offer both symmetric and asymmetric data rates. A gigabit passive optical network (GPON) provides 2.5 Gbps downstream data rates with 1.2 Gbps upstream data rates for a 2:1 ratio. The Institute of Electrical and Electronics Engineers (IEEE) 10G ethernet passive optical network (EPON) downstream might be paired with either a 1G or 10G upstream for 10:1 or 1:1 ratio. In the International Telecommunication Union (ITU) world, XG-PON pairs 10 Gbps downstream with 2.5 Gbps upstream (i.e., 4:1 ratio) while XGS-PON provides a symmetric 10 Gbps in both directions for 1:1 ratio.

HFC systems have traditionally been extremely asymmetric, but these trends are changing. In the upcoming network capacity modeling section, a 2.5 Gbps upstream SLAs is paired with the 7.5 Gbps DS SLA on a 1794/396 MHz plant.

2.4. Determining Service Group QoE based on Probabilities

The Peak Busy Period Average Consumption and maximum Service Tier Burst components are well known and easily obtained. Much traffic engineering research has since focused on quantifying the Peak Busy Period Ripple component for QoE as it is impacted by all inputs, not just T_{max_max}.

It became apparent that quantifying the SG subscribers QoE needed to focus on the probabilities for SG capacity. And to predict behavior across different SG with different parameters, a network capacity transmit model for individual subscribers was necessary.

Our research found that there is a massive amount of data and many complicated variables at play here. It turns out that providing sufficient QoE for traffic engineering is a problem that is suited to Big Data Analytics. Our goal is that Big Data Analytics can be leveraged to not only select optimum QoE margins

in existing networks but become a tool to predict how networks will morph and the QoE margins of the future. It is important to note that the operator can choose how much margin they would like to build in.

Once single subscriber BW probability distribution functions (PDF) were in place, it is then possible to create a SG BW PDF to analyze the behavior at the SG level. An example of the SG BW DS probabilities is shown in Figure 4. This is the output of a Monte Carlo simulation with 100K trials. It is a SG that consists of 128 subs, all of which have a 1G DS service tier. The DS Tavg = 15 Mbps which represents a time in the future.

Figure 4 – Mapping Traffic Eng formula unto SG Probabilities

Note the asymmetry in the curve – there is a much longer tail to the right. Various cumulative distribution function (CDF) probability thresholds are shown (i.e., 90%, 99%, 99.9%, 99.99%) to provide an insight as to the probability the SG BW reaches different capacities.

The blue candlestick in Figure 4 shows how the traffic engineering formula overlays the SG PDF. In this instance, the formula forecasts 3,120 Mbps is required. Note that this is sufficient for ~99.5% of the peak busy period time. For the remaining 0.5% of the time, the buffers may be temporarily filled, and some latencies introduced. Note that 0.5% represents ~50 seconds out of every evening. For most of those 50 seconds, the delays should be insignificant and not noticed by users. This is normal network behavior and why many users can share a single network pipe. Please keep in mind how low the probabilities are for the Tmax_max burst regions as shown above.

Some new revelations of CommScope's probability research are discussed further in [HOWALD_2022].

3. Broadband Subscriber Traffic Consumption – 2022 Update

ARRIS/CommScope has the most extensive broadband capacity usage monitoring history in the industry. Data collection started in 2010; done at the start of every year since; and covers 10's of millions of modems from multiple MSOs. Subscriber usage has been monitored from the same group of MSOs for consistency. This dataset has been compared and maps closely to many other MSOs globally.

3.1. Downstream Peak Period Average Bandwidth per Subscriber, DS Tavg

Figure 5 shows the average subscriber downstream consumption, DS Tavg, during peak busy period for several MSOs over a ten-year period. At the start of 2022, DS Tavg was 3.5 Mbps per sub averaged across all the MSOs.

Figure 5 – DS Tavg, Average Subscriber Downstream Consumption

It turns out that the DS Tavg growth rate was much higher last decade and continues to tail off in recent years. The DS Tavg is up only 12% from 2021. Looking across a 3-year window, the DS Tavg has grown roughly 21% per year. That is half the compounded annual growth rate (CAGR) from five years ago.

3.2. Upstream Peak Period Average Bandwidth per Subscriber, US Tavg

The 2022 US Tavg is almost 300 Kbps as shown in Figure 6. This is up 14.5% from the 2021 COVID inflated numbers. The 3-year CAGR for US Tavg is 28%, which is higher than DS Tavg CAGR for the first time and up from five years ago.

3.3. Downstream to Upstream Peak Period Average Bandwidth Ratio

The DS:US ratio as shown in Figure 7 peaked at 14.4 to 1 ratio in 2020. As of 2022, the average DS:US ratio in this post-COVID new normal seems to have stabilized around 12:1. There was significant variation between the different MSOs with a range of 8:1 to 18:1 ratio.

Figure 6 – US Tavg, Average Subscriber Upstream Consumption

Figure 7 – Tavg, Downstream to Upstream DS:US Ratio

4. Broadband Traffic Growth Trendlines

As operators plan their network migration for the next decade or two, Tavg growth becomes a critical component in that planning. This drives our network investment strategies. Growth rates appear to be changing dramatically of late and have cast a lot of uncertainty around future consumption growth rates.

The real multi-billion-dollar question is what will be the BW consumption growth for coming decades? Has Tavg growth slowed to a lower CAGR (e.g., doubling every 3-4 years) or is it no longer exponential? Some folks claim exponential growth is dead, and that BW growth is linear or following the Adoption S-curve. S-curves have exponential growth in early years, linear growth during middle years, and flattens out in later years. E.g., will Tavg reach a limit of 2½ UHD streams per home (~25Mbps) and stay there? Or will another S-curve (e.g., VR/AR driven) start a new era of high growth?

Before looking at each possible growth trendlines, it is useful to review last decade's growth patterns.

4.1. Broadband Traffic Growth in retrospect

4.1.1. DS Tavg Growth – 2010-22

The year-over-year (YoY) changes in DS Tavg are shown as the blue candlesticks in Figure 8. Through 2018, there were many years with ~30% YoY change and then a couple years with larger 50%-70% YoY change. The giant spurts in DS Tavg often coincided with new DOCSIS technology improvements (e.g., going from 8 to 16 or 16 to 32 bonded 3.0 single carrier quadrature amplitude modulation (SC-QAM) channels).

After 2018, things started to change. The 2019 and 2020 YoY changes were only ~20%. During the COVID lockdown of 2021, DS Tavg only went up ~32%. Then 2022 DS YoY clocked in at only 12%.

Figure 8 – DS Tavg YoY & 3-yr CAGR for 2010-22

Given the volatility of the YoY data, the CAGR for a sliding 3-year window was investigated. This is shown by the orange candlesticks in Figure 8. The 3-year CAGR hovered around 40% last decade, but then started dropping noticeably after 2018 as shown by the red arrow. The fact that the 3-year window is constantly dropping implies that the DS TavG growth rate is either dropping to a much lower percent or it is no longer exponential. The next section looks at these possibilities.

In any respect, 2018 appears to be an inflection point for DS TavG growth. There is no known obvious reason as to what caused this change. It started well before COVID and appears to be continuing in our new normal post-lockdown world.

Using the powers of Excel, multiple types of trendline were matched against DS TavG data from 2010 to 2018. For each trendline, Excel's R^2 (R-squared) metric is also shown, as an estimate of trendline's "goodness of fit". R-squared quantifies a trendline's percentage of variation compared to the actual subscriber consumption, TavG, over the given length of time [Investopedia R2], [Wiki R2], [Excelltip R2]. In cases where R-squared was not an available option on the graph, excel "RSQ" function was used to produce the R-squared value shown. (An alternative way to calculate it is to use the squared value of the correlation coefficient [CORREL], which is a covariance of the trendline with data, divided into the product of standard deviation of trendline times standard deviation of data).

The value of R-squared varies between 0 and 1, and closer to 1 it gets, better the trendline explains the data. A line fit with $R\text{-squared} = 0.9959$, for example, means that 99.59% of the variation is explained by the trendline, and this is valid in the time interval considered. However, projecting these trendlines outside of the time where data exists is best done with a "caveat emptor" (buyer beware!) warning – there are no guarantees the adherence to the trendline will continue in the future. This is analogous to the stock market adage of "past performance not indicative of future results"!

Figure 9 – DS TavG Growth Trendline – 2010-2018

Analyzing the 2010-2018 DS Tavgr data creates an exponential trendline that resulted in a 43.5% CAGR DS over that 8-year window. That equates to doubling in slightly less than every other year. This is shown in Figure 9. For the 2010-2018 DS data in Figure 9, R-squared (R^2) = 0.9959 which is an excellent match of better than two 9's of accuracy. So, in 2018, the DS Tavgr growth projection would have been:

- 2018 DS Growth projection => DS Tavgr = **100 Mbps/sub by 2030**

At this consumption growth rate, many people thought that operators would need Fiber to the Premise (FTTP) for all their subscribers by then.

4.1.2. US Tavgr Growth – 2010-22

The YoY changes in US Tavgr are shown as the purple candlesticks in Figure 10. The 3-year sliding window CAGR is shown with the pink candlesticks.

Up until 2018, the US YoY would bounce from 10% or less to the 20%-25% range. The 3-year sliding window smooths out some of that YoY variation and showed an US CAGR around 17%. The US data saw some large YoY spikes >40% in 2018 and then again during the 2021 COVID lockdown. However, the other years (i.e., 2019, 2020, 2022) showed less than 20% US growth. The US 3-year sliding window has shown a definite uptick and has been in the 20% to 30% range since 2018.

Figure 10 – US Tavgr YoY & 3-yr CAGR for 2010-22

The 2010-2017 US Tavg growth trendline was 17.3% CAGR as shown in Figure 11. There is much more volatility in the US data, so US $R^2 = 0.9805$ is not nearly well matched as the DS. If the 2018 spike is introduced into this data, then R-squared became significantly worse.

At this point in time, the US Tavg growth projection was:

- 2017 US Growth projection => US Tavg = <1 Mbps/sub by 2030

The US Tavg consumption was not on anyone's radar in 2017. However, this projection also implied that the DS:US ratio would exceed 100:1. [ULM_2017] speculated whether the DS:US ratio would "stabilize" around 15:1, but it wasn't clear if that would happen due to DS growth slowing or US growth increasing. It turns out that both happened.

Figure 11 – US Tavg Growth Trendline – 2010-2017

4.2. Correcting for the COVID Bump

The Coronavirus Bandwidth Surge wreaked havoc on our long-term consumption growth planning. Growth patterns started shifting pre-COVID in 2019 and early 2020, but then things were turned upside down during lockdown with our January 2021 Tavg numbers. [ULM_2021] spelled out this impact on cable networks.

The 2022 Tavg numbers represents the first data points being seen since a return to the "new normal". Some of the Tavg impacts from the COVID lockdown were anomalies that need to be disregarded while other impacts appear to be a permanent shift. To calculate our current growth trendlines requires the anomalies to be factored out.

Ignoring the 2021 data for a second, DS Tavg increased 48% from pre-COVID Jan '20 to post-lockdown new normal in Jan '22. That maps to a 21.8% growth each year if not for the COVID bump. The blue candlestick in Figure 12 shows the estimated 2021 DS Tavg without the COVID bump. The pink candlestick on top of the 2021 data shows the size of DS anomalies estimated during the lockdown. Note that this was less than 10% additional DS traffic. For our growth trendline analysis, the blue candlesticks are used, and the COVID bump anomalies shown in pink will be ignored.

Figure 12 – DS Tavg – Estimating COVID bump in '21

Figure 13 – US Tavg – Estimating COVID bump in '21

Figure 13 shows that the US Tavg grew 80.5% from pre-COVID Jan '20 to post-lockdown new normal in Jan '22. That maps to a 34.35% growth each year if not for the COVID bump. The blue candlestick in Figure 13 shows the estimated 2021 US Tavg without the COVID bump. The pink candlestick on top of the 2021 data shows the size of US anomalies estimated during the lockdown. Note that this was almost 20% additional US traffic, much higher than the DS. For our growth trendline analysis, the blue candlesticks are used, and the COVID bump anomalies shown in pink will be ignored.

4.3. Various Downstream Growth Trendlines

4.3.1. DS Exponential Growth Trendline

Conventional wisdom for the last couple decades was that broadband traffic grows exponentially. That is the first growth trendline considered. Since 2018 appears to be an inflection point, Figure 14 shows the exponential growth trendline from 2018 to 2022. This accurately maps to a 21.1% CAGR DS, which is Tavg doubling roughly every 3.75 years. The data was extremely well matched with DS $R^2 = 0.9998$, almost four 9's accuracy.

Figure 14 – DS Tavg Exponential Trendline – 2018-2022

By comparison, Figure 15 looks at the DS Tavg exponential for the 2016-22 span. Including the 2018 spike certainly skews the data. This results in a 27.6% CAGR but DS $R^2 = 0.9789$ shows a much poorer fit than the 2018-2022 trendline in Figure 14. Visual inspection of Figure 15 also shows how the trendline is obviously pulling away from the actual 2022 datapoint. Another reason why the 2018-2022 CAGR is the exponential trendline of choice for our DS Tavg growth projections.

Figure 15 – DS Tavg Exponential Trendline – 2016-2022

4.3.2. DS Linear Growth Trendline

Recent discussions have speculated whether the DS Tavg has entered a phase of linear growth rather than exponential growth. The 2017-2022 linear trendline analysis is shown in Figure 16. Various time windows were considered starting in 2016, 2017 and 2018. The 2017-2022 had the best linear match with the DS $R^2 = 0.9912$. While this is not as close as the exponential match above, it is still better than two 9's of accuracy. This is a viable contender and should be considered as one of the possible DS Tavg growth projections.

Figure 16 – DS Tavg Linear Trendline – 2017-2022

4.3.3. Other DS Growth Trendlines

Since the door was opened to look at trendlines other than exponential, our research also looked at polynomial, power and logarithmic trendlines to see how well those might match.

The 2016-22 order of 2 polynomial trendline is shown in Figure 17. It had a very good match with DS $R^2 = 0.997$. This was better than linear but not as good as exponential trendlines. For polynomial trendlines, starting in 2016 had a better match than 2017 or 2018. This is another option to consider for our long-term growth projections.

Figure 17 – DS Tavg Order of 2 Polynomial Trendline – 2016-2022

Figure 18 – DS Tavg Power Trendline – 2017-2022

The 2017-2022 power trendline is shown in Figure 18. It had a very good match with $DS R^2 = 0.9907$. This match tracked the linear trendlines and is another option for consideration. For power trendlines, a starting window of 2017 provided the best results.

The logarithmic trendline is shown in Figure 19. This was a relatively poor match with $DS R^2 = 0.9322$. This trendline is not a candidate for our long-term growth projections.

Figure 19 – DS Tavlg Logarithmic Trendline – 2017-2022

4.3.4. DS Adoption Curve (S-curve) Growth Trendline

One recent school of thought is that broadband consumption is following an Adoption Curve, a.k.a. S-curve, that other technologies have followed. The S-curve theory has been around for multiple decades. Some overviews are given in [CHR_1992] and [ARK_BLOG].

In S-curve theory, there is a period of exponential growth rate in the early years. This then levels off to linear growth rates in the middle years which is followed by slowing to zero growth in the latter years. Figure 20 shows this form in a chart from [CHR_1992] with the basic S-curve equation below it. We inserted the red arrow to show where the DS Tavlg might currently sit on a S-curve.

The rationale for broadband traffic following an S-curve goes like this:

1. From 2010 to 2018 – video usage over the internet grew rapidly due to applications like Netflix and YouTube. Video penetration and video bit rates increased extensively resulting in exponential growth year to year.
2. From 2018 to present – video use on the internet approaches 80%, so slowing increase in video streams results in slower growth rates. The net result is linear growth.
3. From present to late 2020's – video bit rates continue a slow shift towards 4K Ultra-HD resolution; operators migrate to IP video. Growth rates continue to decline.
4. From late 2020's into 2030's – video penetration reaches saturation with no more growth. Growth rates are very slow to zero.

As an example, the DS Tavg might peak once operators deliver 2½ unique 4K streams to every home, so every customer has their own private UHD video stream. This might lead to the DS Tavg point being ~25 Mbps/sub in 10-20 years.

$$f(x) = \frac{L}{1 + e^{-k(x-x_0)}}$$

$f(x)$ = output of the function

L = the curve's maximum value

k = logistic growth rate or steepness of the curve

x_0 = the x value of the sigmoid midpoint

x = real number

Figure 20 – The Technology S-Curve and Equation

In reality, one technology wave may be followed by another wave, and then another. [CHR_1992] showed this possibility in a chart that is copied in Figure 21. As an example, maybe Netflix + YouTube adoption was part of the 1st S-curve which has reached maturity. A second S-curve is underway that is a migration to managed IP video delivery with 4K UHD streams. A third S-curve based on Augmented Reality (AR) and Virtual Reality (VR) is in the early stages and goes mainstream in another decade.

Figure 21 – Prescriptive S-Curve Strategy

For our research, models were created for a single, double and triple S-curves. A best-fit algorithm was then run to match these curves to the 2010-2022 DS Tav_g datapoints. Figure 22 shows two possible single S-curve growth trendlines mapped to the 2010-2020 DS Tav_g (i.e., before COVID). The actual DS Tav_g is the blue curve. The green single S-curve was our original S-curve model that assumed an upper asymptote of 26 Mbps/sub. In 2020, it had a reasonably good match with DS $R^2 = 0.9903$.

The purple dotted curve in Figure 22 shows another single S-curve fit. This one did not make any initial assumptions about the upper limit and used a best-fit algorithm to optimize DS R-squared values. This resulted in an even better DS $R^2 = 0.9963$. But notice in Figure 23 how much both S-curves diverge even though both have pretty good matches. One hits a limit of 26 Mbps and the other 4 Mbps. This illustrates the sensitivity in making these projections.

Figure 22 – Mapping a Single S-curve to 2010-2020 DS Tav_g

Figure 23 – Mapping a Single S-curve to 2010-2020 DS Tav_g thru 2040

As the 2021 and 2022 datapoints are added to the blue curve, it plots a path that is right in between these two 2020 single S-curve projections. The best-fit single S-curve was run again with 2010-2022 data and the results are shown as the light blue dotted curve in Figure 24. S-curve '22 DS R^2 improved further to 0.9975, while the two '20 projections got worse. With this update, the upper limit increased 33% to ~5.4 Mbps/sub. This is still significantly lower than the original green single S-curve trendline in Figure 25.

Figure 24 – Mapping a Single S-curve to 2010-2022 DS TavG

Figure 25 – Mapping a Single S-curve to 2010-2022 DS TavG thru 2040

The next step makes a best-fit growth trendline combining two S-curves as shown in Figure 26. The midpoint of each S-curve is the year 2018 and 2028 respectively while the other parameters are optimized. There is an excellent fit with DS $R^2 = 0.9982$. The individual S-curves are dotted lines with the sum of the two represented by the dashed dark blue curve. The double S-curve reaches an upper limit of ~28 Mbps, very close to the original green single S-curve which is also in Figure 26 and Figure 27.

Figure 26 – Mapping two S-curves to 2010-2022 DS Tavg

Figure 27 – Mapping two S-curves to 2010-2022 DS Tavg thru 2040

Figure 28 and Figure 29 shows the best-fit results for a trendline using three S-curves. The mid-point is set for years '18, '28 and '38 respectively and the other parameters are optimized. There is a good fit again with DS $R^2 = 0.9982$. The individual S-curves are dotted lines with the sum being the dashed dark blue curve. Figure 28 zooms in on the triple S-curve scenario to give a better look at how it matches the 2010-22 data. It also clearly shows the contribution of each of the three individual S-curves over time.

Figure 28 – Mapping three S-curves to 2010-2022 DS Tavg

Figure 29 – Mapping three S-curves to 2010-2022 DS Tavg (Zoomed In)

The original green single S-curve is also included. The triple S-curve remains close to it through 2030 as seen in Figure 28, but then the two diverge significantly during that next decade as shown in Figure 29. This divergence is caused by the third S-curve ramping up. This might represent the adoption of VR/AR technology that takes off in the 2030's. The triple S-curve eventually reaches an upper limit of ~70 Mbps in 20+ years.

4.4. Mapping DS Tavg Growth Projections over a 10-15 Year Span

Now it is time to pull all these growth projections together to see how they compare. At this stage, there is not enough evidence to warrant one option over another. A handful of the trendlines at the extremes with a poor fit have been disregarded (i.e., 2016 exponential, power, log trendlines). All the DS Tavg growth trendlines for years 2017-2032 are plotted in Figure 30. The red circles show the growth trendlines of interest and represent the amount of uncertainty between the different projections.

In five years, 2027, DS Tavg is expected to be in 5-12 Mbps/sub range. A decade from now, 2032, that increases to a 7-25 Mbps/sub range. By considering these multiple potential growth trendlines, there is now a “cone of uncertainty” that grows over time. Notice that the window of uncertainty has almost doubled from five to ten-year window.

Figure 31 now extends the growth trendlines out 15 years to 2037. It resembles a spaghetti plot for a hurricane path! By 2037, the DS Tavg is 8-65 Mbps and the cone of uncertainty has doubled once again.

In an earlier section, it was noted that in 2018 with 43.5% CAGR, the expected DS Tavg would reach 100 Mbps by 2030. Looking at our current growth projections, the high growth projection (21% CAGR) hits 100 Mbps in 2040; while the low growth linear projection takes 200+ years to reach that!!!

From a network capacity planning perspective, our conclusions on considering multiple growth trendline options are:

- the 5-year window gives us reasonably high confidence for near-term planning
- the 10-year window gives us a range of high, moderate, and slow growth scenarios for longer term planning
- the 15-year window shows too much variance to be used for network capacity planning and is more of an academic exercise.

The authors view these growth trendline projections as an on-going process that gets updated and adjusted every year.

Figure 30 – DS TavG Growth Projections for 2022 to 2032

Figure 31 – DS TavG Growth Projections for 2022 to 2037

4.5. Various Upstream Growth Trendlines

Upstream consumption growth over the last 4-6 years has been very different from DS growth. US growth rates have increased while DS growth has declined considerably. Upstream consumption has also been more volatile than DS, with very large spikes in 2018 and again with the 2021 COVID lockdown.

4.5.1. US Exponential Growth Trendline

The 2016-22 US exponential trendline is shown in Figure 32 while the 2018-22 period is in Figure 33.

Figure 32 – US Tavg Exponential Trendline – 2016-2022

Figure 33 – US Tavg Exponential Trendline – 2018-2022

The 2016-22 exponential growth trendline has a 23.7% CAGR with US $R^2 = 0.9726$. The 2018-22 exponential growth trendline has a 22.1% CAGR with US $R^2 = 0.9244$. The 2016-22 trendline is a much better fit and the one that will be used as our high growth exponential scenario. Including the extra two years made for a better fit this time.

4.5.2. US Linear Growth Trendline

Figure 34 shows the US linear growth trendline. The US $R^2 = 0.9195$ which is a relatively poor fit. Linear growth assumes a slowing growth rate, but the upstream has seen an increased growth rate. As such, this trendline is not a candidate for consideration at this time.

Figure 34 – US Tavg Linear Trendline – 2017-2022

4.5.3. Other US Growth Trendlines

The order of 2 polynomial growth trendline does provide a good fit. The 2016-22 trendline is shown in Figure 35 with the 2018-22 trendline in Figure 36. The 2018-22 trendline has the better fit with US $R^2 = 0.9948$ compared to US $R^2 = 0.9737$. It is even a better fit than the 2016-22 exponential trendline.

The 2016-2022 US power trendline is shown in Figure 37. It had a very poor match with US $R^2 = 0.8984$. The logarithmic trendline was even worse and is not even shown. These trendlines are not candidates for our long-term growth projections.

Figure 35 – US Tavg Order of 2 Polynomial Trendline – 2016-2022

Figure 36 – US Tavg Order of 2 Polynomial Trendline – 2018-2022

Figure 37 – US Tavg Power Trendline – 2017-2022

4.5.4. US Adoption Cure (S-curve) Growth Trendline

As noted above, the upstream growth behavior is very different than downstream one. The 10G initiative will be opening up a world of new applications. Many of these could start driving upstream bandwidth consumption further. This may come from a plethora of IOT devices in the home, or maybe more affordable HD resolution video cameras pushing content to the cloud.

Figure 38 and Figure 39 show the mapping of a single S-curve to the 2010-22 US Tavg data. The first figure is a view up until 2028, while the next figure zooms out to 2040. The US Tavg data is shown both with and without the COVID bump. The trendline without the COVID bump provides the best results with $US R^2 = 0.9815$, a relatively good fit for the upstream.

The upper bound on the US S-curve is 3.71 Mbps/sub. Note that the single S-curve midpoint is the year 2033. From an S-curve perspective, the US consumption is still in its early years of exponential growth.

Our modeling then calculated a best fit for two S-curves shown in Figure 40. The second curve ended up with a midpoint that was 20 years into the future and has minimal impact on the present day (i.e. <0.1 Kbps). The result is that the single and double S-curve scenarios are nearly identical for the next 12 years. It is almost 15 years before a separation between the two becomes obvious. Again, this shows that mapping out to 15+ years is more of an academic exercise.

Figure 38 – Mapping a Single S-curve to 2010-2022 US Tavg

Figure 39 – Mapping a Single S-curve to 2010-2022 US Tavg (Zoomed Out to 2040)

Figure 40 – Mapping a Double S-curve to 2010-2022 US Tavg (Zoomed Out to 2040)

4.6. Mapping US Tavg Growth Projections over a 10-15 Year Span

The upstream traffic growth projections have fewer options since the slower growth trendlines like linear are not currently under consideration. This obviously could change in the future as more Tavg data is collected and there is a better understanding of the “new normal” in this post-COVID lockdown world.

Figure 41 shows the US Tavg growth projections for the next decade. The trendlines at the lower extremes with a poor fit have been disregarded (i.e., linear, power, log trendlines). The red circles show the growth trendlines of interest and represent the amount of uncertainty between the different projections.

In five years, 2027, US Tavg is expected to be in 0.7-1.1 Mbps/sub range. A decade from now, 2032, that increases to a 1.2-2.5 Mbps/sub range. Notice that the upstream “cone of uncertainty” is smaller than the downstream, but it still has almost doubled as it goes from the five to ten-year window.

Figure 42 now extends the growth trendlines out 15 years to 2037. By 2037, the US Tavg is now 2-7 Mbps/sub, and the cone of uncertainty has roughly doubled once again.

Figure 41 – US Tavg Growth Projections for 2022 to 2032

Figure 42 – US Tav Growth Projections for 2022 to 2037

4.7. DS:US Tav Ratio projections

Now let's put the DS and US Tav growth projections side-by-side. This is shown in Table 1. From here, an estimate for the DS:US ratio can be made over time. The authors believe that there is some interdependence between the DS and US Tav consumption growth, so it is highly unlikely that the DS and US will hit opposite ends of their low and high projections. The low and high ratio range in the table is slightly tempered from these extremes.

With the upstream showing a slightly higher growth trajectory, the mid-range of the DS:US ratio is expected to ease from the current 12:1 down to something closer to 10:1. Over the longer term, there is no evidence that the mid-range of the DS:US ratio will vary much from 10:1.

Table 1 – Tavg Growth Projections: DS, US & DS:US

Tavg Growth Projections	DS Tavg Range		US Tavg Range		DS:US Ratio Range		
Year	Low	High	Low	High	Low	Mid	High
2022	3.5		0.3		12:1		
2027	5	12	0.7	1.1	6:1	10:1	15:1
2032	7	25	1.2	2.5	5:1	10:1	18:1
2037	8	65	2	7	4:1	10:1	20:1

5. Network Capacity Modeling for Low to High Growth Projections

So, how do these BW growth projections drive our network investment strategies? Our next step plugs various Tavg growth trendlines into the CommScope network capacity modeling tool to analyze 1218/204 MHz and DOCSIS 4.0 plant. It shows their useful plant lifetime using various growth projections and explores whether low growth might eliminate the need for 4.0; or just delay it, giving precious time for the operator to transition.

Over recent years, there has been a slowing in the downstream usage growth rate (i.e., DS Tavg) compared to the service tier growth rate (i.e., DS Tmax_max). This has a number of consequences including the network becomes more “bursty”. It also means that the overall utilization of the network is lower. In this respect, it is important to try and maximize subscribers per service group (SG) to take advantage of statistical multiplexing and to get better economics. This analysis focuses on the number of subscribers that a service group can support over time for a given configuration.

5.1. Network Capacity Modeling Assumptions

The CommScope network capacity model contains 100’s of different inputs that can vary from year to year. The paper uses a relatively good to best case scenario that was taken from modeling work done for several operators based on their current network migration plans.

Many HFC plants today are still 870 MHz, 750 MHz or even lower. The model assumes that the HFC plant is upgraded to at least 1218/204 MHz plant by 2024 (and as needed to extended spectrum DOCSIS (ESD) by 2025). The modeling starts with 400 subs per SG as the maximum, then reduces max subs per SG as needed over time. Note that this is an extremely large SG that could represent a node in the 600 to 1,000 homes passed region.

From DOCSIS perspective, it assumes that up to 400 typical data subs per cable modem termination system (CMTS) Service Group (SG) as the starting point. And from a DOCSIS combining perspective – 1 node per CMTS SG for both DS & US to start (e.g., 1x1 Remote MAC-PHY device, RMD). If the upstream ever becomes the limiting factor, then the upstream will be split (e.g., 1x2 RMD). If an operator starts with a 1x1 RMD, then a migration to 2x2 RMD enables SG splits down the road.

Legacy video begins with 60 total quadrature amplitude modulation (QAM) electronic industries association (EIA) channels today. But a rapid migration to 100% IPTV in 2024 reduces that to zero QAM EIA channels. These scenarios assume there are no video on demand (VOD) QAM channels, no Analog video spectrum, and no switched digital video (SDV) QAM channels.

For DOCSIS Services, the beginning includes 32 DOCSIS 3.0 SC-QAM channels. DOCSIS 3.1 (D3.1) modems are used for all the top tiers. Older DOCSIS 2.0/3.0 modems are phased out over time until there is 100% D3.1/4.0 modems by 2025.

The model uses the broadband consumption numbers from this paper. DS Tav_g = 3.5 Mbps in 2022. Modeling runs were then done from 2022 to 2032 for high growth (i.e., 21% CAGR), moderate growth (i.e., 16% CAGR) and low growth (i.e., linear) scenarios. US Tav_g = 300 Kbps in 2022; with 23% CAGR growth from 2022 to 2032. Our findings show that the plant tends to be downstream BW limit so there was no need to consider low to moderate growth upstream scenarios. These result in:

- DS Tav_g High Growth: 21% DS CAGR = 24 Mbps by '32;
- 23% US CAGR = ~2.4 Mbps by '32
- Note that this is still a 10:1 DS:US ratio

The CommScope network capacity model has a lot of flexibility and allows us to adjust Tav_g per service tier (e.g., Top Billboard tier is 2X Flagship tier). The DS Tav_g and US Tav_g listed are the weighted average across all subscribers in the SG.

For the DOCSIS Physical (PHY) layer, the model assumes:

- D3.1 orthogonal frequency-division multiple access (OFDMA) US = 7.58 bps/Hz (1024 QAM, 4K fast fourier transform (FFT), 1.875us cyclic prefix (CP))
- D3.1 orthogonal frequency-division multiplex (OFDM) DS = 9.7 bps/Hz (4096-QAM, 8K FFT, 1.25us CP) up to 1218MHz
- 1794 MHz plant drops to 8.58 bps/Hz on average (2048-QAM, 4K FFT, 1.25us CP)
- 'Normal' amp spacing = ~9.0 bps/Hz; 'Stretch' amp spacing = ~8 bps/Hz

The service tier mix is shown in Table 2. The Top Billboard tier jumps to 5 Gbps DS with a 1 Gbps US in 2024 for the 1218/204 MHz plant. Note that a 5G DS Tier requires four bonded OFDM channels on a D3.1 plant. This can easily be handled with DOCSIS 4.0 modems operating in D3.1 environment. The 1794/396 MHz plant has a Top Billboard tier of 7.5G DS X 2.5G US. Any tiers 500/50 or higher are assumed to be immediately moved to D3.1 modems only.

Table 2 – Network Capacity Model – Service Tier mix and 3.0/3.1 mix

Service Tier	Mix %	2022	2024	2026	2028
Top Billboard	2%	2G/400	5G/1G or 7.5G/2.5G		
Performance	13%	1G/100	2G/200	5G/1G	5G/1G
Flagship	50%	200/20	500/50	1G/100	2G/200
Economy	35%	100/10	200/20	200/20	500/50
% D3.1 modems		50%	75%	100%	100%

Regarding video services, the managed IPTV bundle grows to 100% penetration by 2024 replacing all Legacy Video subs. It assumes 50% of high-speed data (HSD) subs take IPTV bundle (e.g. 150 IPTV subs out of 300 HSD subs). The IPTV service is 100% Unicast delivery with the following mix of video bit rates:

- HD streams: 5 Mbps per today; dropping to 3 Mbps by 2030
- 4K UHD streams: 5% @ 20 Mbps in '23 growing to 50% @ 8 Mbps in 2032

5.2. Making the Most of 1218/204 MHz HFC Plant

With so much interest in slowing DS Tavgr growth rates, the first case study considered standard D3.1 1218/204 MHz plant offering a 5G DS tier with a 1G US tier. What is the maximum sized SG that can be supported over the next decade?

The model was run for high (21% CAGR), moderate (16% CAGR) and low (linear) DS Tavgr growth rates. That leaves DS Tavgr a decade from now at 24, 15 and 8 Mbps/sub respectively. The US Tavgr with a 23% CAGR reaches 2.4 Mbps/sub while the lower growth projections are just above 1.5 Mbps in 2032.

Figure 43 shows the max number of subs per SG for low, moderate, and high DS Tavgr growth projections. All projections can support 400+ subs through 2025. In 2026, the high growth scenario needs to gradually reduce the max subs/SG each subsequent year. It is still supporting 300 subs/SG until 2028, 200 subs/SG through the end of the decade and 150 subs/SG in ten years. The moderate growth rate follows a similar curve only delayed about two years. The slow linear growth is still supporting 400 subs/SG at the end of the decade and 350 subs/SG in 2032, a decade from now.

Figure 43 – Max Subs per SG for Low, Moderate & High DS TavG growth, 1218/204 MHz

For comparison purposes, Figure 43 also shows the 2018 projections using the 43% CAGR uber growth. It had projected that max subs per SG would drop to 28 subs by 2030. This drove many people to think that FTTP would be required by then. The reality is that a 1218/204 MHz plant supporting 5G x 1G tiers can easily last into the next decade, maybe even further if the slower growth projections hold.

Figure 44 maps two max subs/SG scenarios onto the DS TavG trendline charts from Figure 28. When DS TavG = ~11 Mbps, the max subs/SG supported is ~300 subs. This is the lower horizontal red dashed line. When DS TavG = ~23 Mbps, the max subs/SG supported is ~150 subs. This is the upper horizontal red dashed line. For a given trendline, it can support that SG size until it crosses that dashed line. Looking at the 150 max subs/SG as an example, the highest growth projections show it lasting until the end of this decade while multiple slower projections don't even reach the mark in 15 years. The slow linear growth takes multiple decades. If an operator is at 150 subs/SG today, they will stay there for a very long time (provided the 5Gx1G tier is sufficient!). This might be true for markets where there is limited demand or need for multi-gig upload speeds.

Figure 44 – 1218/204 MHz Max subs / SG vs. various DS Tavg projection trendlines

Figure 45 – 1218/204 MHz System – Spectrum Utilization

Figure 45 shows the spectrum utilization for the 1218/204 MHz plant scenario. The 204 MHz high split is introduced in 2024. The US spectrum is on the bottom of the chart. In that same year, the operator has finished the IPTV migration and the legacy video spectrum (in red) is reduced to zero. The overall

spectrum requirements are reduced with these savings, even though the IPTV spectrum (in purple) had increased slightly. Note – there are many inputs that impact IPTV BW consumption, so savings may vary from operator to operator depending on their particular situation.

In 2025, the 5G DS tier is introduced which fills up most of the available 1218 MHz of spectrum. Note that the SG size is still at 400 subs. After 2025, the SG size is reduced as needed to keep within the allotted 1218 MHz. Note that the IPTV spectrum is shrinking over time. This is due to both fewer subs and the video bit rate reductions, despite higher UHD %.

Figure 46 shows the models outputs for DOCSIS usage in Mbps broken out into three components:

- QoE Delta (i.e. $K \cdot T_{max}$), $N_{sub} \cdot T_{avg}$ and IP Video

It shows these three components for both D3.1 modems and 3.0 modems (which are removed by 2025). The redline on the top is the total available system capacity. Note that the 1218/204 MHz plant is providing a total of >9 Gbps usable capacity. That is higher than a 10G PON at 8.6 Gbps.

Figure 46 gives a good visual of the proportion of capacity needed for each component. The sum of the three components needs to be below the total available capacity. Note that this scenario is reasonably balanced between the consumption and burst components. Cutting the SG size in half would only provide an extra 1.5 Gbps of capacity, not enough to drastically change the 5G DS tier.

Figure 46 – 1218/204 MHz System – DOCSIS DS Usage: Tmax, Tavg, IP Video

Figure 47 – 1218/204 MHz System – DOCSIS US Usage: Tmax, Tavg, IP Video

The US DOCSIS capacity usage is broken out in Figure 47. Supporting a 400 Mbps US tier in 85 MHz during 2022-23 is a bit tight, but there is plenty of capacity after the 204 MHz high split upgrade. As can be seen, the Tmax component dominates over time. Figure 47 assumes the SG size is being set based on a moderate DS Tavg growth projection of 16% CAGR while the US Tavg is on a high growth 23% CAGR. See that the US has sufficient capacity until 2032. At this point, the operator might consider switching from 1x1 to 1x2 RMD configuration. Also, the DS:US ratio has dropped all the way to 6:1.

Perhaps the key point of this 1218/204 MHz case study is that a node with 150+ subs can be upgraded to 1218/204 MHz and support a service tier of 5 Gbps x 1 Gbps for the next decade and beyond. There is no pressing near term need to push the HFC to very small (and inefficient!) SG sizes, that could be, for example, achieved in N+0 systems.

5.3. Matching 10G PON on a 1794 / 396 MHz ESD Plant

The next case study focused on a DOCSIS ESD 1794/396 MHz plant offering a 7.5G DS tier with a 2.5G US tier. The primary goal here is to match the 10G PON DS service tier level. As before, the model was run for high (21% CAGR), moderate (16% CAGR) and low (linear) DS Tavg growth rates. The DS Tavg and US Tavg both hit the same numbers in 2032 as the previous case study.

Figure 48 shows the max number of subs per SG for low, moderate, and high DS Tavg growth projections. All projections can support 400+ subs through 2024. In 2025, slightly earlier than the previous case study, the high growth scenario gradually reduces the max subs/SG each subsequent year. It

is still supporting 250 subs/SG until 2028 and ~130 subs/SG in ten years. The moderate growth rate follows a similar curve only delayed about two years. The slow linear growth supports 400 subs/SG through 2026 and 300 subs/SG in 2032, a decade from now. For comparison purposes, Figure 48 also shows the 2018 projections using the 43% CAGR uber growth.

Figure 48 – Max Subs per SG for Low, Moderate & High DS TavG growth, 1794/396 MHz

Figure 49 maps two max subs/SG scenarios unto the DS TavG trendline charts from Figure 28. When DS TavG = ~8 Mbps, the max subs/SG supported is ~300 subs. This is the lower horizontal red dashed line. When DS TavG = ~19 Mbps, the max subs/SG supported is ~150 subs. This is the upper horizontal red dashed line. For a given trendline, it can support that SG size until it crosses that dashed line. Looking at the 150 max subs/SG as an example, the highest growth projections show it lasting until 2027 while the slow linear growth will take multiple decades. For a 150 subs/SG today that is upgrade to 1794/396 MHz ESD plant, it can stay there until 2029 with high growth but for a very long time with slow linear growth. Thus, node splits on the ESD plant become very sensitive to which DS TavG growth trendline it tracks. A proactive operator might want to deploy a 2x2 RMD in that location even though 1x1 may be adequate for many years.

Figure 49 – 1794/396 MHz Max subs / SG vs. various DS Tavg projection trendlines

Figure 50 – 1794/396 MHz System – Spectrum Utilization

Figure 50 shows the spectrum utilization for the 1794/396 MHz plant scenario. The 204 MHz high split is introduced in 2024 at the same time the DS expands to 1794 MHz. Then the US split is reconfigured for 396 MHz in 2026. The legacy video and IPTV spectrum follow the same trajectory as before. The first big spectrum jump in 2024 is the 5G DS introduction. The 2nd jump in 2026 is the 7.5G DS tier introduction.

Note that the SG size is at 400+ subs until 2024, then the SG size is reduced as needed to keep within the allotted 1794 MHz. As before, the IPTV spectrum is shrinking over time due to both fewer subs and the video bit rate reductions, despite higher UHD %.

Figure 51 shows the 1794/396 MHz model outputs for DOCSIS usage in Mbps broken out into three components:

- QoE Delta (i.e. $K \cdot T_{max}$), $N_{sub} \cdot T_{avg}$ and IP Video

The redline on the top is the total available system capacity. Note that it is initially 1794/204 MHz plant with >13 Gbps usable capacity, but then settles back to ~11 Gbps for the 1794/396 MHz plant configuration. This is significantly higher than a 10G PON at 8.6 Gbps.

Figure 51 gives a good visual of the proportion of capacity needed for each component. The sum of the three components needs to be below the total available capacity. Note the T_{max} burst component is starting to dominate the usage. Cutting the SG size in half provides minimal benefit, ~ 1 Gbps of additional capacity. If an operator would prefer additional plant life, they might consider backing down the DS T_{max} to 5 or 6 Gbps.

Figure 51 – 1794/396 MHz System – DOCSIS DS Usage: Tmax, Tavg, IP Video

Figure 52 – 1794/396 MHz System – DOCSIS US Usage: Tmax, Tavg, IP Video

The US DOCSIS capacity usage is broken out in Figure 52. As can be seen, the Tmax component dominates over time. Figure 52 assumes the SG size is being set based on a moderate DS Tavg growth projection of 16% CAGR while the US Tavg is on a high growth 23% CAGR. See that the US has sufficient capacity through 2032. It remains a fairly balanced 1x1 RMD configuration despite the DS:US ratio dropping to 6:1.

Perhaps the key point of this 1794/396 MHz case study is that a node with 150+ subs can be upgraded to 1794/396 MHz, but the timing of additional node splits on the ESD plant becomes very sensitive to which DS Tavg growth trendline it tracks. A proactive operator might want to deploy a 2x2 RMD in that location even though 1x1 may be adequate for many years. As with the previous case study, there still seems to be no pressing near term need to push the HFC to very small (but inefficient!) SG sizes such as those found in N+0 systems.

5.4. Other 1794 MHz ESD and FDX Options

The D4.0 specification [DOCSIS_4.0_PHY] provides operators with lots of different choices and options. From the highest level, D4.0 offers both Extended Spectrum DOCSIS (ESD) and Full Duplex DOCSIS (FDX). ESD DS spectrum goes up to 1794 MHz, a.k.a. 1.8 GHz. The specification offers five different upstream split options going from 204 MHz up to 684 MHz. The DS spectrum starts after a guard band above the US. The size of the guard band increases proportionately with the US split.

FDX shares US + DS spectrum in the FDX Band. This is variable width. The FDX Band starts at 108 MHz and can go as high as 684 MHz. While the top of the DS spectrum is nominally 1218 MHz, many operators considering FDX do not want to replace their taps, so they may be limited to 1002 MHz of DS spectrum, at least initially.

Table 1 shows the maximum DS + US service tiers supported by the various ESD and FDX options. The table also provides the max number of subs per SG for two different DS Tav_g – 7 and 15 Mbps/sub. The 7 Mbps DS Tav_g might occur 3-8 years from now depending on high, medium or low growth rates; while the 15 Mbps DS Tav_g happens in a much longer window that is 8-20+ years from now.

The max tier calculation uses mostly best-case assumptions including:

- 100% IPTV, no Legacy Video spectrum
- 100% DOCSIS 3.1/4.0 modems
- DS Tav_g = 7 or 15 Mbps/sub
- 4096-QAM for dedicated DS below 1218 MHz and 1024-QAM US for dedicated US
- A range from 1024-QAM to 4096-QAM for ESD DS > 1218 MHz and FDX DS in FDX Band
 - Previous network capacity modeling used an average of 2048-QAM

Most of the max tiers are shown in Gbps except for ‘2G’ = 2 x 940 Mbps and ‘5G’ = 5 x 940 Mbps.

As a reference point, the final row of the table provides the max tier and SG sizes for a 10G PON network. This includes the symmetric versions: 10G EPON, 10G XGS-PON and NG-PON2. It does not include XG-PON which only has 2.5G US optics and is limited to a 2G US tier. Note the 10G PON SG size limits as DS Tav_g increases.

Table 3 – DOCSIS 4.0 Maximum Service Tiers and Max Subs per SG

DOCSIS 4.0 Max Service Tiers		Max DS Tier	Max US Tier	Max Subs per DOCSIS/PON SG			
				DS Tav _g = 7Mbps		DS Tav _g = 15Mbps	
				1K-QAM	4K-QAM	1K-QAM	4K-QAM
ESD 1.8GHz	204 / 258	12G	1.25G	194	371	90	173
	300 / 372	11G	‘2G’	182	360	85	168
	396 / 492	10G	2.5G	162	340	76	159
	492 / 606	9G	3G	151	328	70	153
	684 / 834	7.5G	‘5G’	54	232	25	108
FDX	1002 / 108-684	6G	‘5G’	220	353	114	176
	1218 / 108-684	7.5G	‘5G’	305	400+	154	216
10G PON		7.5G	7.5G	128		64	

With the ESD options, an operator can choose how symmetric or asymmetric to make their system. For this analysis, the service tiers were maximized at the expense of SG size. This is yet another trade-off the operator can make. Note – by reducing max DS tiers, the ESD SG size can be significantly increased as our case study showed.

With the asymmetric 204 MHz split, the operator could offer a 12 Gbps DS tier, far eclipsing the 7.5G DS tier with 10G PON. This system is roughly 10:1 DS:US ratio as a 1.25 Gbps US tier pairs with it. Even with DS Tavg = 15 Mbps, the SG size is still a reasonable 173 subs at 4096-QAM.

The most symmetric ESD option is the 684 MHz split. This can achieve 7.5G DS with ‘5G’ US, but SG sizes start to get squeezed.

The middle of the road 1794/396 MHz ESD case study previously considered can be optimized a bit further. Going with smaller SG, improving HFC plant for even better QAM modulations and eliminating the managed IPTV service can buy enough capacity to push the DS tier to a true 10 Gbps. This is paired with a 2.5 Gbps US tier. If an operator can’t make these improvements, they could drop to a 300 MHz split to still get the true 10 Gbps, but now the US tier is reduced to ‘2G’ (i.e., 2 x 940 Mbps). In the FDX camp, a 1002 MHz system can support up to 6G DS with a ‘5G’ US with reasonably large SG sizes. If the operator pushes this plant up to a true 1218 MHz system, then the DS tier goes up to match 10G PON at 7.5 Gbps DS tier.

6. Conclusion

The CommScope (formerly ARRIS) team has led industry traffic engineering research for over a decade. [CLO_2014] introduced broadband QoE using a simple formula with basic network capacity components. This evolved and [ULM_2019] gave an updated insight into calculating the SG capacity requirements:

Modified “COMMScope/CLOONAN’S CAPACITY EQUATION” Traffic Eng Formula:

$$C \geq (N_{sub} * T_{avg}) + (K-1) * T_{max_max} + T_{max_max} \quad (2)$$

The subtle change is that there are now three main components to the traffic engineering formula:

1. Peak Busy Period Average Consumption (i.e., $N_{sub} * T_{avg}$)
2. Peak Busy Period Ripple for managing QoE (i.e. $(K-1) * T_{max_max}$)
3. Headroom for maximum Service Tier Burst (i.e., $1 * T_{max_max}$)

While burst and ripple components manage a subscriber’s QoE, the consumption component is key to SG sizing. The T_{avg} growth rate has seen much research and is the focus of this paper. ARRIS/CommScope has the most extensive broadband capacity monitoring history in the industry, collecting continuously since 2010 from the same MSOs. The 2022 data is in and DS T_{avg} growth continues to slow.

The paper looks at the consumption growth so operators can drive their network investment strategies for coming decades. Has T_{avg} growth slowed to a lower CAGR or is it no longer exponential? Several possible growth trendlines were investigated including exponential, linear, Adoption S-curve and others. Our research measures how accurately each trendline matches last decade’s data. These BW growth trajectories are mapped out for 5/10/15 years. The resultant spaghetti plots in Figure 53 show a cone of uncertainty that grows over time, roughly doubling every 5 yrs. To understand the impact of these slowing growth rates, consider the following comparison to projections from just four years ago:

- 2018 DS Growth (43% CAGR) projection => DS T_{avg} = 100 Mbps/sub by 2030
- 2022 DS High Growth (21% CAGR) projection => DS T_{avg} = 100 Mbps/sub by 2040
- 2022 DS Low Growth (Linear) projection => DS T_{avg} = 100 Mbps/sub in 200+ years

The implication is that *the need for FTTP to all subscribers may be pushed back multiple decades*. From a network capacity planning perspective, our conclusions on multiple growth trendline options are:

- the 5-year window provides a reasonably high confidence for near-term planning
- 10-yr window provides high, moderate, and slow growth ranges for longer term planning
- the 15-yr window shows too much variance and is more of an academic exercise.

The CommScope network capacity model studies raise several key points. The 1218 MHz case study shows a 500HP node with 2x2 RMD and 150+ subs/SG upgraded to 1218/204 MHz supports 5G x 1G service tier for the next decade and beyond. This may work for markets where there is limited demand or need for multi-gig upload speeds. The 1794/396 MHz case study in Figure 54 shows that a node with 150+ subs can offer 7.5G x 2.5G tiers; but the timing of additional node splits on the ESD plant is sensitive to which DS T_{avg} growth trendline it tracks. In either case, there is no pressing need to push the HFC to very small (but inefficient!) N+0 SG sizes.

Operators need to consider the low/medium/high growth scenarios when formulating their network migration strategy. A companion paper to this, [ZORAN_2022], looks at the economic impacts of these

different growth scenarios for different cable and FTTP architectures. The goal is to minimize up front investments while maintaining flexibility to increase network capacity and manage uncertainty risks.

Introduction

1.1. Comcast History and Community Initiatives

For nearly 60 years Comcast has held to a consistent truth: The customers and the communities that we support are at the focal point of our decision making. In recent years, Comcast has created a multitude of programs to best support the diverse communities we serve. In 2011 Comcast introduced Internet Essentials. This program has delivered high-speed Internet to over 10 million Americans, bringing the technology required in today's world to be successful in education and work, and which now has also become social gathering space and center of entertainment. In 2020 the Lift Zone program was created. Additional sites are created every year, with over 1000 sites now available. This past year Comcast started to participate in the Affordable Connectivity Program, a government run program which has been able to help over 11.5 million households obtain reliable, quality Internet services through its partnerships with Internet providers¹. These programs show that Comcast's commitment is more than simply providing broadband connectivity. The company prioritizes being a strong community partner as well. We have commitment to bridge the digital divide by partnering for these programs and creating additional grants which have supplied more than \$16 million in grants and \$75 million in-kind support to thousands of small businesses².

Comcast's commitment also spans into being a responsible steward of the environment, with various initiatives to hold ourselves accountable to specific environment-friendly target goals. A first of its kind recycling program for coaxial cables was established this year. With this program, approximately 70% of our coaxial cable waste will be recycled every year. We stand by our commitment to be carbon neutral by 2035 and have initiatives in place to drive to that outcome.

In this paper, we discuss how the landscape of rural broadband (RBB) is evolving quickly, and strategic network investments being made to serve these areas and help to close the digital divide in the years ahead. Today, over tens of millions of Americans do not have reliable high-speed Internet³, and many are in these rural areas. With a foundation of virtualization and distributed access architecture (DAA) serving our coaxial footprint, Comcast is building on this to bring to life the DAA vision of a converged access infrastructure, and its introduction is timely and effective for RBB initiatives.

1.2. Technology Path Alignment

In 2020, the world was faced with a challenging situation. Having pioneered the deployment of a DAA beginning in 2017 combined with business-as-usual node segmentation that pushes fiber deeper into our network, Comcast was in an enviable position to handle the instantaneous pandemic-related capacity demands that 2020 presented^{4,5}. The pandemic shifted daily norms of work, education, and social interaction.

Comcast's DAA is based on the remote PHY specification⁶, as shown in Figure 1. The introduction of DAA five years ago began the preparation for new processes, practices, tools and technology, starting with our most familiar and powerful workhorse – DOCSIS[®]. DAA was a fast follower to our prioritization of DOCSIS 3.1, which was deployed as soon as it was available. The launch of DOCSIS 3.1 represented yet another instance of recognizing the importance of building new capacity well ahead of demand. In 2020, this turned out to be very prescient, enabling Comcast and other operators to mostly absorb the COVID-induced traffic spike with loss of capacity margin as the primary impact – not customer issues as seen in **Figure 0**⁴. These investments not only allowed Comcast to meet the extreme capacity demands of the pandemic, but it validated the years of decisions based upon untapped potential

of the HFC network and continuing to leverage that network and the coaxial connections to millions of homes.

Figure 0 - Highly Utilized CMTS SG Trending⁴

As we continue to deliver on continuous capacity growth and demand for increased speeds, RBB highlights a renewed focus on the digital divide in rural America. We have evaluated the approaches to delivering on RBB requirements, which typically come in the form of request for proposals (RFPs). We have considered the underlay of the environment, needs and expectations of customers, and the growth projected for these areas in years ahead.

There is new technology being developed that is well-suited to deliver on RBB requirements in these RFPs. In this discussion, we highlight how Comcast's DAA and vCMTS foundation will enable us to drive the latest technology and capability into RBB by introducing a new remote OLT (R-OLT) that is particularly effective for RBB, as shown in Figure 2. The R-OLT and accompanying virtualized platform SW will enable efficient and effective delivery of fiber-to-the-home (FTTH) broadband services to the RBB customer base. Historically, to deploy passive optical network (PON) technology, companies used centralized optical line terminals (OLT). These are classic "big iron" chassis consuming significant power, space, and cooling capacity in headend facilities. Furthermore, with their proprietary hardware and software implementations and the large scale of users subscribed to a single chassis, they are relatively costly to deploy, operate, and upgrade.

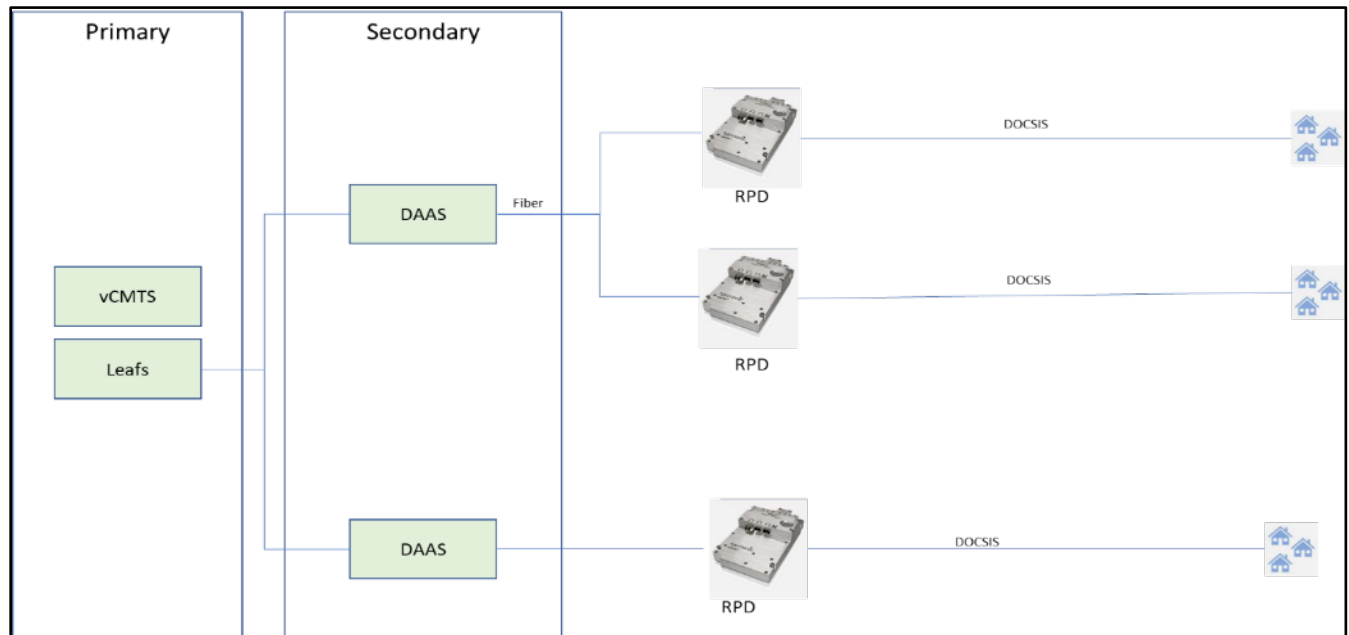

Figure 1 – Diagram of DAA Basic Infrastructure from Headend to Home

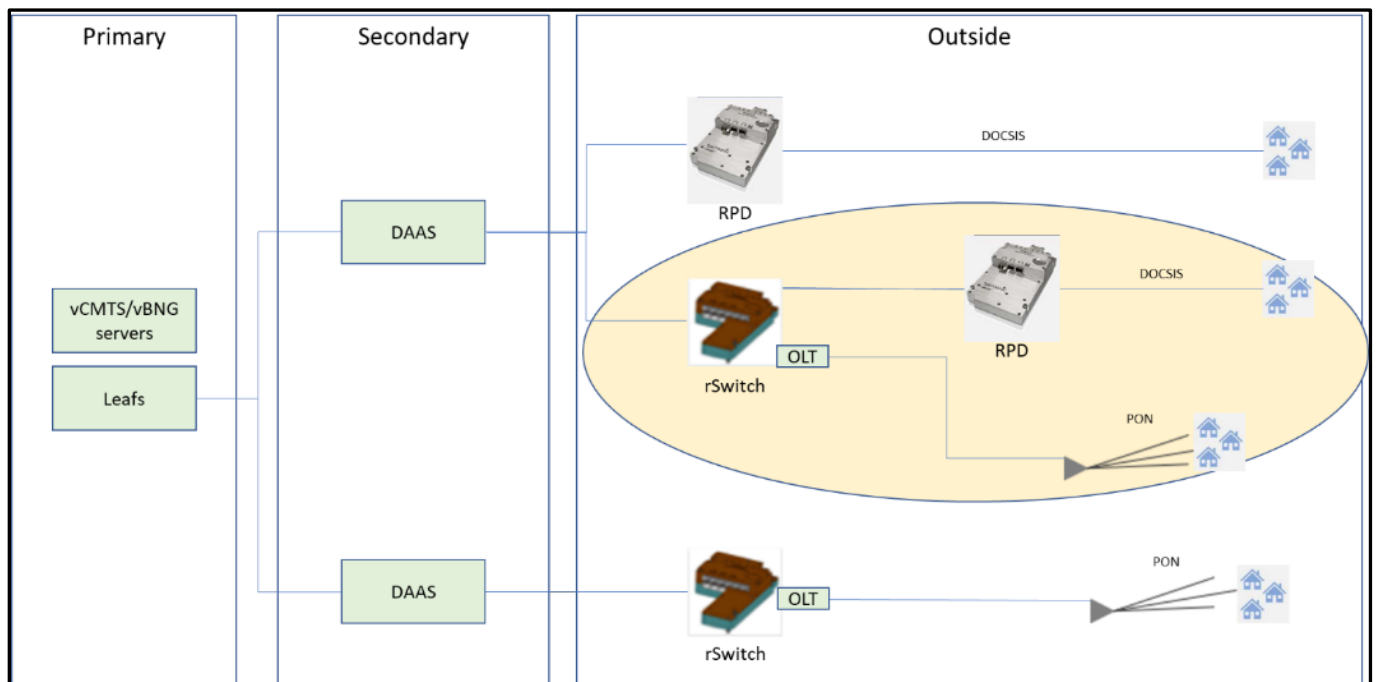

Figure 2 – DAA Basic Infrastructure Demonstrating Converged Access

The above description for PON chassis can also apply to DOCSIS, where “OLT” can be replaced with “I-CMTS” or “I-CCAP,” where “I” is for integrated. However, as noted, Comcast began moving to vCMTS

five years ago and continues to aggressively upgrade to vCMTS nationally. Nonetheless, most operators still have an integrated CMTS dominant footprint.

Working within the limitations of these integrated chassis platforms, major parts of budget strategies over the years have been focused on periodic SW upgrades and timing of procurements for growth and new features. In addition, while large scale chassis solutions do have efficiency advantages for supporting high density areas, they are not ideal for low density areas.

Other solutions have served and/or been proposed for these rural communities. Copper pair systems are simply inadequate – too slow – by today’s broadband standards. Wireless-based systems can be impacted by poor weather and other factors, and not be able to deliver the consistent, reliable performance customers expect and deserve. Leveraging DAA investments with vCMTS and digital nodes is a pathway to efficiently deploy a R-OLT-based FTTH solution into RBB areas. This architecture provides the flexibility to implement PON service very granularly and on demand. It will enable reliable services to penetrate anywhere deep into the existing footprint, while also expanding the radius of reliable Comcast broadband service to rural customers.

2. The Foundation of Distributed Access Architecture

Because of persistent year-on-year compounded annual growth rate (CAGR) of downstream and upstream traffic, operators found it increasingly difficult to keep up with upgrades to the network and spectrum using business as usual (BAU) processes such as node splits and incremental adjustments to spectrum allocation. New processes and tools were needed to replace BAU approaches before the scale made it too challenging or costly to execute upgrades.

Among the most powerful tools developed to address this were the distributed access architecture specifications developed through CableLabs. These specifications were a collaboration among operators, vendors, and CableLabs subject matter experts (SMEs) to address many of the anticipated challenges for operators as data traffic and speed demands continued to grow year over year. Among the first to be published was the “Remote PHY” (R-PHY) specification in 2015⁶. Technology development had begun well before the completion of the specification, and Comcast embraced the transition to DAA using R-PHY as part of its network evolution plan in 2015.

Note that the CableLabs work continued to develop another version of DAA based on the flexible MAC architecture, or FMA. As part of its strategic planning for DAA migration, Comcast deeply evaluated both options to determine which would better position the Comcast network for the long term. In the final analysis, the R-PHY approach was selected as it better aligned to key network objectives such as centralization of high SW complexity, lightweight distributed compute for low-touch, high-reliability outside plant locations, and simplifying interoperability of ecosystem components.

Comcast began deploying R-PHY based DAA in 2017 and has over 30,000 remote PHY device (RPD) equipped nodes from multiple vendors in production today, and that number is rapidly increasing as a major network upgrade plan to digital nodes and vCMTS takes place. There is no large-scale deployment of the FMA architecture to date. The Comcast DAA network now exceeds the availability performance of our mature, standard HFC deployments, as was anticipated with the migration to DAA.

2.1. Benefits of DAA

Distributed access architecture delivers multiple powerful advantages. It represents one of the most powerful technology upgrades to cable, nearly as powerful as the introduction of fiber itself to all-coaxial RF systems decades ago.

Among the benefits that can be attributed to the move to digital optics, and specifically Ethernet-based digital optics, in place of cable-specific analog optical (AM) technology are:

1) Optical wavelength efficiency

With increasing node splits and deeper fiber migration, significant numbers of new nodes are installed every year. The use of wavelength division multiplexing (WDM), where multiple links to RPDs can share a fiber, maximizes the use of the existing fiber infrastructure. The use of digital optics means up to 80 dense wavelength division multiplexing (DWDM) wavelengths/nodes can be aggregated on a single fiber (or more). Standard HFC AM optics are restricted typically to 16 wavelengths to manage the nonlinear effects on modulation error ratio (MER) for typical HFC optical links lengths. This means a more cost-effective deployment and less fiber needed to support the nodes.

2) Reach of digital optics vs AM optics

As noted above, longer optical links from headend transmitter to node historically meant that fewer wavelengths can be used on that fiber to meet a given end-of-line MER. Digital optics eliminate this dependency in practice for common HFC optical links. In fact, a DAA-based CMTS core, outfitted with digital optical outputs, could be moved closer to the core if headend consolidation is an objective.

3) SNR and MER performance improvement of eliminating the DS and US AM HFC optics

DOCSIS 3.1 and DOCSIS 4.0 enable higher order modulation profiles, increasing the bandwidth efficiency by up to 50% over DOCSIS 3.0 in the downstream and up to 100% in the upstream. In standard HFC, the end-of-line (EOL) MER is dominated by the performance of the AM optics. The CMTS RF ports provide an extremely high MER of 48 dB (set by the DOCSIS Downstream RF Interface Specification, or DRFI) for DOCSIS 3.1, which gets degraded by the AM optical link to the node in the field to below 40 dB, depending on optical link length and other variables and that is *before* the RF amplifier cascade acts to degrade it further.

With DAA, the digital link to the node eliminates the AM optics, and the MER degradation caused by it. Instead, the DRFI requirement is met at the node RPD port, gaining back the lost fidelity of the AM optics nearly completely. This maximizes the capacity possible for DOCSIS 3.1 DS output and US input signals.

4) Space, power, cooling efficiencies in the hubs and headends

Moving some of the CMTS functionality to the node leaves less behind in the hub or headend to power, cool, and consume space. The density of RF connectors and isolation requirements on a typical CMTS tend to set the density of these chassis. With the RF ports of the CMTS distributed into the plant, the density of the core can now be redefined since the density of optical connectors is much higher. Also, integration of digital infrastructure for video and data services allows for the elimination of large RF combining networks.

5) Alignment with virtualization of the CMTS, and more broadly towards convergence into a common virtualized platform serving multiple last-mile coaxial and fiber access technologies

This is discussed in the next section.

2.2. Virtualization

Cable operators' inside plant equipment and networks historically have been based on a collection of purpose-built video, voice, and data platforms of integrated hardware and software. This has been a successful formula for over 30 years of service introduction and service growth including digital video, high-definition (HD) video, voice, data, and video on demand (VOD) and FTTH implementations of the same services.

Unfortunately, with these monolithic platforms, in particular DOCSIS CMTS platforms, it is difficult to keep pace with exponential traffic increases. Also, considering the construction aspect of splitting nodes, typical network augments – node splits – cannot accelerate to match the trajectory of traffic growth.

Network function virtualization (NFV) and software defined networking (SDN) are enablers of cost effective, efficient, exponential network and service change velocity. Historically, the continued growth in traffic and mounting node splits to support that growth meant the addition of CMTS RF ports and line cards.

Bringing this concept down to operational practice, in a DAA implementation, these RF ports are distributed into the field. However, supporting line cards of the CCAP core would still be necessary if the digital node is connected to an existing I-CCAP.

In a virtualized implementation, however, this purpose-built hardware core, designed to be tightly coupled to the output RF interfaces, is instead implemented in commercial off-the-shelf (COTS) server hardware. This is made possible simply through Moore's Law. The compute power and resources needed are available in standard processors today, allowing CMTS functions to be executed in such platforms. This approach is shown in Figure 3.

Figure 3 – Virtualization of Edge Access Platforms

The potential to create SW-based CMTS on standard server platforms has enormous implications for cost, space and power savings in facilities, and service velocity. As with DAA nodes, the advantages of a migration to virtualized edge platforms are so compelling that figuring out this transition from integrated

architectures to distributed architectures, and to virtualized *and* distributed is essential. At Comcast, every RPD node is connected to a vCMTS core. Traffic growth and new product speeds now revolve increasingly around compute power, which scales with Moore's law, and spectrum re-allocation, which no longer involves massive re-wiring inside plant because it is empowered by automated RPD configuration for channel line-up changes.

In summary, the Comcast DAA implementation is based on an Ethernet switch fabric feeding R-PHY-based DAA nodes. The previously purpose-built CMTS hardware core is instead virtualized in COTS platforms. This architecture is shown in Figure 4, envisioned here as migration of existing HFC architecture – I-CMTS and analog fiber node to vCMTS, digital infrastructure, and digital nodes (RPDs). Not pictured here for simplicity is the substantial RF and analog optical headend equipment in the secondary that exists between the I-CMTS and analog node.

A significant item to note is that with DAA the vCMTS location is consolidated back to the primary – a benefit of the digital optics and scalability, with the switching infrastructure deployed into the secondaries rather than the CMTS itself.

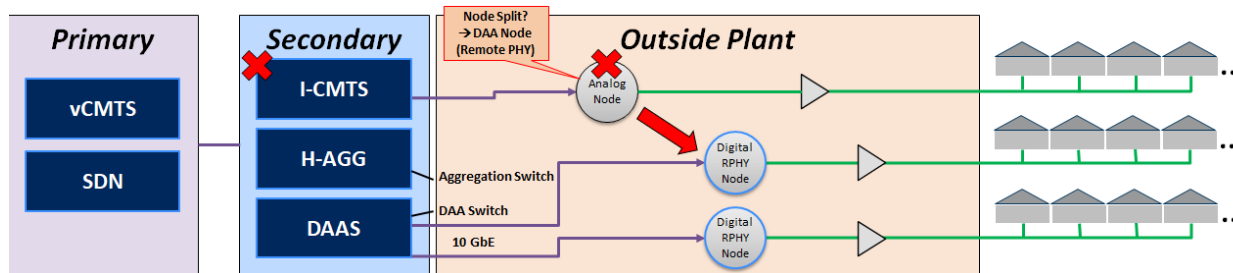

Figure 4 – Comcast DAA Architecture based on Remote PHY Node and vCMTS

3. DAA Extensibility and the Access-Agnostic Last Mile

DAA benefits extend beyond the considerable advantages it provides to cable systems. Most operators within their strategy also build and operate FTTH systems, consider the role of FTTH as HFC network upgrades take place, and think about how to efficiently transition to it where and when it makes sense to do so.

As the HFC architecture takes fiber deeper and builds out DAA based on vCMTS, the power of deep network Ethernet connectivity comes to the forefront. Ethernet is a Layer 2 foundation of global scale, and the workhorse of modern fiber and copper WAN and LAN communications. Virtually any last mile access technology will interface to an Ethernet-based system. Furthermore, by terminating these links in OSP in a fiber node, the node platform becomes a multi-purpose platform of plug-in modules supporting various last-mile options. For cable systems today, the most obvious next scenario and fast-follower of DOCSIS into DAA is EPON FTTH. Unfortunately, HFC architectures are not built to the physical standards of optical reach, homes passed per fiber, and wavelength plan of a “classic” EPON architecture. Because of these differences, a key component of the existing EPON solution is a “PON extender” module in a node housing, which solves both fiber utilization and distance constraints of classic PON system overlaying HFC. This node location now serves as the perfect place to instead utilize an R-OLT. As part of a node housing, the node platform itself now becomes a multi-access last mile, architected for dual use in this case as shown in Figure 5.

The basis for both last miles is similar – deliver 10 gigabit Ethernet connectivity to an access module inside of the node. Current nodes support RPD modules already. A node of the future for FTTH last miles now includes the addition of an EPON R-OLT. The PON portion of network (where the PON protocol lives) then extends from the R-OLT port to business and residential customers, based on the same PON optical budget standards that exist today. These PONs are standard-compliant for optical link budget, as the PON is being served from that deeper physical location closer to FTTH customers, just as with the PON extender.

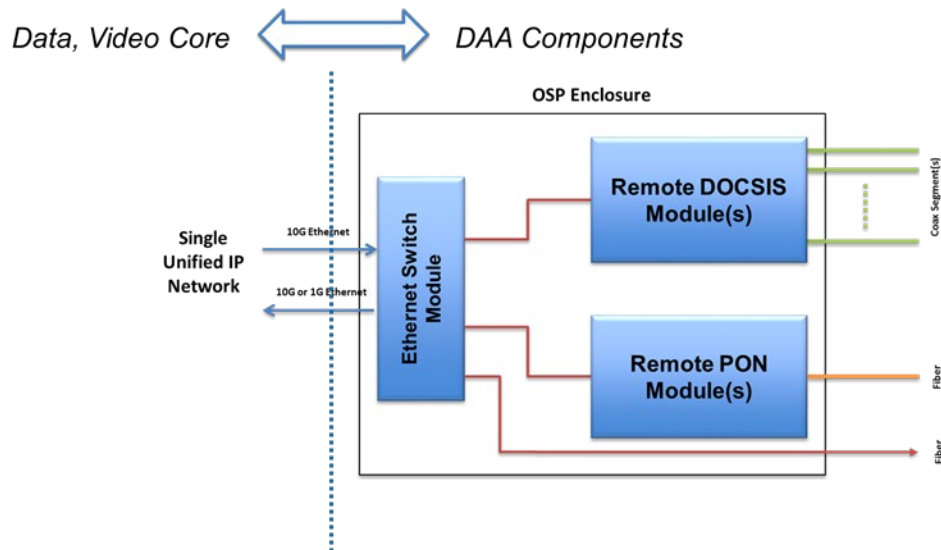

Figure 5 – DAA Enables Access-Agnostic IP Network Architecture Convergence

3.1. Integration of EPON FTTH into DAA Infrastructure

Last-mile access convergence does not end with an R-OLT HW module, however. Today's R-OLTs are simply smaller, hardened versions of centralized OLT platforms. Those were designed to support thousands of customers in large FTTH build-outs, such as the telcos have been doing in targeted ways for about 20 years. Cable operators generally deploy FTTH more tactically. Specific properties and developments built as FTTH are sprinkled about a ubiquitously deployed coaxial network. As mentioned, the R-OLT approach allows for ease of granularity of adding a single PON port at a time to manage growth most efficiently in the fashion it is deployed by most cable operators.

Aside from the properly sized HW platform, and as indicated previously, the virtualized infrastructure built and matured for DOCSIS DAA can be leveraged now for EPON, rather than operating DOCSIS and PON as two independent, parallel systems that happen to share the same optical infrastructure and switches. This introduces the virtual broadband network gateway (vBNG) platform SW component to the ecosystem

Consider Figure 6, which compares cable and telco implementation models for deployment of PON services, Open Systems Interconnection (OSI) alignment, and networking configuration. The telco PON architecture was developed to drop into existing DSL architectures, with a Layer 2 OLT taking over the role of the digital subscriber line access multiplexer (DSLAM).

Similarly, cable operators developed PON to drop in-line with existing DOCSIS deployment models, which has a more intricate integration of Layer 2 and Layer 3 functionality at the edge router (CMTS) for historical reasons. The more flexible EPON standard was used, and an SW abstraction layer called DOCSIS provisioning of EPON (DPoE) developed to accommodate the technology within a DOCSIS end-to-end system. DPoE assigns each ONU as a virtual cable modem (vCM) inside of the OLT, allowing operation and management of it via DOCSIS tools and back-office systems. This is what is commonly used in most EPON systems today in the cable operator community.

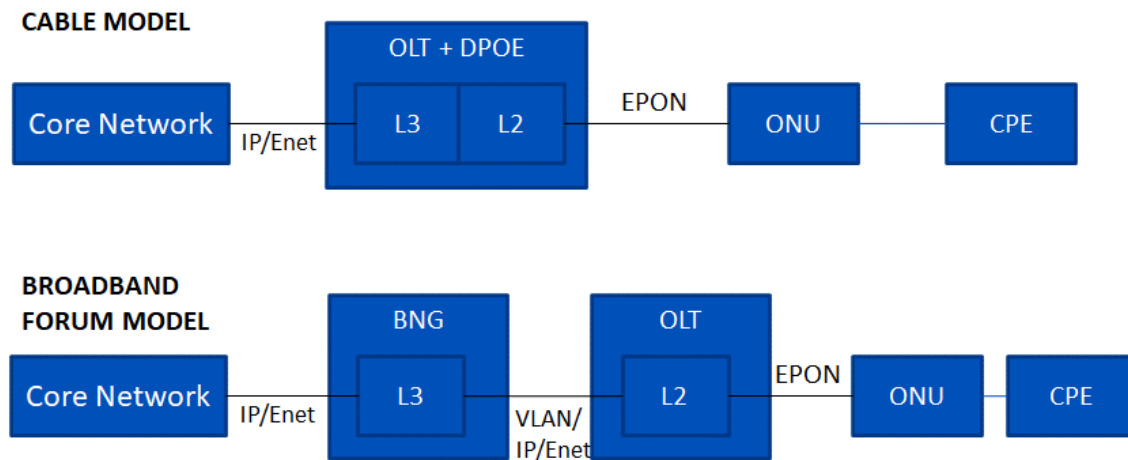

Figure 6 – Cable and Telco PON Network Models

For vBNG, however, this emulation of DOCSIS functionality in the R-OLT is eliminated. Rather than remotely deploying complex OLT SW with DPoE, the R-OLT is simplified, becoming more of a wavelength, scheduling/multiplexing, and protocol converter that integrates directly to subscriber management SW in the vCMTS platforms alongside DOCSIS. The vBNG data plane can be run in the network processing unit (NPU) of today's COTS server platforms, while the control plane can be run in the cloud.

Developing the architecture for incorporating FTTH into the production DAA system brought to light opportunities for synergy between DOCSIS and PON. The first obvious area of synergy is simply that the remote switch (rSwitch) and R-OLT are connected to already existing DAA infrastructure. This produces a very low barrier to entry to deployment time and saves on construction costs. It also allows the reuse of field processes that technicians have become accustomed to when installing RPDs. With this experience combined with experience from also having deployed EPON in scale in production, the learning curve is significantly reduced, and less new training needs to be developed.

Other major benefits to the sharing of the physical infrastructure include:

1. Transit fiber feeding DAA components in the field is efficiently used and shared between the access networks either through high-speed switch networks or via multiplexer combining of the Ethernet wavelengths to the RPD and rSwitch devices.
2. Routing infrastructure is combined, so the IP infrastructure costs are made to be as efficient as possible. This means that PON customers and DOCSIS customers will utilize the same IPv4 and IPv6 scopes and all the same security risk management practices.

3.2. The Road to RBB Is Through vBNG/R-OLT

One of the most powerful advantages of the DAA-based EPON implementation is the ability to take advantage of over five years of production deployments of DAA with vCMTS for DOCSIS customers, and leverage that knowledge for PON customers over that same DAA infrastructure with vBNG (instead of vCMTS) and R-OLT (instead of RPD). In the vCMTS, the core of the software is all built into a single Kubernetes “pod,” which is a tight knit group of containers. For PON, the software is built in three primary pods, identified in Figure 7: the vBNG itself, the access controller, and the service activation pod. Splitting these functions allows us to separate the complexities of service provisioning and device control away from the compute-intensive but relatively simple function of the vBNG to pass the customer’s traffic.

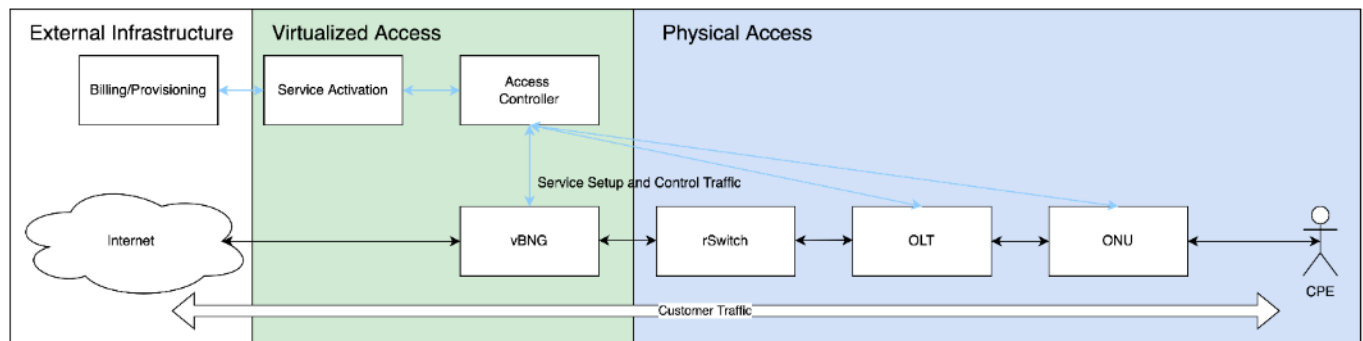

Figure 7 – vBNG-Based PON: Service Components and Traffic Flow

Let us detail further the functionality of these components:

Service Components – vBNG – This is the most familiar component in the system. The job of the vBNG is to guarantee the quality of service (QoS) parameters associated with the customer’s services, enforce security policies, provide basic IP services such as Address Resolution Protocol (ARP) and neighbor discovery, and to consistently pass the customer’s Ethernet frames to and from the Internet. This component has a high CPU resource requirement and must be highly available with a maximum downtime, counted in a handful of seconds. Simplicity and consistency are the primary operational considerations.

Access Controller – This component is primarily responsible for the configuration and monitoring of the R-OLT and ONU. It also provides service level configuration to the vBNG for its consumption. The PON interfaces and the service definition can become quite complex necessitating close adherence to both standards documents and actual implementation details within the R-OLT and ONU. This complexity does not impact the availability of customer services. However, for customer services, the access controller is only needed during initial provisioning in that the vBNG, R-OLT, and ONU will continue to provide the services they were configured with even if the access controller is down. It is still preferred that the controller be available if only for monitoring purposes, but the acceptable downtime can be measured in minutes. While the service activation and vBNG components will largely be common to all Ethernet based access technologies, the access controller must be replaced or redesigned significantly to support other technologies.

Service Activation – This component is responsible for all per subscriber service level configuration. Today for most cable operators that means that it will create a vCM to interface with a DOCSIS compliant back office. However, unlike a DOCSIS cable modem, information about the ONU devices can

be provided through telemetry rather than being polled via Simple Network Management Protocol (SNMP). This greatly simplifies the vCM itself, essentially becoming a DHCP emulator with a means of downloading configuration files and translating them into a common API to communicate with the access controller. The superpower of the service activation component, however, is that it is not tied to the DOCSIS back office. Having this component as part of the system allows the operator to add to, change, or replace this mechanism with the newest and/or most convenient APIs for back-office integration. This is an ability that is difficult to take advantage of in the short term but encourages movement in that direction just by existing. Much like the access controller, this component is only necessary at initial provisioning and the acceptable downtime can be measured in minutes.

The final critical and strategic attribute that should be highlighted about the DAA-powered PON architecture, founded upon the rSwitch, R-OLT, and vBNG components is not just the value it brings today, but also its value for future evolution. This system is constructed of six independent sets of services, as shown in Figure 8: management, provisioning, service fulfillment, routing, backplane, and access technology. These services can and are being improved upon without impacting the other services. The ideal future state is one where we have the best in breed services in each of these areas which can then be continually optimized within their own technology domains. By doing this, we will also be continuously improving network capability, services offered, and the customer experience while increasing network reliability for all commercial and residential customers. We can even consider third and fourth last mile access technologies to integrate in the future.

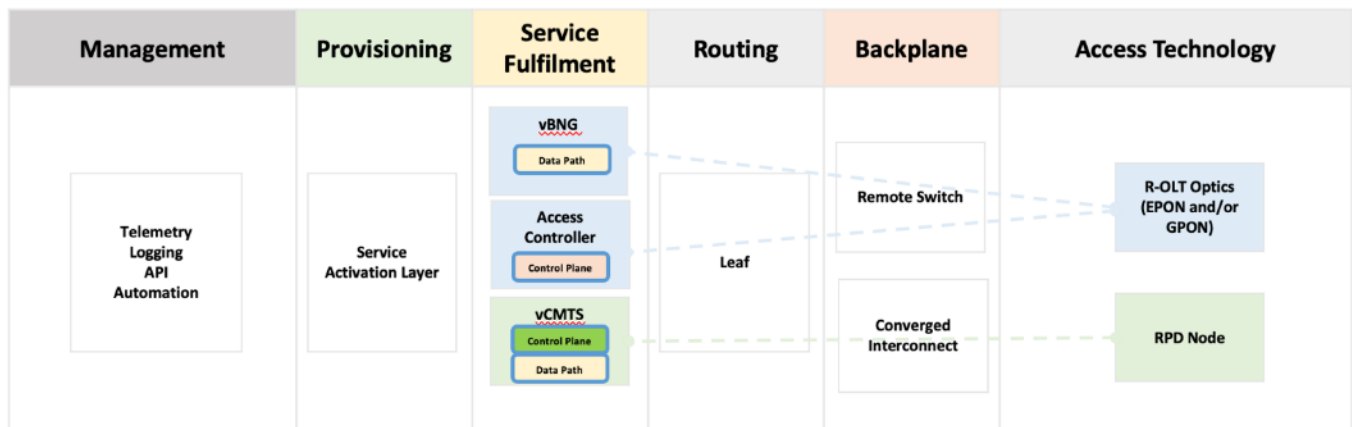

Figure 8 – Abstract Layers of DAA System

3.3. Distance Matters

Deployment of traditional HFC plant in very low-density has been limited historically. The cost of large-scale network construction has to be balanced against the number of customers that will be reached. Signal attenuation of the coaxial cable is a major factor in low density due to longer runs of cable, requiring long RF amplifier cascades and more power to run them.

Fiber optic cable has a much lower attenuation per mile compared to coax, so is better suited to cover very long distances efficiently. As such, the R-OLT and vBNG bring an opportunity to support rural deployments very effectively, as well as streamline the deployment of Comcast's EPON FTTH network by converging it with the existing DAA infrastructure.

In addition to the last-mile distance to homes in low-density areas, another challenge to serving these rural communities is the distance from Comcast's core network and primary facilities to these areas. A conventional chassis OLT requires deployment in a secure and environmentally controlled environment and access to the core network. From that centralized location the standard PON deployment can reach commercial and residential customers as far as 20 km of fiber away, assuming the 128-split ratio of the PON standard. Unfortunately, as noted previously, these parameters are not well-aligned to an implementation to cover a distant rural footprint. A proprietary PON extender solution developed by a technology partner enables the PON network to extend up to 80 km from the conventional OLT. In this implementation, the EPON network is transported from the OLT using conventional 10G DWDM transport to a node-type housing. Up to eight fiber link modules (FLMs) are contained in the node housing, making up to eight 10G EPON networks possible, supporting up to 1024 passings. This technology breaks up the optical transportation from OLT to ONU network into two parts, the OTL (optical transport link) and the ODN (optical distribution network) as shown in **Figure 9**.

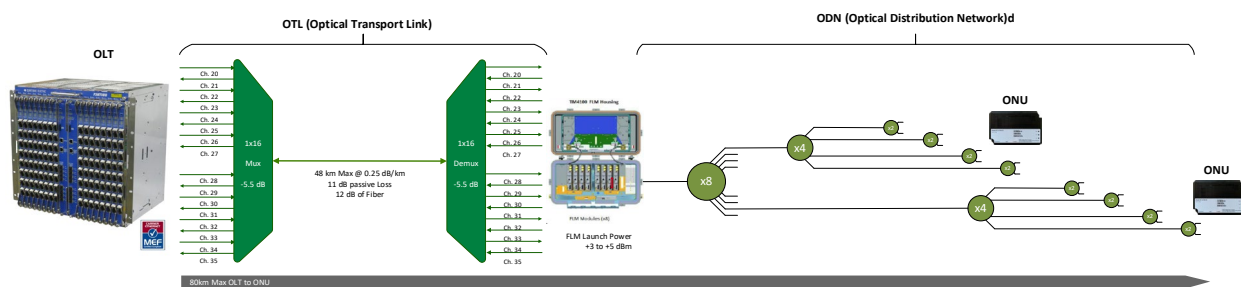

Figure 9 – PON OLT, OTL and ODN Architecture

As effective as PON extenders are to FTTH deployments, they represent a bandage to a fundamental architecture incompatibility that exists between telco-based PON standards and cable network principles. The R-OLT, by contrast, aligns PON technology to how HFC technology has evolved, in particular with DAA – use of Ethernet-based optical infrastructure feeding flexible, modular, multi-use platforms.

An example R-OLT is shown in Figure 10, in this case developed by Harmonic, one of Comcast's DAA business partners. The deployment is made up of three parts, the housing ("Ripple"), rSwitch "Jetty-1", and the single-port R-OLT itself, the "FIN-1".

This node housing for the R-OLT can also support an RPD, simultaneously. The Jetty-1 is a remote switch that connects to the distributed access architecture switch (DAAS) through a standard 10G DWDM link. The switch could support additional application, but for this paper we will focus on EPON. The Jetty-1 contains six SFP ports, two designated as uplink ports and four multipurpose ports. Up to two rSwitches can be mounted in this housing.

The FIN-1 enables simple plug-and-play 10G PON capability from rSwitch. Up to four FIN-1's per Jetty-1 are expected to typically support EPON deployments.

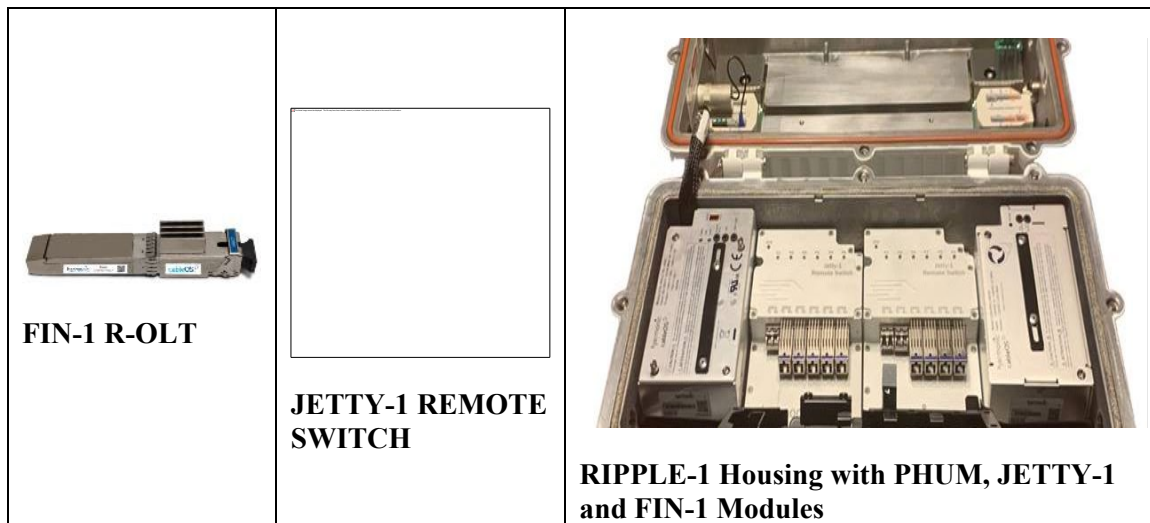

Figure 10 – Remote OLT (R-OLT) Hardware Components

Standard fixed or tunable 10G SFP+ are deployed to provide connectivity from the DAAS port and the rSwitch port. 12, 24 or 48 port DWDM 4.0 optical filters provide multiwavelength connectivity on a single fiber from the DAAS facility to the R-OLT housing. This is shown in **Figure 11**.

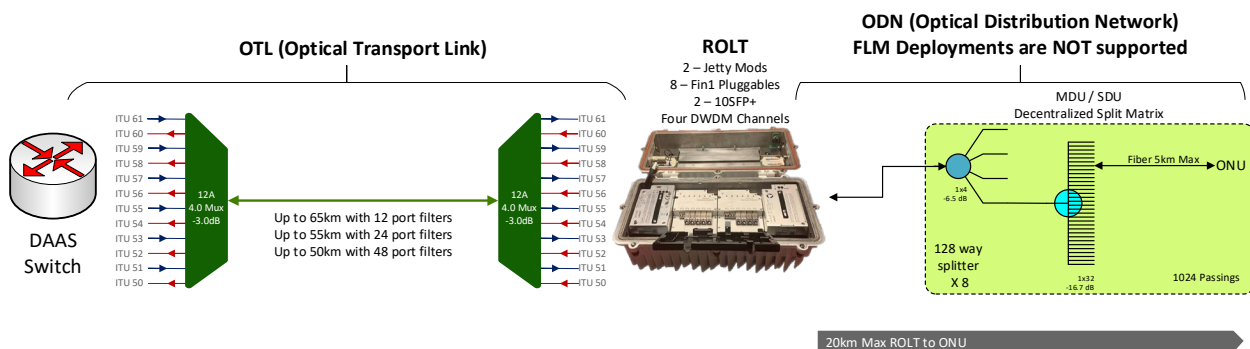

Figure 11 – DAA-Based PON – Optical Connectivity

The engineering and design of the ODN does not change with the deployment of the R-OLT when replacing an FLM-based EPON deployment. Of course, the OTL becomes standardized across the DAA deployment footprint including access to production tools and provisioning developed during the vCMTS rollout. The overall distance from the DAAS port to the ONU increases by 5 km reaching a maximum of 85 km from the DAAS to the ONU, enabling a solution that enables the deployment of EPON into the rural markets that is much simpler and faster – and where most of the end-to-end mileage is already built!

4. Operational Benefits

4.1. Software Over Hardware

As noted, Comcast has been investing in DAA for years. As part of the architecture development, decisions were made to drive to a more software-centric solution wherever possible. What does this mean

when talking about the access network? In many cases it means having the ability to upgrade software features and capabilities instead of requiring physical replacement of deployed elements in the network.

The large-scale deployment of vCMTS / RPDs demonstrates this, and the same vision, capability, and intelligence in the network is part of the vBNG / R-OLT design. Through DAA, we have never-before available visibility into the network, in real-time. We are leveraging the cloud and machine learning to create intelligent automation and configuration of components error-free and in-scale, all in SW. As an example, the process of increasing speeds and change spectrum allocations on the plant is a few clicks that can ultimately touch hundreds or thousands of production nodes.

Maximizing use of software in the architecture enables flexibility to, for example, push new speed tier offerings throughout the network in months rather than years. By designing a more intelligent outside plant, we are able to push configuration changes via software, obviating the need for a technician to go into the facility to perform re-wiring and/or into the field to make configuration changes. It opens the doors to automation that drives rapid scalability. With that scalability comes the need for improved network resiliency and visibility. Figure 12 is an example of a dashboard showing real-time information related to activation of OFDMA as part of a mid-split network upgrade. Currently, approximately 90% of updates and configuration changes introduced into the DAA footprint are delivered via automated tools, with a goal to increase this to 99% by the end of 2022.

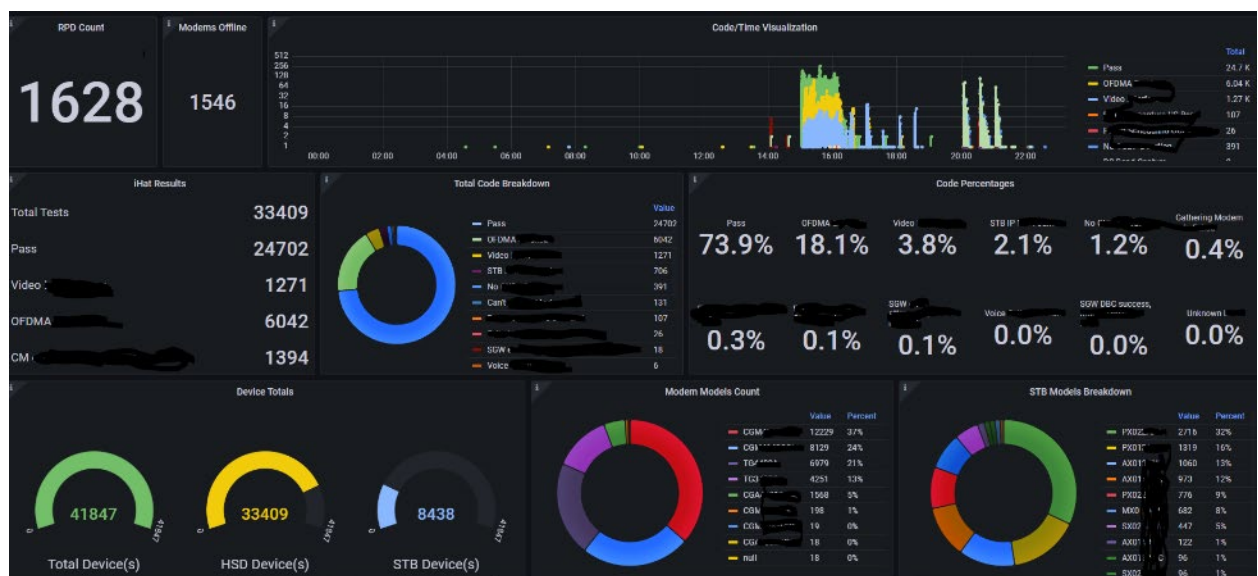

Figure 12 – Real-Time Network Stability

Increased intelligence means substantially more telemetry available to observe and manage the network. Data can be processed and filtered into dashboards focusing on performance, availability, and capacity management in real-time. These data sets will be available in R-OLT through the DAA investments, just as they are in DOCSIS RPD deployments. With metrics and real-time traffic data, new RBB deployments can be optimized very efficiently as the understanding of network characteristics and traffic dynamics associated with these new environments is learned. Available information includes operational data at each component of the network. This is an unprecedented amount of data compared to traditional HFC systems. The challenge then becomes how best to use this deep, real-time information. How should this data be managed? Who can use it effectively? Are there new tools that we must develop to convert this data into actionable information?

4.2. Network Telemetry – Breadth and Depth Across the Ecosystem

We break down the information and the benefits of this capability across equipment and serviceability elements below:

- **Platform**
This includes the base level hardware and software of the virtualized system that support the microservices, and the infrastructure to instantiate and maintain them. Invaluable information that speaks to the health, efficiency and workload within this view includes memory utilization, CPU load, Kubernetes state and host state.
- **Software deployment**
Deploying software in a non-customer impacting way – in-service upgradeability – is extremely important when there are hundreds of independent microservices that all rely on each other. This allows us to upgrade code and augment features with maximum flexibility and without traditional operational practices focused on customer care management. Current versioning, downtime, error notifications, and level of impact in case of a failure are all important metrics in this view.
- **Service Orchestration**
Bringing up the right software instances at the right time to the right customers is vital for success. How do we coordinate data from the field with information such as location, network devices, and physical connectivity of construction and network maintenance with the delivery of vBNG or vCMTS-based services? Automation and scripting are vital to doing this effectively at scale and without human error. This enables the efficient, widescale activation of services quickly as network builds such as RBB take place in parallel across the footprint.
- **Outside Plant**
With the distribution of smart components in the field, we have access to new and valuable data closer to the customer pertaining to their experience. This data can be analyzed via machine learning algorithms to trigger preemptive repair before a customer notices a problem. For DOCSIS, this includes RF data from the RPD and future smart amplifiers. For either DOCSIS or FTTH, real-time information on fiber impairments, fiber cuts, and power supply health and status provides important telemetry to preempt network outages or improve MTTR.
- **DAA Network**
As we push Ethernet out into the field via connectivity to the rSwitch and RPDs, we create increased connectivity complexity compared to traditional HFC, but also a much better opportunity to manage and monitor capacity, utilization, and scalability. Traditional network monitoring must be augmented to work effectively in a cable operator's physical network where an out of band connection cannot always be relied upon.
- **Customer Services**
This view of the network most directly impacts the customers. Who is impacted by a physical outage? Are the devices working in a degraded state? What are the network services that the customer is entitled to? This is the most traditional and vital view of the network for cable operators. Being able to observe real-time ONUs and CM behavior via streaming telemetry of the virtualized platform is an opportunity to address device issues before a customer notices service issues, which has a huge positive customer experience impact.

There are many other great ways that the system can be viewed, but this gives us a reasonable cross section to make some important observations.

The virtualized core and DAA infrastructure are very similar, no matter which last mile access technology is being used. Beyond the nuances of PON and DOCSIS, the system is run the same way using the same hardware with very similar, if not the same, software. Much of information gathered is similar, with some

obvious differences in the specific last mile RF data vs FTTH data. Most importantly, the information coming from this data is operationally transformative, creating significant efficiencies of scale while simultaneously adding deeper diagnostic value. They lend themselves to leveraging cloud services and infinite possibilities of dashboard views that can be spun up quickly and iterated upon to maximum effectiveness by users, as seen in Figure 13, showing a dashboard view of CM online status.

Figure 13 – Real-Time Customer Cable Modem Telemetry

With the amount of new and possibly overlapping data, algorithms using machine learning are needed to transform this data into actionable intelligence. For example, with new data comes new thresholds for alarms and triggers. If there are multiple alarms going off, how do we ensure they are correlated with one another? Do they have the same root cause? Can the system help direct the people managing the network to the source of the issue faster? Can the system learn enough to be able to correct itself when it is possible? This is a key part of the operational ecosystem under development.

5. Operational Impacts

5.1. Sustainability

Sustainability has been at the forefront of Comcast practices for many years. Whether it is proactive decommissioning for a network upgrade project, reducing energy use or managing customer network traffic most efficiently, Comcast is considering the impact on our environment. As we build out our network for RBB and continue to upgrade our HFC footprint, we are committed to being environmentally responsible.

5.1.1. Fiber

For RBB, and more generally for all EPON FTTH deployments going forward, integration of PON into existing production DAA system – re-using already built infrastructure for FTTH services – provides construction-related savings, and outside plant power savings.

In addition, because of the significant difference in the signal attenuation of fiber compared to coaxial distribution the PON distribution network is approximately 90% more power efficient than the typical HFC network that would be needed to cover the same low-density footprint. Thus, for RBB, the vBNG with R-OLT represents a significant advantage in terms of sustainability.

5.1.2. Coaxial Cable

As we continue to upgrade the HFC footprint, there are sustainability opportunities available also. Comcast uses thousands of miles of coaxial cable every year. New partnerships are strengthening our recycling programs for coax. Earlier this year Comcast launched an enhanced recycle program for coaxial cables that have reached their end of life. In partnership with Echo Environmental, we can now break down the cable to create new raw materials that can be reintroduced, resold, and reused.

Here is how it works: Coaxial cables are multi-layered “cords” that consist of 27 different polymers, all of which need to be separated to make them usable in new products. Traditional recycling efforts can recover the metals contained within the wires, but not the insulation and jacketing around them. Echo Environmental created a solution to address this issue, all without the use of hazardous chemicals or incineration – and now, thanks to their technology, 70% of our coaxial waste can be recycled for reuse each year, significantly reducing landfill waste. The remaining 30% of our cable waste will still be recycled, as it is now, with plans to recycle 100% for the purpose of reuse in the future.

“It is incredibly gratifying to develop sustainable solutions for underserved market products,” says Brian Hays, Echo Environmental Project Developer. “Our unique process combines traditional recycling systems with methods from other industries, resulting in the ability to extract target polymers cleanly. This outside-the-box thinking not only sets us apart in our industry, but also enables us to deliver meaningful, real-world solutions for our clients and our environment.”

5.1.3. HFC

Comcast has hundreds of thousands of nodes and millions of amplifiers in our HFC network, and all of these devices require power to operate. To support this infrastructure, Comcast has one of the largest power distribution networks in the United States. Operation of this power network with a high level of efficiency is a high priority.

As Comcast upgrades HFC plant, there is major focus on the power efficiency of the network and the health of the grid to make sure it is operating efficiently. The simple act of upgrading 20-year-old amplifiers introduces significantly more efficient amplifier technology – so much so that we can extend the bandwidth to 1 GHz, launch that additional power downstream with a tilt, and still come out approximately neutral on total power consumed, or even slightly ahead. The bps/Hz/W has improved dramatically as families of power amplifiers – silicon-based, gallium arsenide (GaAs), gallium nitride (GaN), and iterations of each, have evolved over the last 20+ years.

New technologies aimed specifically at power savings are now also available, such as digital pre-distortion (DPD), envelope tracking, and automatic bias adjustment for RF load. These technologies are

reflected in our specifications, as are recommendations for power-factor corrected (PFC) supplies inside of our actives. PFC enables the AC supplies feeding the network to operate efficiently.

With historical efficiency gains over time and new technologies aimed at power savings we believe that today's HFC power grid is well-suited to support migration to 10G within the bounds of today's power grid. The perspective here is less about the absolute savings of power, but doing much more for the customer with the available existing power.

5.2. Workforce

As the vBNG and R-OLT solution moves into the field, we will be able to assess the actual implications to the field and to sustainability as identified previously. Another important aspect is how the solution will impact internal teams and field technicians. In 2017, Comcast launched the industry's first large-scale initiative to deploy DAA using RPDs and vCMTS. We did this expecting a bumpy road at the outset as the new technology and practices slowly matured. With vBNG and R-OLT, the advantage of lessons learned from that experience is with us and embedded into practices, documents, and the knowledge base. The deployment plan accounts for the change impacts to these downstream teams. Back-office and XOC support teams are working with this new technology in their labs to determine how it fits into existing processes and what potential impacts it would have to current staffing trends to ensure seamless deployments.

Previous PON solutions were so different than DOCSIS that the thought of having common staff maintain and manage both was a challenge, and at a minimum required technicians supporting both to augment existing knowledge with the "new" skills needed to support PON. Some of this is unavoidable in the last mile, of course. However, by aligning the architecture, platform, tools, and processes, and pushing the fiber and intelligence of the network further into the field, we've significantly converged the access network and correspondingly reduced the need for excessive additional training.

Our field technicians have become DAA experts with over five years of learned experience behind them. Training was developed internally and strong partnerships built between headquarters technologists and the practitioners in the field who would be called upon to operate the network. The smarter components themselves of DAA have played a role also, providing our technicians better insight into the network than they have ever had before once they have learned to use the tools. This commonality benefits the vBNG/R-OLT operational model, reducing the need for substantial new training. At the same time, the new DAA tools, processes, and converged technology offers growth opportunity for these technicians, much like technicians of prior years had in the vCMTS roll-out, further back in time, during the analog-to-digital video conversion.

6. Conclusion

Comcast has been building and operating DAA systems that virtualize CMTS platforms for over five years. We have gotten really, really good at it and have the network performance metrics to prove it. We are in the midst of rapidly scaling this foundational network upgrade across the vast majority of the footprint. The benefits have been enumerated herein – performance, scalability, availability, automation, deep telemetry, flexibility, sustainability... the list goes on. As we make our way along the path to 10G, DAA and virtualization are the most important pieces of the puzzle. Layering on DOCSIS 4.0 is the next step for the HFC network, a high priority strategy being executed to ready the network for multi-gigabit symmetrical speeds.

Exploding onto the scene in the midst of this very active cycle of HFC initiatives is the RBB initiative. Fortunately, having embraced the capability and vision of DAA, leading us to invest heavily in the baseline architecture, Comcast is in an excellent position to deliver best-in-class services to RBB areas using efficient architectures, align with operational simplification and sustainability objectives, and continue growth of our EPON footprint in areas where it makes the most sense to deploy FTTH.

We are not just bridging the digital divide as we turn up RBB – we are installing a 10G-enabling highway that will be maintained and managed with the power of proven DAA tools, back-office monitoring and automation, and deliver that best-in-class experience we strive for all of our customers, from the most dense high rise to the now-farther reaches of the Comcast plant.

Abbreviations

AC	alternating current
AM	amplitude modulation
API	application programming interface
ARP	Address Resolution Protocol
BAU	business as usual
bps	bits per second
bps/Hz/W	bits per second per hertz per watt
CAGR	compounded annual growth rate
CCAP	converged cable access platform
CM	cable modem
CMTS	cable modem termination system
COTS	commercial off-the-shelf
CPU	central processing unit
DAA	distributed access architecture
DAAS	distributed access architecture switch
dB	decibel
DHCP	Dynamic Host Configuration Protocol
DOCSIS	Data-Over-Cable Service Interface Specifications
DPD	digital pre-distortion
DPoE	DOCSIS provisioning of EPON
DRFI	[DOCSIS] Downstream RF Interface [Specification]
DS	downstream
DSLAM	digital subscriber line access multiplexer
DWDM	dense wavelength division multiplexing
EOL	end-of-line
FLM	fiber link module
FMA	flexible MAC architecture
FTTH	fiber-to-the-home
EPON	Ethernet passive optical network
GaAS	gallium arsenide
GaN	gallium nitride
GHz	gigahertz

HD	high-definition
HFC	hybrid fiber/coax
HW	hardware
I-CCAP	integrated converged cable access platform
iCMTS	integrated cable modem termination system
IP	Internet Protocol
km	kilometer
LAN	local area network
MER	modulation error ratio
NFV	network function virtualization
NPU	network processing unit
ODN	optical distribution network
OLT	optical line terminal
ONU	optical network unit
OSI	Open Systems Interconnection (the standard's full name is "ISO/IEC 7498-1 Information technology – Open Systems Interconnection – Basic Reference Model: The Basic Model – Part 1")
OSP	outside plant
OTL	optical transport link
PFC	power-factor corrected
PHY	physical layer
PON	passive optical network
QoS	quality of service
RBB	rural broadband
RF	radio frequency
RFP	request for proposal
RPD	remote PHY device
R-PHY	remote physical layer
R-OLT	remote optical line terminal
rSwitch	remote switch
SDN	software defined network(ing)
SFP	small form-factor pluggable
SNMP	Simple Network Management Protocol
SW	software
US	upstream
vBNG	virtual broadband network gateway
vCM	virtual cable modem
vCMTS	virtual cable modem termination system
VOD	video on demand
WAN	wide area network
WDM	wavelength division multiplexing

1 Introduction

In today's world, reliable internet connectivity is a necessity. The COVID-19 pandemic has accentuated the need to stay connected while also highlighting the digital divide that exists across the globe. When we talk about the "digital divide", we typically think about serving remote and rural areas. But a lesser-recognized digital divide exists in dense urban areas. Socio-economic factors in developing countries have provided broadband internet access to upper income, educated communities while economically disadvantaged neighborhoods are left unserved or, at best, underserved.

These unserved and underserved areas pose multiple challenges for providing affordable service using traditional deployment models where end-user service is provided as a post-paid recurring subscription via a Consumer Premise Equipment (CPE) installed to a household with a billable home address. These models focus on postpaid subscription for the address where, over time, the ROI model recoups the cost of installation, the CPE, and recurring costs to bring connectivity to the household.

Overcoming the challenges of installation cost, installation logistics, device / CPE security while unleashing the purchasing power of the unbanked in these economically disadvantaged neighborhoods is key to bridging the digital divide and allows for deployment models across high-density, shared residential and MDU communities.

In this paper we present a novel approach based on the CableLabs[®] Custom Connectivity (CC) architecture to delivering internet service, directly to a device and/or to a group of devices without the need for an in-home deployed CPE or requiring a fixed household address for broadband service delivery. This Custom Connectivity architecture, implemented in collaboration with Liberty Latin America and Veeva Inc, enables alternate deployment models utilizing edge compute based shared Wi-Fi access points that provide on-demand virtualized home gateways to subscribers. The rest of the paper is organized as follows

Section 2 (Background) talks about traditional CPE based deployment architecture and some of the shortcomings of that model.

Section 3 (The Digital Divide) dives into the unique constraints in some of the unserved and underserved communities that hinders broadband services delivery using the traditional CPE based model.

Section 4 (Custom Connectivity Architecture) provides an overview of the Custom Connectivity architecture and some of the unique capabilities provided by that architecture.

Section 5 (Panama Trial) describes the technical and business requirements that shaped the trial implementation of the Custom Connectivity architecture to provide broadband services to the underserved and unserved communities.

Section 6 (Implementation) explains the functional components that collectively allows delivery of broadband services directly to subscriber's devices through an on-demand subscriber specific virtual home gateway service that is hosted using the shared-CPE design.

2 Background

Traditionally broadband services are delivered to a physical home address with a consumer premise equipment (CPE) like a cable modem or an ONU terminating the access network. The subscriber's billing relationship is also tied to the address where the CPE is installed. This model has served well over the past few decades where the focus was on delivering cable video as well as broadband services to a household with a limited number of consumer devices connecting to the network. Over time the number of consumer devices connecting to the network have been increasing and continues to increase exponentially. Consumers are also connecting an increasingly wider variety of devices to the network and these devices may have specific connectivity requirements. For example, security cameras require

increased upstream bandwidth compared to a Smart TV and/or a work computer. These trends have highlighted several constraints with the existing deployment model:

- The need for a CPE to be installed and activated for each subscription adds to the cost of servicing a subscriber. This cost goes beyond just the cost of the CPE and includes the costs associated with inventory management, installation logistics, CPE security and maintenance etc.
- Operators typically do not have visibility into the devices behind the CPE that are connecting to the network. This makes it difficult to troubleshoot problems caused by individual devices and makes it harder to deliver custom service(s) to a device or group of devices.
- The billing for the subscription is typically tied to the home address where the CPE is installed instead of the devices to which the services are being delivered to. This prevents the operators from offering device-centric value-added services that can optionally be tied to different payers.
- It prevents sharing of CPE across subscribers which, as described below is one of the factors that contributes towards the difficulty in offering broadband services in certain unserved and underserved communities.

3 The Digital Divide

The global COVID-19 pandemic brought into focus the importance of reliable internet connectivity in our lives and the devastating consequences to people and communities that did not have access to reliable internet connectivity. While a majority of the population in developed countries were able to sustain themselves and their families by depending on reliable broadband services, there was a significant population in low-income communities in Latin America and other developing countries across the globe that were either unserved or underserved in terms of broadband connectivity. The impact to these communities was substantial. Children were unable to access educational content and adults were largely unable to participate in today's digital economy. A lot of these communities were composed of daily wage earners and the gig-economy participants that primarily lived in high-density neighborhoods. These neighborhoods had remained largely unserved or underserved because the traditional CPE based service delivery model did not scale economically in these neighborhoods. A number of factors contributed to it being non-viable for the operators. First and foremost, the costs associated with the CPE (see [Section 2](#)) resulted in a negative ROI in most cases due to the low-ARPU in these communities. A significant population in these communities were unbanked which made it difficult to establish a BSS relationship with the subscribers. In certain instances, there wasn't a fixed home address to deliver the service to. The subscribers preferred a subscription model that was more on-demand, where they could stop/disable their service on certain days and not have to pay for it. Such on-the-fly service activation/deactivation is hard if not impossible to support with the existing home-address based billing model. These factors contributed to creating a digital divide for these communities and put them at a significant disadvantage during the pandemic.

4 CableLabs[®] Custom Connectivity Architecture

4.1 Architectural overview

The Custom Connectivity architecture encompasses a set of technologies that collectively enable the delivery of broadband services using an alternate device-centric service delivery model. In particular, Custom Connectivity provides per-device credentials and per-device policy for consumer-grade wireless

devices – essentially providing enterprise-grade device access and management capabilities to non-enterprise devices.

The core of the Custom Connectivity system is the Custom Connectivity Controller (CC Controller) – which coordinates wireless access points to provide access for the provisioned network services and associated devices. The Controller interfaces with the operator OSS/BSS systems and customers via the Custom Connectivity Portal (CC Portal) – which is adapted to the operator's infrastructure. Service and device configuration and monitoring, as well as AP provisioning and deployment, can be performed using the Custom Connectivity Controller API – either via a stand-alone operations interface or integrated with existing network operations interfaces and tools. Similarly, the Custom Connectivity telemetry interface can be used to monitor the health of the network(s) and, along with the network operations interface, provide customer support.

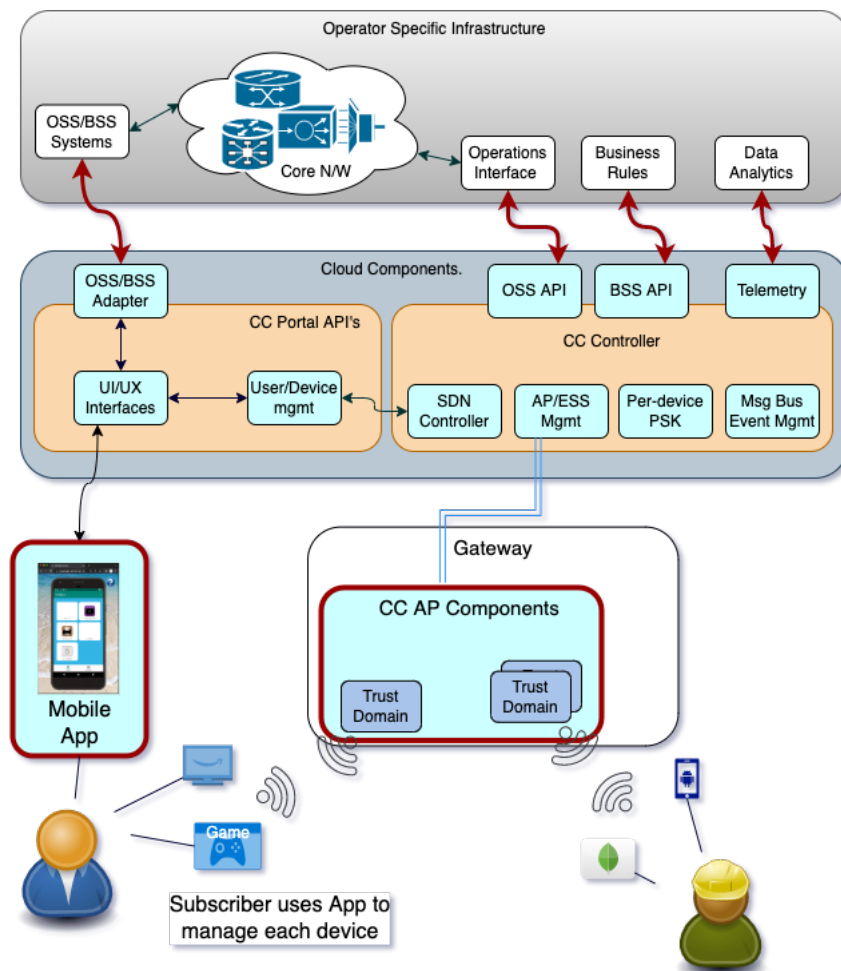

Figure 1: Custom Connectivity high-level architecture

4.2 The Custom Connectivity Controller

The Custom Connectivity Controller contains the information regarding ... and operational state information for the Custom Connectivity network and has the responsibility of keeping all parties in a Custom Connectivity network synchronized so that all elements are operating with a common network/device model. In particular, the Controller provides:

- REST API's to manipulate the Custom Connectivity Service model
- The Custom Connectivity PSK Engine – for identifying valid PSKs and determining device associations
- A reference operator interface for provisioning Custom Connectivity-enabled Wi-Fi access points
- An MQTT Broker to communicate model changes to provisioned access points
- REST API's to for access points to communicate Wi-Fi telemetry and device connectivity status

4.3 The Custom Connectivity Portal

The Custom Connectivity Portal is the communication bridge between the Controller, operator OSS/BSS infrastructure, and mobile application communication. The Portal is intended to be highly adaptable to the operator network and infrastructure. The Portal is responsible for:

- Interfacing with the provider's customer-facing systems/applications – which can be used by the customer to setup their Custom Connectivity Service, determine funding, establish per-device access rules, onboard Wi-Fi devices, confirm device additions, and manage their services/devices.
- Communicating with the Custom Connectivity Controller to manipulate the service/device objects on behalf of the customer.
- Communicating customer-initiated service/device changes with OSS/BSS infrastructure.
- Associating Custom Connectivity Services with customer subscription plans and maintaining service according to the subscribed plan and payment status – including handling expiration times/dates.
- Process notifications from the Controller regarding service/device object status changes (e.g. when a device connects/disconnects) and communicating the changes to the customer and OSS/BSS infrastructure.

4.4 The Custom Connectivity Gateway Agent

Every wireless access point that supports Custom Connectivity must include a Gateway Agent provisioned with credentials to connect and communicate with the Custom Connectivity Controller. The Gateway Agent is responsible for:

- Establishing and maintaining a connection with the Controller using credentials provisioned by the vendor and/or operator
- Performing initial setup of the AP by interrogating the Controller and setting up Wi-Fi credentials, VLANs, bridges, and inter-AP VXLAN connections to support the Custom Connectivity services and devices provisioned for the AP the agent is running on
- Handling DHCP requests for Custom Connectivity devices and providing IP addresses according to the Custom Connectivity service model provided by the Controller
- Delegating Wi-Fi 4-way handshake authentication requests for devices which are being onboarded to the Custom Connectivity Controller – which in-turn performs the necessary decryption steps to determine if/which device is associated with the presented password

- Handling MQTT messages from the Controller to update the access point to reflect changes to Custom Connectivity services/devices associated with the access point
- Setting up and maintaining inter-AP VXLAN tunnels – to support the CC inter-AP mesh
- Providing per-device telemetry to the Controller
- Routing Internet inbound/outbound traffic to the access network
- Routing intra-Service device-to-device traffic across inter-AP tunnels when devices within the same Service are connected to different APs (mesh routing)

The Custom Connectivity Reference Implementation includes a reference gateway implementation with the components outlined in Figure 2: Custom Connectivity AP Component

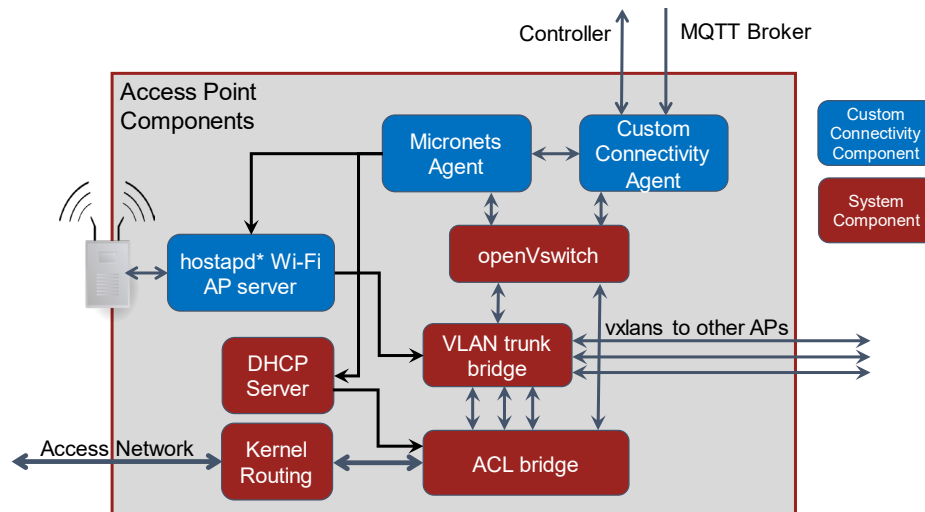

Figure 2: Custom Connectivity AP Components

4.5 The Custom Connectivity Administrative Interface

For monitoring and managing a Custom Connectivity system by network operators and customer support the Custom Connectivity Controller provides a REST Operations API and notification support for enabling web- and/or smart device-based management interfaces. This Operations API can enable existing operation center user interfaces to incorporate Custom Connectivity administrative/support functions and/or enable the implementation of stand-alone management interfaces.

The Custom Connectivity Reference Implementation includes a reference web interface which allows for:

- The enumeration of Custom Connectivity services, devices, AP groups, and APs and their various association
- The provisioning of APs using public keys and registration tokens
- The monitoring of devices with live updates on connected devices and associated APs
- The creation of APs and AP groups, as well as associating/disassociation of APs with AP groups

Some illustrations of the Custom Connectivity management reference web interface can be found in Figure 3 and Figure 4.

Figure 4: Custom Connectivity Reference UI - Service Detail Page

4.6 The Custom Connectivity APIs

The Custom Connectivity APIs are used to manage a common Custom Connectivity entity model. The ability to modify different elements of the model is grouped into four functional areas that have group-level access controls.

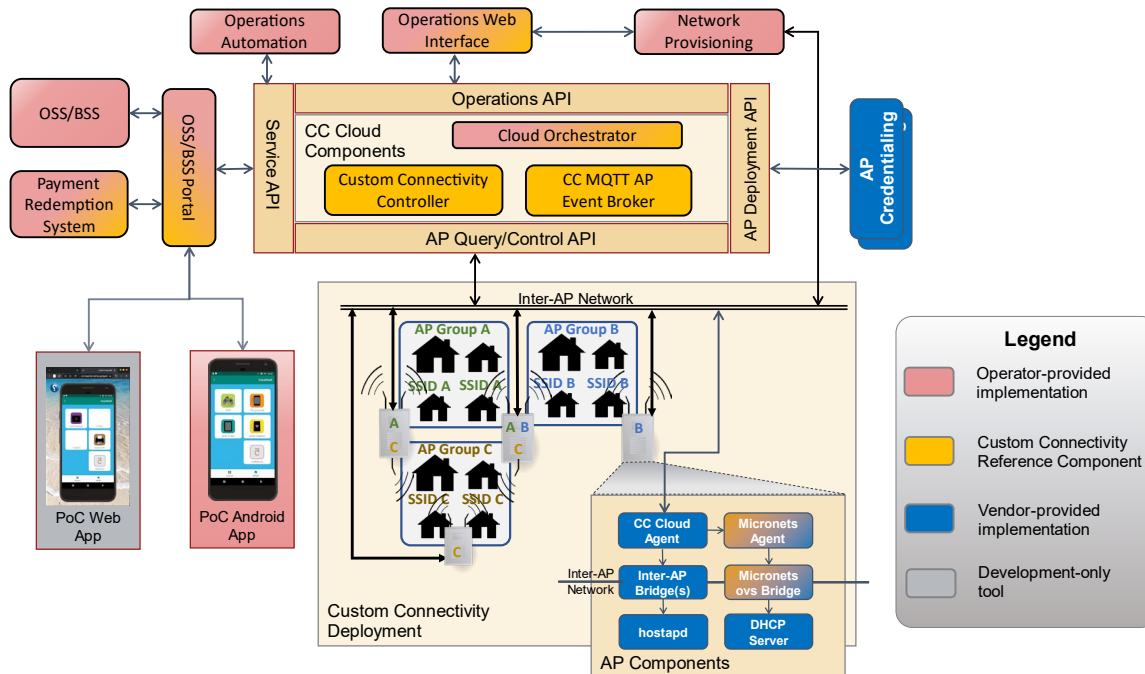

Figure 5: Custom Connectivity Component Interoperation

The Custom Connectivity Controller APIs help ensure interoperability between vendors components, operator components, and the Controller. The intent of the Custom Connectivity architecture – and having well-defined APIs - is to enable either the operator or a service provider to host and manage the Controller on behalf of the operator. This can enable different degrees of regional colocation based on desired cost, reliability, and scaling factors.

The Custom Connectivity APIs are divided into the following functional groups:

- **Service API:** While the Custom Connectivity Portal primarily communicates via interfaces which are OSS/BSS-specific, Portal implementations expose a single REST endpoint that the Custom Connectivity Controller uses to notify the Portal of changes to Custom Connectivity Services and associated Devices. The Portal in-turn uses the Controller APIs to enact changes and enable/disable services and associated devices based on customer subscription/payment changes, service expirations, and/or customer preference.
- **AP Deployment API:** Supports the creation of authentication credentials for APs and putting APs into/out of service. This interface enables credential provisioning in a variety of ways – either at time of AP manufacture/configuration or at initial power-on the AP using provisioning tokens.

APs can also be put into/out of service in a controlled fashion to facilitate replacement, relocation, debugging, and/or network upgrades.

- **AP Query/Control API:** Custom Connectivity-enabled APs are informed of changes in the Custom Connectivity data model via MQTT and update their internal state by performing queries to the Controller regarding affected model elements. APs also use these APIs to update the state of Device elements based on physical device state (e.g. “authenticated” or “connected”) and connection quality (e.g. the station’s RSSI and error rate).
- **Operations API:** These APIs enable operators to administrate and automate the Custom Connectivity system. Network operators and automated tools can monitor the state of the APs, Services, and Devices to help identify potential issues in concert with network backhaul monitoring. APs can be organized/reorganized into different AP groups to optimize the access and backhaul network and ensure sufficient wireless coverage. This API also enables customer service to diagnose device and network connectivity issues and take corrective actions.

5 Panama Trial

5.1 Service Requirements

The Custom Connectivity Architecture described in Section 4 provides an alternate service delivery model that is based on a shared-CPE paradigm and rather than linking a subscribers’ broadband services to the CPE, it focuses on providing those services directly to the devices. This paradigm made the architecture suitable for bridging the digital divide and providing broadband services to the unserved and underserved communities (see [Section 3](#)). Our goal was to validate the architecture by running a limited trial in a representative unserved community. Consequently, a small neighborhood in Panama was selected for the trial where the houses were grouped along a street with utility poles along the street. The service would be delivered through external AP’s mounted to the utility poles and the subscriber’s devices would connect directly to these AP’s. The following technical and operational requirements were addressed for the trial.

- Service to each subscriber was to be provided directly over Wi-Fi without the need to run any wiring to the subscriber’s home
- The subscriber should be able to connect their devices anywhere within the service area and not have to select any specific AP to connect to (seamless to them)
- The subscriber’s connectivity experience should resemble a traditional home Wi-Fi experience where they can connect any device including Smart TV’s, printers, casting devices, tablets, Chromebooks etc. and be able to discover and communicate amongst them.
- The subscriber should be able to connect any standard Wi-Fi enabled device without having to perform any special procedure on those devices (i.e no captive portal interactions, no mac address registration, no custom software). The only interaction required on the device to be connected is to select the service set identifier (SSID) and enter the Wi-Fi passphrase.
- The service provider has the capability to apply rate limits (packet data rates) by subscriber independently, with option to provide different service tiers per subscriber.
- Capability to add extenders (future capability) for improved indoor coverage (with Wi-Fi as a backhaul from the extender)
- Be able to use any backhaul technology including standard FTTH/xPON from the AP’s/shared-CPE’s.

5.2 User Experience Considerations

In addition to the technical and operational requirements described above, another goal for the trial was to ensure that the entire service experience, from service activation to service and device management to billing and payment – was to be kept simple and familiar to the subscriber. In this neighborhood, most subscribers were accustomed to activating and managing their pre-paid cellular plans using pre-paid vouchers that they purchased from the local stores. The following requirements were taken into account while developing the overall user experience

- Since the subscribers were accustomed to using pre-paid vouchers, we leveraged the existing voucher-based BSS system and integrated it with the BSS interfaces on the Custom Connectivity Portal. This allowed the users to use the same pre-paid vouchers to either renew their cellular plans or activate their Wi-Fi based home broadband service plan.
- The only requirement imposed on the user was for them to install and/or use a mobile app that allowed them to self-manage their services - creation of a new account, redeeming vouchers, service activation, adding/managing devices and their credentials etc.
- The subscriber should be able to self-manage their subscription, i.e be able to choose how long they would like their service enabled and be able to suspend their service if they did not need it on a given day.
- The subscriber should be able to renew their subscription as and when needed.

The sequence diagram in Figure 6 shows the overall user experience that was developed and provided in the trial.

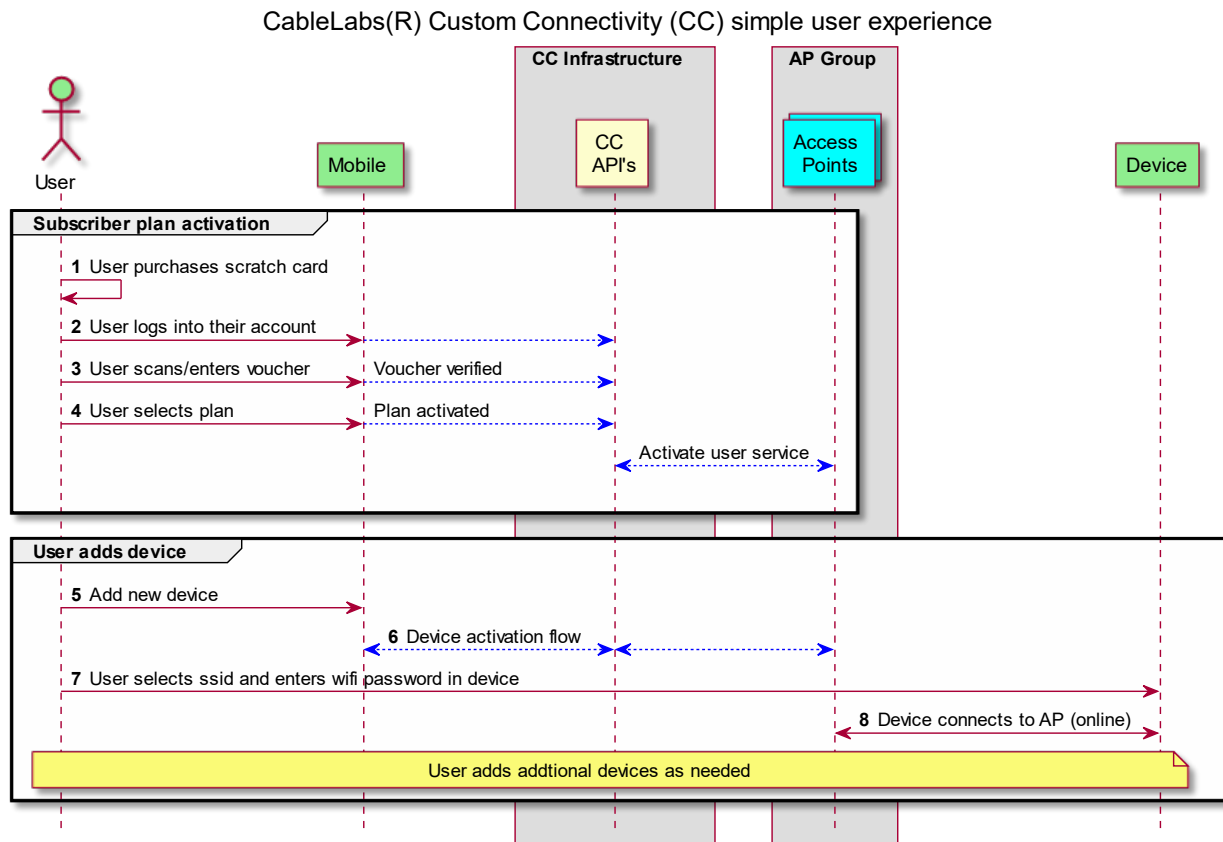

Figure 6: Custom Connectivity User Experience

6 Implementation Details

CableLabs[®] Custom Connectivity offers to deploy Internet access without a drop, a CPE, or an in-home wireless access point. And unlike hotspot or captive portal solutions, Custom Connectivity offers to also provide a complete home network that works with all Wi-Fi devices - including smart TVs, IoT, and home assistant devices. In short Custom Connectivity offers a full CPE+AP experience without a CPE.

We attempt to provide some details below on exactly how Custom Connectivity provides this functionality – and how it can be done in an interoperable multi-vendor way.

6.1 Network segmentation on shared Access Points

The logical segmentation of physical ethernet networks using VLANs has been a reality for decades. When Wi-Fi technology (see [2][3]) was adapted for enterprise use, capabilities were added to enable devices to be authenticated via the use of a user-associated identity/credential. Devices could all join the same SSID with each device being optionally designated for a particular VLAN. While these enterprise features require special Wi-Fi device support (that most home devices don't have) and a complicated AAA server to create/authenticate credentials, this fundamental capability for per-device credentials and VLAN association was and is present in the core Wi-Fi technology today. (see [1])

Using its unique device onboarding system, Custom Connectivity leverages the core capability present in Wi-Fi to associate non-enterprise Wi-Fi devices with an identity, encryption key, and VLAN all on a shared SSID. This means that devices cannot discover, communicate, or observe each other's traffic without explicit policy enabling them to do so. Custom Connectivity utilizes this separation capability to group devices by household (and optionally subzones within a household) into discreet segments – each associated with a VLAN – providing the same separation for a household as one would get with a discreet in-home Wi-Fi AP and switch.

6.2 Per-device credential management

As part of the onboarding process, the Custom Connectivity system provides each device a unique passphrase which is used to provide the device access and, additionally, as a means to robustly identify the device. The process for the user is straight-forward:

1. Using a mobile app (logged into the account provided by the operator), the user selects an option to add a new device to their service (see Figure 7),
2. The user enters a couple details about the device (e.g. a name and device type),
3. The app provides an SSID and passphrase for the new device,
4. The user enters the SSID and passphrase into the device,
5. When the new device attempts to authenticate with the AP, the AP – in conjunction with the Custom Connectivity Controller – performs the necessary cryptographic logic to determine which passphrase was provided by the device,
6. The device completes authentication, and the AP associates the Wi-Fi session with the device – setting up necessary interconnects for the device and signaling the Controller,
7. The controller signals all other APs of the new device to enable interconnects and roaming.

Figure 7: Adding a device using a Custom Connectivity-enabled mobile app

The details of how robust association of devices with unique credentials can be achieved is discussed in a previous SCTE paper, *Wi-Fi Passwords: The Evolving Battle Between Usability and Security* [1].

6.3 Roaming within the Multi-AP mesh

A single AP can only cover a limited area, so Custom Connectivity enables a large number of APs to be grouped together to form an AP group and hence cover a larger area such as a neighborhood or campus. All APs in the mesh will offer identical service, so a client may connect to any AP in the group and even move between different APs within the group at any time. Irrespective of the AP within the group that the client connects to, the client will see their own home network and all their devices connected to it. From a client's perspective, the Custom Connectivity AP mesh acts as a single large AP covering the entire area with a single SSID.

When devices which are part of the same household service are connected to different APs in a Custom Connectivity AP group, inter-device packets must be exchanged between the APs to facilitate the inter-device communication. In Custom Connectivity, this inter-AP communication is accomplished with VXLANs. When Custom Connectivity recognizes that there are devices in the same household/segment connected to multiple APs, the APs establish bi-directional VXLAN channels between the APs to facilitate the device-to-device communication over a shared AP backhaul network.

For device-to-Internet traffic the Custom Connectivity architecture enables each AP to independently egress/ingress Internet access for connected devices without any intermediate network components. See Figure 8 for an illustration of how APs setup VXLAN, inter-AP, and extender connections.

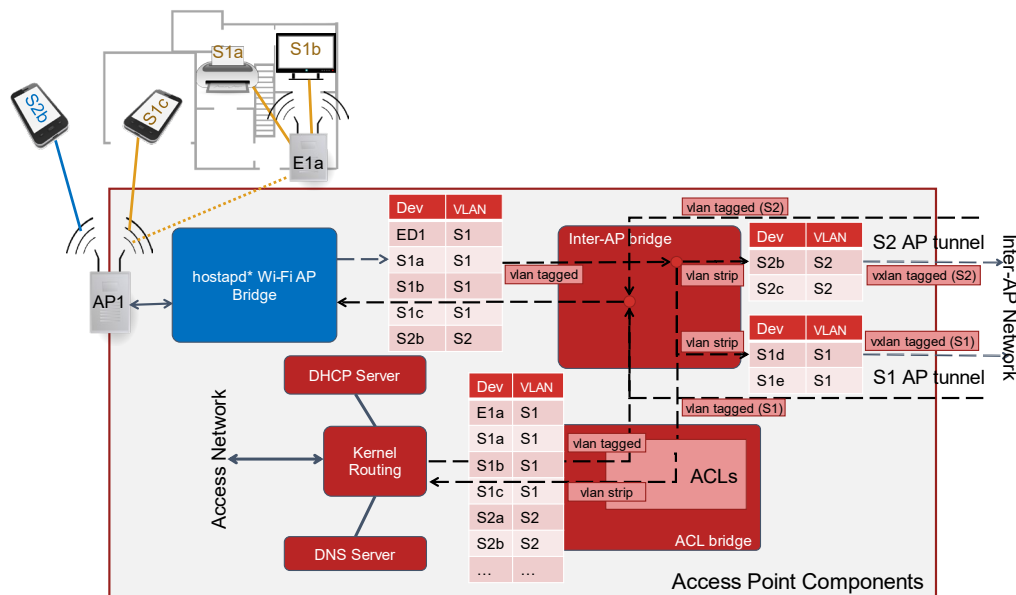

Figure 8: Inter-AP VXLAN, Extender and Access Network Interconnects

6.4 Enforcement of Service policies

Custom Connectivity's device-level identity and visibility allow for a wide variety of user-defined and operator-defined policies to be applied at both the device level and the service level.

For instance, operators likely will want to offer particular service offerings capped particular upload and download speeds. Custom Connectivity allows the maximum downlink/uplink BPS to be specified on a per-service basis – which can be specified by the operator via the Portal. As APs can independently egress traffic for a service, they share their respective egress/ingress rates to collectively enforce the limits using a distributed traffic shaping algorithm. This ensures that the subscriber’s service policy isn’t exceeded, irrespective of the distribution of their devices across the group.

Another example is the ability for users to assign per-device scheduling policy. Custom Connectivity allows for access hours limits to be defined and enforced more robustly than similar policy systems on other offerings. Since the policy is associated with both the identity and credentials of the device, a simple trick like changing the device’s MAC address will not result in policy circumvention.

Many other policies are easily defined for Custom Connectivity – with the same ability to be tightly bound to the service and/or device identity and associated credentials.

7 Conclusion

The success of the trial allowed us to validate the capabilities of the Custom Connectivity architecture and helped us in taking one step closer to addressing the digital divide discussed in [Section 3](#). We also learned a number of lessons from the trial that helped us refine our architecture as well some of the usability requirements.

This proof of concept helped us assert that as part of the overall evolution of cable broadband services and the build out of the 10G platform, the CableLabs[®] Custom Connectivity architecture provides another tool in the overall toolkit to the operators in the form of an alternate device-centric service delivery model.

1. Introduction

Network connectivity products such as Software-Defined Wide Area Network (SD-WAN) or cybersecurity are becoming critical enablers of needed connectivity as businesses of all sizes re-configure and consolidate network services and solutions using software-driven and virtualization technologies. Large service providers such as multiple systems operators (MSOs) who want to provide innovative solutions in this space have been developing expertise that can drive customer success. This paper will use insights from real projects to detail the ways in which those wishing to deploy these technologies can be guided by simple principles and industry best practices to kickstart successful networking platform initiatives.

In the past, connectivity providers have been very successful deploying networking gear, operating it at scale, and delivering value by executing well. They may not have created their business engines around a core of software technologies or on large-scale virtualization in quite the same way the largest internet platforms have been driving their businesses. Hardware-based technologies provide very high performance in a reliably fixed and predictable architecture, with key differences being variations in speeds, feeds, protocols, or connectors. The technologies and expertise needed to launch software products, by contrast, can often feature dynamic architectures having unpredictable variations, needing data-driven insights to manage.

Organizations with different strengths/expertise who now wish to adopt technologies that have grown up in the era of large internet platforms must become skilled in techniques tied to the software-based infrastructure which brought those platforms to life. Comcast's launch of software-driven networking services could be considered as one such case study. Luckily, many of the lessons that were learned were related to a few fundamental software best practices, which are very well-documented and to which all modern practitioners should already have access.

In this paper, we will share a few key challenges and lessons learnt through real projects and detail the ways in which those wishing to move ahead in deploying networking software at scale can be guided to successfully kickstart similar products and platform initiatives.

2. Challenges and Solutions

Software-based network services such as software-defined networking/network function virtualization (SDN/NFV) connectivity approaches involve abstracting network functions and services out of silicon and into software, separating the connectivity service into administration plane, control plane, and data plane vectors, each of which is coordinated and controlled via software components operated as a platform.

The data plane is transported physically over white-box devices with all the logic for routing and services instantiated across the platform. Control plane services allow update to the configurations and changing the behaviors of the data plane, including adding software-based network functions, such as firewall, traffic steering, or anti-virus in line with packet processing (in a process called "service chaining"). Customers and operators manage the control plane services via the admin plane, exposed via application programming interface (API) or graphical user interface (GUI) into complex orchestration software.

In hardware-based network services, all aspects of the service are well-defined and fixed into the design of the devices being deployed. The ways in which the devices can be configured is therefore more or less pre-determined by the vendors. If more capacity is needed, then new hardware is purchased and deployed.

In software-based network services, all aspects of the service might be distributed across multiple software components, each of which could be instantiated on a variety of different hardware options. Each choice in architecture and configuration results in a potentially wide range of capabilities and trade-offs that must be evaluated and carefully calibrated. Different layers of software abstraction, of operating systems and virtualization layers, and of interoperability between the layers, creates combinatorial numbers of variations which could affect the behaviors of the customer service.

Embracing this complexity and developing techniques to make the problems tractable and in line with the strategies for being handled within hardware was a core part of the challenge in successfully deploying a software-based networking product.

Below is a list of high-level principles we embrace in design and operations in order to resolve the above challenges:

- Keep it simple: Leverage **cloud-native architecture** and **standard technologies** like edge routers, border gateway protocol (BGP), generic routing encapsulation (GRE) tunneling, proxies, and load balancers (LB) for system integration.
- Emphasis on standardization of configuration in version-control, combined w/ logical inventory in change management database (CMDB) plus strict change control policies to facilitate **automation-first deployment, move/add/change/delete (MACD), & disaster recovery (DR)** for operations to reduce unforced errors
- Embrace **test-driven development** using fully-automated unit and integration tests to ensure version-after-version quality consistency
- Forwarding to data lake, aggregation of time-series data combined with intelligent machine learning, to achieve **observability and data-driven capacity planning**

3. Keep-It-Simple

When introducing the SD-WAN product, our main goal is to integrate vendor solutions seamlessly with our existing eco-systems and business strategies.

Nowadays cloud infrastructure virtualization has become a dominating technology because of the set of benefits it brings. These include a wide range of hardware selections, improved economies of scale, reduced costs to resource efficiencies, operational flexibility, and faster time-to-market, etc. To keep our product competitive in the market, we embraced the “keep-it-simple” design principle and make use of industry standard technologies and best practices. For example, we adopted cloud-native architecture design, deployed our platform services in geographical-redundant data centers (DCs), and utilized standard networking technologies to facilitate communications between DCs and to the Internet. Figure 1 below illustrates the high-level architecture design of our cloud-based SD-WAN platform.

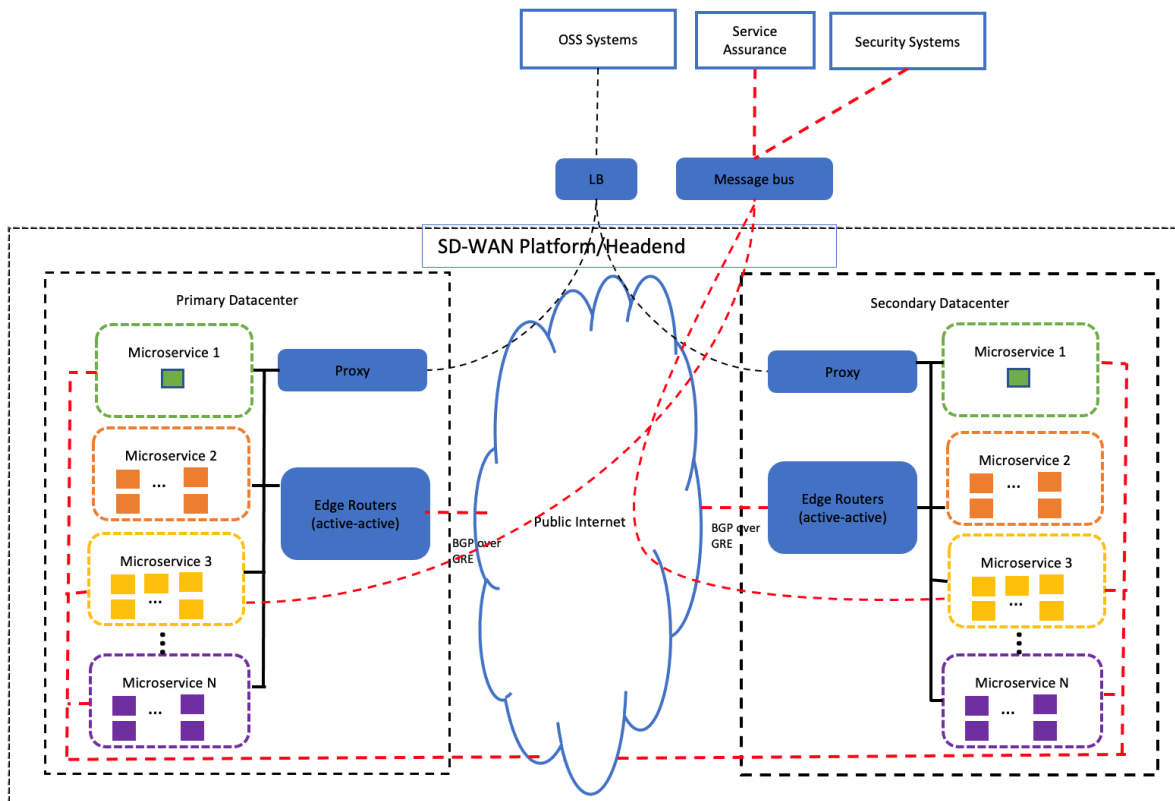

Figure 1 – SD-WAN Platform Architecture Design

Microservices are the core of cloud-native architecture design. The complex SD-WAN control plane and management plane functionality is broken down into multiple microservices, each of which serves a specific function and could scale in/out independently based on its workload. We take advantage of microservices because they support DevOps, and improve scalability, while also allowing flexibility with respect to infrastructure growth. Within the same data center, microservices are interconnected with one another via traditional technologies, e.g., application programming interfaces (APIs), load balancers (LBs), etc.

To achieve SD-WAN platform high-availability (HA) and guarantee business continuity, we deploy our platform (including microservices and data) across geographically diverse DCs (i.e., located in different regions of the country). This geographical redundancy approach is an industry standard best practice that provides business resiliency against natural disasters and catastrophic events which might bring a DC down for certain period of time. Even when disaster happens and one of the DCs is down, our platform remains available since services are still running in the other DC. Once the impacted DC is recovered, everything returns to normal. Different microservices in Figure 1 have different HA designs (e.g., active-backup, active-active, or cluster-based) depending on the nature of the functionality and requirements.

To keep the design simple but efficient, we also adopted standard network technologies to facilitate the inter-connectivity between data centers and the communication between the SD-WAN platform and applications/devices from the Internet. As shown in Figure 1, edge routers and Border Gateway Protocol (BGP) over Generic Routing Encapsulation (GRE) are used to provide HA and dynamic traffic steering for components to communicate with each other between DCs. Standard proxy and load balancer

technologies are adopted to facilitate the communication between upstream systems and components in our platform. Message buses are used to distribute platform telemetry data to service assurance systems and security monitoring systems.

With these high-level design principles in mind, we keep refining and optimizing our platform architecture to make it more scalable. For example, we observed that breaking down big microservices into smaller microservices is an effective way to reduce per-platform cloud footprint. Figure 2 and Table 1 show that our optimization could successfully reduce the per-platform cloud footprint by 9%, 9%, and 62%, respectively, for the best case scenario, the average case scenario, and the worst case scenario. This benefit grows with the platform capacity. When the platform capacity doubles, per-platform cloud footprint could be further reduced by 19%, 19%, and 82%, respectively, for the best case scenario, the average case scenario, and the worst case scenario.

Figure 2 – SD-WAN Platform Architecture Optimization

Table 1 – Per Platform Cloud Footprint Reduction for Different Scenarios

Scenarios	Current Capacity	1.5 X Current Capacity	2 X Current Capacity
Best case	9%	21%	19%
Average case	9%	15%	19%
Worst case	62%	82%	82%

4. Automation-First Lifecycle and Test-Driven Development

When silicon-based network capabilities get implemented as software distributed across multiple components, whether or not on a cloud platform, the pattern is still microservices, and each software component provides a subset of overall system functionality. An orchestration function is then frequently placed between the components to coordinate the components into more advanced processes, such as enabling a new network feature by updating the customer configuration. In some cases, each microservices component might be a separate software product in itself, with its own behaviors and release schedule. This distributed structure provides maximum flexibility and reuse, and can allow for simplification and different optimizations for the operator, at the possible cost of complexity of implementation.

In our case, service reliability was of paramount concern. Given the wide range of network features and functionality being launched, the tight integration between the administration plane and the control/data plane behaviors demanded a comprehensive validation of all capabilities for backwards compatibility, to prove the proper working of all services before moving any new software code to production. This was a non-negotiable requirement, in order to preserve the confidence of customers and operations that software changes would not be disruptive to their experience. But we soon found that traditional approaches to bench testing would not alone be enough to capture sufficient details regarding the individual health and wellness of each component independently, let alone to build a comprehensive picture of overall service reliability.

While we understood that minimizing any risk of disruption would necessitate comprehensive regression before every significant change, we also knew that the tedious manual testing exercises of the early development phase would not suit the needs of our customers. Our approach shifted towards development of a custom, reconfigurable testing platform, integrated with our continuous integration/continuous deployment (CI/CD) pipeline. This high-level framework is depicted in Figure 3. It resulted in reliably repeatable validation cycles, covering an ever-growing set of test cases across all components. This switch to automated testing added new development in the sense of coding test cases, but eventually test design and coding merged into the same practice. Overall, it cut our testing cycles by multiple orders of magnitude, allowing us the flexibility to increase velocity of deploying the latest code, resulting in faster improvement of reliability and features releases to our customers.

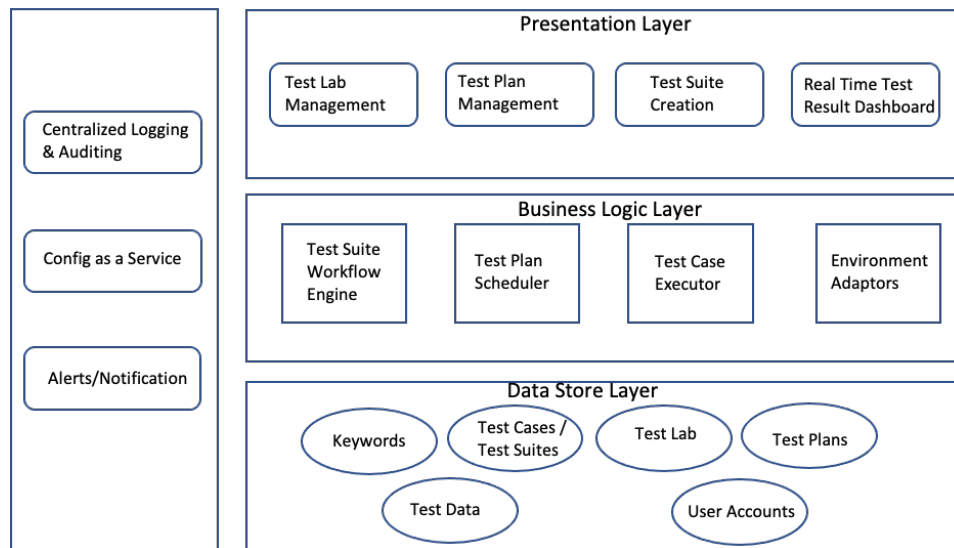

Figure 3 – Test Automation Framework

We also addressed several important challenges. For one, we could not always rely on a fixed set of software versions in production; that is, in the field, due to many different teams operating over time and different field requirements or business realities, there could be different versions of each component running, other than what got initially deployed. All these different variations would need to be supported uniformly from a feature perspective. Further, operations teams maintaining microservices-based systems, having numerous components with different behaviors distributed geographically, would face the tedious exercise of having to manage extreme amounts of detail during maintenance windows, requiring large teams of highly-skilled engineers maintaining superhuman focus for hours at a stretch, attending to every detail when performing upgrades.

The most crucial aspect of successfully managing these details turned out to be perhaps one of the most difficult to achieve in practice: configuration standardization, such that the configurations being tested and deployed have known behaviors that can be used as baselines when our teams are trying to resolve something that isn't behaving as expected in the wild. This is something done very well in software, but very difficult to achieve manually. These system complexities made clear that manual administration of even a small number of environments would be untenable over time. As has been discovered by other software-driven organizations, we resolved that an automation-first strategy was required to make even simple administration tenable.

Another early indicator that tipped the scales towards platform automation was the realization that there would be numerous instantiations of the fundamental datacenter software stacks which powered our service – so many, in fact, as to make manual administration of all those system instances impossible in practice. There could never be enough skilled engineers to manually log in and take care of all the many traditional Day 2 activities which invariably would arise when running complex software systems – password changes, template updates, patches, even disaster recovery. Neither could these systems reliably and repeatably be deployed, day after day, week after week, retaining the same level of quality with the 15th as with the first; nor could they reliably be restored after a disaster using a manual checklist alone.

We thus adopted a platform strategy for our systems lifecycle applications, a technique that is also widespread in the software industry. Starting with a common framework of basic services, such as data, API, GUI, communications, and logging, we ensured that all applications participating in this platform would also enjoy common performance and availability optimizations, such as blue-green deployment for live upgrades, and site-diversity for fault tolerance. On top of this framework was developed a portal, into which bits of functionality could be dropped. Initially just a wrapper for some crude management utilities, it has become the one-stop-shop for platform operations teams, who leverage automation at every step in the lifecycle of our production systems. The portal's extensibility enables it to be used not only for large milestones such as deployment, upgrades, or disaster recovery, but also to perform more routine tasks such as license management, password rotation, and security patches.

The most important benefits from the repeatability and reliability of this standardized approach to operations are clear and have proven value from the start; many serious issues that could typically have resulted from hand-crafted configurations, varying from environment to environment, have been completely avoided. Taken as a whole, the benefits due to the automation are irrefutable, with time-in-motion improvements typically measured in (sometimes multiple) orders of magnitude, as illustrated in Table 2. To paraphrase computing legend Larry Wall, it "makes hard tasks easy, and impossible tasks possible."

Table 2 – Platform Lifecycle Automation Benefits

Platform Lifecycle Category	Execution Timeline Improvement with Automation
Regression Testing	>99%
Production VM Build / Software Deployment	92%
Disaster Recovery / High Availability Testing	>70%

5. Data-Driven Proactive Monitoring

Modern operational visibility has expanded beyond sysadmins and ITOps analysts. It is required not only to monitor the status and performance of running applications/services/systems and to detect issues in real-time but also to understand why, project the trends, and provide feedback to DevOps teams and customers. Additionally, the nature of cloud technology and SD-WAN technology, namely the separation of data plane, control plane, management plane, virtual resource, and physical resources, adds more complexity to the platform monitoring and data analysis.

Following the industry standard, we embrace data-drive proactive monitoring approaches and cross-layer correlation to achieve observability at all layers. It is a straightforward architecture pattern which allows us great flexibility in adding or changing features and service. Figure 4 shows our high-level data-driven monitoring architecture design.

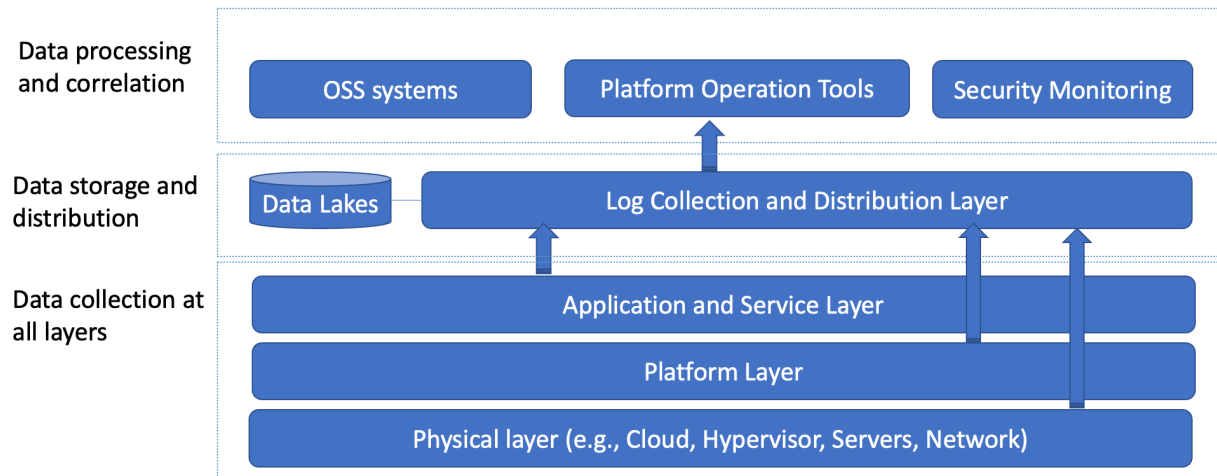

Figure 4 – SD-WAN Platform Data-Driven Monitoring

The data collection layer utilizes industry standard tools or vendor supported features to collect data and provide observability from all layers, including the physical layer (e.g., cloud, hypervisor, servers, hosts, network, etc.), the platform layer, and the application/service layer. The data collected includes all three pillars – logs, metrics, and traces – that are needed for observability.

The data storage and distribution layer uses industry standard technologies and shared platforms to store and distribute telemetry data to the upstream systems. The volume and velocity of the data needed for observability is huge. Thus, our design requirement on systems and platforms used at this layer mainly focuses on scalability, performance, and HA.

The data processing and correlation layer consists of multiple systems that are designed and developed to provide visibility from different perspectives. For example,

- Customer portal: provides the overall health status at the customer service level.
- Operation team tools and portal: provides in-depth health status of all layers from an engineering perspective.
- Security monitoring portal: provides in-depth telemetry data from a security perspective.

Our data-driven monitoring infrastructure has become a critical piece in the entire product ecosystem. It provides insightful information and feedback from many product perspectives, as in Figure 5 (a) below.

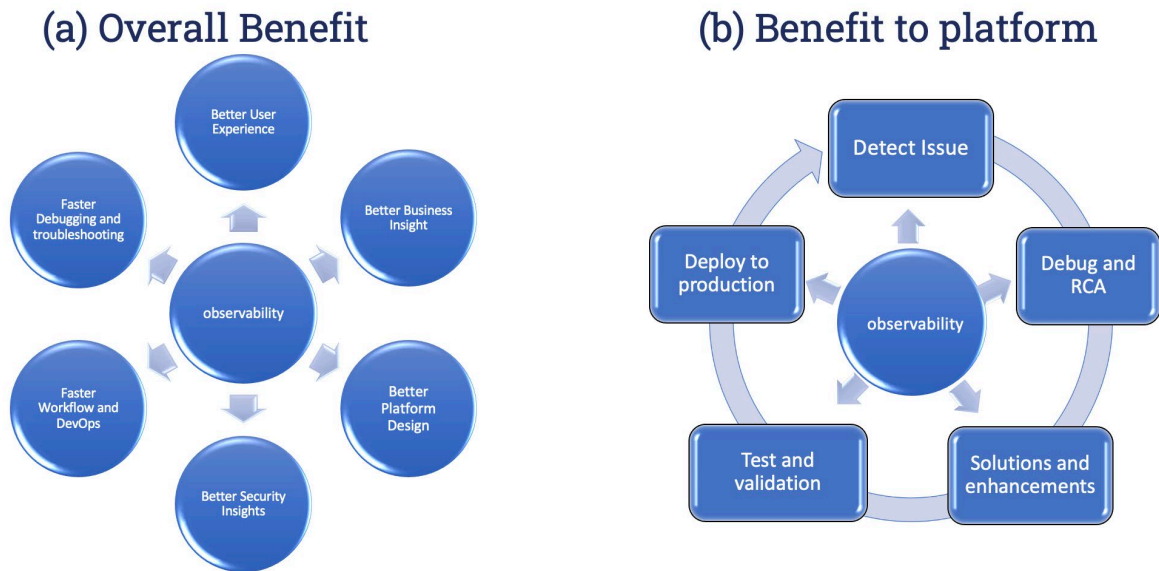

Figure 5 – Benefits of Observability

From a platform perspective the main benefits include but not limited to:

- Fast operation reaction to issues: we are collecting health metrics from all layers and triggering notifications to our operation teams to react. The correlation of collected data from all layers also assists in troubleshooting and debugging process, helping operation teams and platform architecture teams to identify the root causes and fix issues even before customers report them (as illustrated in Figure 5 (b)).
- Health metrics collected from the physical layer and the platform layer help us to look for signs that indicate resources may soon run out of capacity, enable us to predict the growth and trend, perform capacity planning, and trigger operation teams to scale out platform components. Figure 6 illustrates the microservices growth projection with increasing platform capacity. The calculation is based on the observability data collected in production. As shown in the diagram, with the increasing platform capacity, different microservices need to be scaled out differently depending on the projected workload. Some microservices do not require to be scaled out even when we plan to double the platform capacity.

Figure 6 – Microservices Growth vs Platform Capacity

In addition, using standard technologies in design and developing this data-driven proactive monitoring infrastructure helps to reduce development cost, to achieve required scalability and reliability, and to hire talent to maintain and operate the platforms.

6. Conclusions

It was the intention of this paper to detail the ways in which we have found that simple software industry best practices could be implemented to great effect as part of the operationalization of networking services. These include leveraging standard networking protocols for implementing core availability behaviors, standardizing configurations in order to apply an automation-first approach to change management, embracing test-driven development to validate changes as quickly as needed by the business, and employing insights collected using modern data management approaches to forecast growth and anticipate changes. Although common among many industries, these techniques differ from hardware-based approaches due to their inherent flexibility in relation to dynamic virtual and distributed software-based systems, allowing greater reliability and availability to be offered.

Abbreviations

API	application programming interface

1. Introduction and Motivation

A passive optical network (PON) that has the benefits of point-to-multipoint passive topology for highly efficient fiber utilization has become the dominant optical access architecture for the operators in the current fiber to the premise (FTTP) deployments. The global PON equipment market is forecast to grow at a compound annual growth rate (CAGR) of 12.3% from 2020 to 2027, approaching \$16bn in 2027, from \$7bn in 2020. FTTP infrastructure builds are gaining momentum in most countries, with the global fiber access household penetration forecast exceeding 47% by 2026 [1], representing more than 1.1 billion subscriptions. Furthermore, 10G FTTP (and higher) is offered to residential subscribers by more than 55 communications service providers (CSPs). Ever-increasing bandwidth demand is the key driver for fiber access, along with demand for low-latency, reduced jitter, and improved quality of experience (QoE) by VR-based games and cloud applications [1].

In a typical PON system, an optical line terminal (OLT) at Hub or central office (CO) performs bidirectional communication with multiple optical network units (ONUs) at customer premises over a passive optical distribution network (ODN). A time-division-multiplexed PON (TDM PON) based on power-split ODN (PS-ODN) represents the most common PON architectures deployed so far. For a TDM PON, the OLT broadcasts the downstream (DS) signal to each ONU in continuous mode on a single wavelength channel. In the case of upstream (US) transmission, each ONU is assigned for a specific timeslot to transmit a burst of upstream data on another wavelength channel. The other type of PON architecture is wavelength-division-multiplexed (WDM) PON. WDM PON assigns dedicated wavelength for each ONU to realize virtual point-to-point optical connection. The corresponding ODN is wavelength-routed ODN (WR-ODN), which has an intrinsic wavelength routing capability through wavelength splitters. Time and wavelength division multiplexed (TWDM PON), in comparison, is the third type of multiplexing technique that combines TDM and WDM. Accordingly, the ODN is wavelength-selected ODN (WS-ODN), which relies on tunable optical filters to provide a wavelength selection capability in the ONUs. Among these different PON architectures, TDM PON offers much higher aggregated bandwidth for efficiently handling bursty traffic and with cost and complexity advantage, becoming the most popular optical access network. Unless otherwise stated, TDM PON is the focus of this paper.

Figure 1 – Standardized PON Evolution

The development of PON systems over the past 20 years has resulted in two families of standards: ITU-T Question 2/Study Group 15 (Q2/15) and IEEE 802.3 Ethernet working group, as shown in Figure 1. Guided by the telco-led Full Service Access Network (FSAN) Group, the ITU-T PON systems are defined primarily in ITU-T recommendations, which cover the system and architecture, physical medium dependent (PMD), transmission convergence (TC), and management layers. The IEEE PON systems are defined by a combination of PMD and data link protocols in IEEE 802.3 while the management/system layers are defined in IEEE 1904.

The G.983 asynchronous transfer mode PON (APON) and broadband PON (BPON) were the first standardized ITU-T PONs in late 1990s with a line rate of 155 Mb/s to 622.08 Mb/s symmetrically. The next PON was the most widely deployed gigabit PON (GPON), standardized as ITU-T G.984 in 2003. The GPON speed was extended to 2.5 Gb/s in the downstream. The maximal reach is 20 km, with a maximal split ratio of 1:64. The Ethernet PON (EPON) is the first type of PON standardized by the IEEE in 2004 as 802.3ah. Data are transformed by Ethernet frames with the line rate of 1.25 Gb/s symmetrically, maximal reach of 20 km, and a split ratio of 1:32. For 10G line rate per wavelength PON, the 10G EPON standard was released in 2009 as 802.3av with 10.3125 Gb/s symmetrical line rate. Then next-generation PON (XG PON) was standardized in 2010 as ITU-T G.987, and the speed was increased to 10 Gb/s downstream and 2.5 Gb/s upstream. The next-generation PON stage 2 (NG-PON2) was standardized in 2015 as ITU-T G.989 with TWDM architecture. The NG-PON2 supports 4–8 wavelengths with broadband speed of 10 Gb/s per wavelength and 40–80 Gb/s aggregated capacity over a single fiber. The next-generation symmetric PON (XGS PON) is a symmetric version of XG PON with 10 Gb/s line rate for both downstream and upstream.

Going beyond 10 G line rate per wavelength, the IEEE 802.3ca Nx25G EPON Task Force recently defined a system based on 25 Gb/s line rate [2]. The initial objective was to standardize a 100G-EPON by bonding four 25 Gb/s wavelength channels together and was scaled back to a 2×25 Gb/s system in November 2017 as neither the technological maturity nor the market needs were present. On the ITU-T side, in 2021, a suite of G.9804 Recommendations or G.hsp was developed in the ITU-T for a 50 Gb/s line rate PON system with a vision of laying the groundwork for future ITU-T PON systems. Common transmission convergence (ComTC) layer in G.9804.2 is defined in a line rate (with fundamental line rate of 12.4416 Gb/s and line rate factor of 1, 2, 4...N) to form the nominal line rate $12.4416 \times N$ agnostic of transmission rates, number of operating wavelength channels, and signal modulation and thus applicable to future TDM and TWDM PON systems [3].

For each generational PON development, operating over deployed ODNs and coexisting with legacy PON systems are two essential system requirements because ODNs are the biggest investment, and they have a lifetime much longer than technology cycle. These requirements can minimize the infrastructure cost and ease a smooth and non-disruptive migration towards new PON system. In comparison, the physical (PHY) layers in ITU-T and in 802.3 are largely equivalent because they both need to support similar operators' ODNs and leverage the common optoelectronic components and devices. The PHY layer generally handles the line rates, coding, forward error correction (FEC), wavelength plan, transceiver optical characteristics, ODN loss budget, reach, and coexisting systems.

All these standardized PONs employ simple intensity-modulation and direct-detection, IM-DD technology with non-return-to-zero (NRZ) format. Standardization of early generation PON was fairly straightforward. Between each adjacent generation, the main considerations were about increasing the data rate, higher launched power, or better FEC to fulfill a 29-dB or higher loss budget, which is the basic requirement for coexistence with legacy PON or reuse the deployed ODN. As shown in Figure 2, 25G EPON adopted low-density parity-check (LDPC) coding at the bit error rate (BER) threshold of 10^{-2} instead of keeping (Reed-Solomon) RS coding of XGS-PON at 10^{-3} . It is expected that 50G PON will

further improve the coding gain by using soft-decision LDPC. It is envisioned that 100 Gb/s per wavelength and beyond will be required in the future to meet continuously growing bandwidth demands. To reach 100 Gbps, IM-DD OLT and ONU transceivers are required to be more advanced, and a much higher degree of complexity compared to previous generational PONs. analog to digital converter (ADC) and digital to analog converter (DAC), and digital signal processing (DSP) unit are required to mitigate or equalize bandwidth limitation penalty, device linearity, and transmission impairments. A high launch power from a range of 8 dBm to 11 dBm is needed potentially with optical amplifiers on both OLT and ONUs for IM-DD 100G PON to stay within the required power budget. Achieving such a high launch power at an ONU side is still too challenging in the upstream. In addition, fiber dispersion causes significant penalties for high-baud-rate signals. Coexistence with traditional PON services makes it challenging to find a suitable transmission wavelength window in the O-band. Therefore, for increasing the data rate for a single wavelength, limited sensitivity will become too challenging for the 100G TDM-PON to meet the required power budget by using direct detection in the O-band, not to mention extended power budgets to cover the long-reach or high-density applications.

Figure 2 – Technolog Options in 100G PON

Coherent optics, on the other hand, more easily reaches 100Gbps because it divides the speed into 4 lanes, two polarizations each with amplitude and phase makes technology operate at 1/4 of the line rate [4]. Coherent optics, a game-changer optical fiber transport technology, has completely transformed optical transmission systems and enabled a widespread upgrade and new deployment of DWDM networks to speeds of 100 Gbps, 200 Gbps, and 400 Gbps per wavelength. Over the past decade, coherent optics has moved beyond its long-haul application origins to metro networks and now it has been introduced into access networks. Employing coherent optics in a PON offers many advantages. Coherent PON (CPON) is like traditional PON with point-to-multipoint topology over passive ODN. However, CPON uses multi-dimension modulation and coherent detection to provide longer reach and higher split ratio with improved optical power budget.

Compared to alternative direct-detect solutions that just use amplitude to represent the signal, only one dimension, coherent optical solutions (shown in Figure 3) use a high-power local laser source as a reference to achieve linear conversion of the optical field instead of optical power used in direct detection. This enables modulation and detection using four independent degrees of freedom, including amplitude and phase in two polarizations. With a local oscillator, significant coherent gain is provided along with wavelength selection without the need of an optical filter. Additionally, power fading induced by chromatic dispersion in direct-detection system is no longer an issue because of optical field recovery in

coherent detection. All these features coherent optics bring to optical transport systems, enable greater modulation efficiency and receiver sensitivity. Coherent detection for short-haul networks enables a superior receiver sensitivity that allows for extended power budget. Its high spectral efficiency enables dense WDM (DWDM) and lead to higher capacity channels and fewer optical ports providing operational simplicity that may lead to overall network savings. Moreover, the multi-dimensional signal recovered by coherent detection provides additional benefits to compensate linear transmission impairments such as chromatic dispersion (CD) and polarization mode dispersion (PMD) and its most efficient use of fiber spectral resources results in more optical spectrum available for future use and enables future network upgrades using multi-level advanced modulation formats [5].

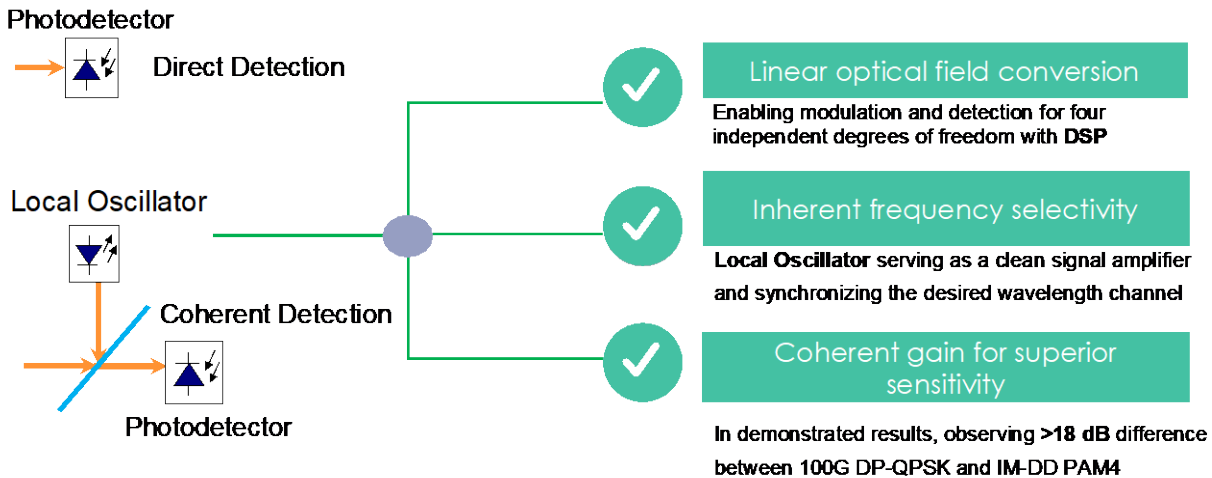

Figure 3 – Technology Comparison: Coherent Optics vs. IM-DD

2. CPON Deployment Scenarios and Use Cases

Leveraging its high sensitivity and powerful digital equalization of fiber transmission impairments, CPON offers unprecedentedly high degree of flexibility in terms of transmission distance and split ratio. Figure 4 shows measured 100G CPON split versus transmission distance topology options along with derived 100G target topology options after adding commercial implementation margin. CPON enables the service provider with significant flexibility on the network topology and reach [6]. Depending on different deployment scenarios, one can choose either very high split ratio at short reach, i.e., 512 split at 20 km transmission distance in Case 1, or low split ratio at longer reach, i.e., 16 split at 80 km transmission distance in Case 2 for rural applications. A hybrid mode in Case 3 that combining various split ratio at different transmission distances can also be achieved, i.e., a CPON port is first tapped at 20 km with a 90/10 passive splitter to support 64 splits, then tapped at 40 km with a 75/25 passive splitter to support 32 splits, finally at 80 km it supports another 8 splits. Case 3 represents the distributed CPON architecture to optimize optical power delivery over passive ODNs. The ample link margin enables flexible deployment of distributed CPON architectures where optical couplers with optimized coupling ratios can be used in a distributed fashion as the need for CPON connectivity is geographically dispersed. Each coupler diverts a fixed or adjustable portion of the CPON signal to a local splitter with the number of ports suitable for the demand of local CPON ONUs. As traffic and penetration evolves, the coupling ratios need to be adjusted. Incorporating adjustable and remotely controlled couplers enable automation and streamline operations.

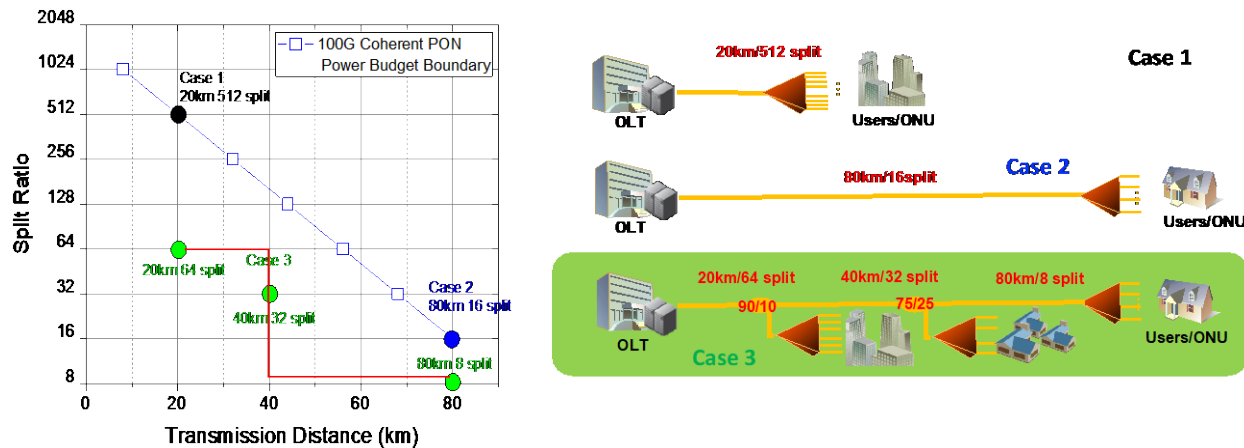

Figure 4 – Split Ratio and Transmission Distances for 100G CPON link

With the increase of CPON ability in higher capacity, longer reach, and higher split ratio, its applications are now extended to support many more optical connections. These include the new radio access network for the high-capacity x-haul transport of 5G and beyond 5G mobile networks, enterprise and business, access aggregation architecture, and even to data centers' aggregated connections. All these present new opportunities as well as challenges of a single platform for convergence of broadband wired and wireless access networks.

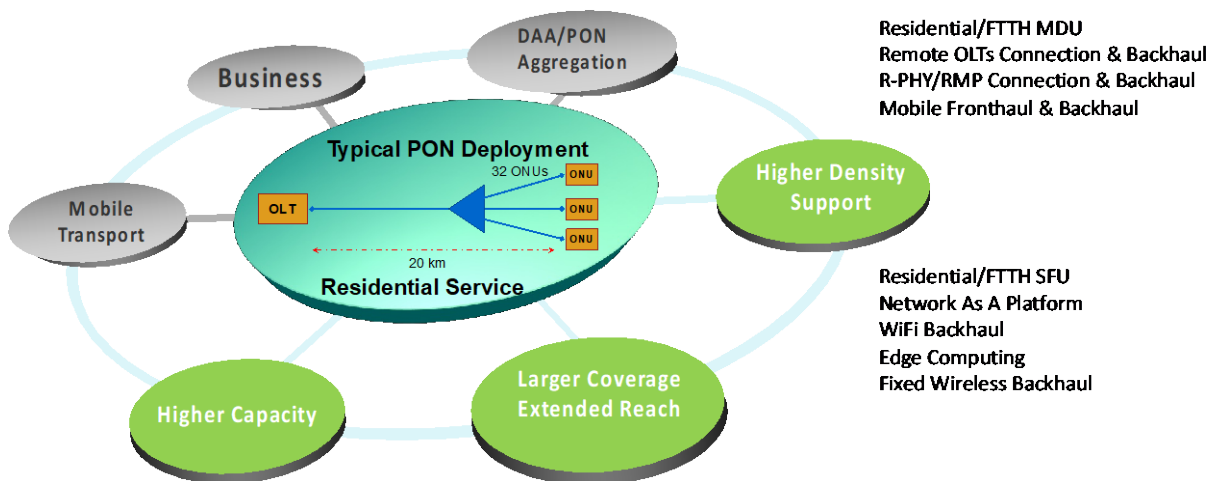

Figure 5 – Extended CPON Use Cases

CPON supports the use case of fiber-to-the-home (FTTH) connectivity. This includes direct fiber connection to either multiple dwelling units (MDUs) or single-family units (SFUs), as shown in Figure 5. CPON offers high density connectivity in densely populated areas, or long link distance connectivity in rural areas and other sparse/lower-penetration environments. In greenfield FTTH deployments without existing services, CPON deployment would ease operations in future years. In brownfield FTTH deployments with existing IM-DD PON, a CPON network could be overlayed using Coexistence modules (CEX), allowing the operator to gracefully migrate certain customers to increase revenue opportunities or lower congestion for other customers on the ODN. Network operators have wireline networks extending to multiple network edge devices that connect to end points such as residences, enterprises, or wireless

access points. Links connecting edge devices consolidate at an aggregation node and are transmitted on a single optical link to a Hub/CO. CPON can be used to support back-haul connectivity to the aggregation node. The aggregation node, for example, can contain multiple remote OLT (R-OLT) devices, which moves the OLT out of the Hub/CO to the aggregation node location that is located close to ONUs. This Remote OLT case could be an important bridge for applications where the distance exceeds IM-DD limits, but where the capacity does not yet exceed the offerings of an IM-DD PON service. The aggregation node can also contain Remote PHY devices (RPDs) and Remote MAC-PHY devices (RMDs), to support distributed Converged Cable Access Platform (CCAP) architectures which offer operators great flexibility and low-cost deployment benefits.

Another use case for CPON is to provide mobile x-haul services. For example, CPON can be utilized to provide base station connectivity and carry back-haul traffic in 5G RAN. CPON can also carry traffic from the mid-haul/front-haul segment of 5G RAN. In this use case, beside meeting peak capacity requirement, CPON will be designed with reduced system latency leveraging low latency MAC mechanism for example, to meet the low latency requirements of 5G RAN.

In addition to FTTH, aggregation connectivity and mobile x-haul, CPON also supports a wide range of existing or emerging applications. For example, CPON can provide access point connectivity to carry Wi-Fi traffic or support fixed wireless back-haul and provide radio connectivity to carry fixed wireless traffic. CPON can serve to connect the users to edge computing nodes/devices located at the Hub/CO sites or provide connectivity from Hub/CO sites to edge computing platforms such as edge nodes near end users/subscribers. Furthermore, a point-to-multipoint local network infrastructure such as Passive Optical Local Area Network (POLAN) can leverage CPON to deliver data to multiple end users within campuses or buildings. CPON can also be adopted in emerging applications such as IoT-based Smart City, or Industry 4.0 Smart Factory, providing connectivity to many sensors and smart devices.

3. CPON Key Technology Development

Despite the numerous advantages offered using coherent optics in next-generation PON systems, major engineering challenges associated with CPONs for access applications remain. The coherent technology in a long-haul optical system utilizes best-in-class discrete photonic and electronic components, such as state-of-the-art digital-to-analog converters (DACs)/analog-to-digital converters (ADCs) and DSP ASIC based on the most recent CMOS process. These solutions are over-engineered, too expensive, too big, or too power-hungry for the access PON. Cost is the first challenge that must be resolved to introduce coherent optics into access networks. A PON is eventually directly connected to end users and is therefore highly sensitive to the cost of the optical and electrical components used in the network because of the enormous market involved. Therefore, the lasers, modulators, coherent receivers, and DSPs in an access network must be optimized to lower the complexity, cost, and power consumption. Meantime, it is worth noting that the total cost of ownership (TCO) should be considered here instead of single device or equipment. Coherent optics fiber spectrum reclamation not only alleviates the pressure to retrench new fiber, but also the low transmit power of coherent optics leads to the ability in placing a larger number of optical carriers on a single fiber strand. Looking at this from an overall system cost perspective, the usage optimization of fiber resources leads to a lowest cost per bit transport [7].

The cost of coherent detection can be broken down into several parts: the laser source, transmitter, receiver, and DSP. The first three parts are mainly optical and electrical components that can be simplified in many ways. In long-haul transmission, laser sources on both the transmitter and receiver sides are generally expensive, high-quality, narrow-linewidth (typically less than 300 kHz) external cavity

lasers (ECLs). Basically, two laser sources are needed in one transceiver, including one signal carrier and one LO. One solution for cost reduction is to use fewer lasers in the ONU. Using a remote laser source from the centralized OLT for each ONU would reduce the overall cost by distributing the laser cost over the whole network. Lower cost distributed feedback (DFB)/distributed Bragg reflector (DBR) lasers, with linewidths of higher than 1 MHz, can also be introduced in coherent systems with minimal impact in performance for access applications [8-9].

Another major simplification is related to the transceiver, especially on the receiver side. A full field optical coherent receiver is typically used in long-haul transmission systems and consists of four pairs of balanced PDs (8 PDs) with polarization and phase-diversity homodyne coherent detection. Consequently, four ADCs are required for signal processing. This setup could be simplified by using fewer PDs. The use of heterodyne coherent detection can halve the number of required balanced PDs, ADCs, and associated TIAs. The system could be further simplified by removing the polarization-diversity receiving system and using polarization scrambling or a special polarization-time block coding method [7].

Therefore, coherent systems traditionally have come at a greater cost, but through access specific re-design, significant simplification and reduction in power consumption can be achieved. In this section, a few potential key technologies developed for CPON application are discussed.

3.1. Optical Phase Modulation

As modulators with low V_{pi} are developed, a simpler modulator design becomes an attractive alternative to traditional IQ modulators. An optical QAM coherent modulator could be implemented with a single-phase-modulator by directly modulating the laser to vary the amplitude, thus trading modulator driver signal complexity with a lower optical loss present in nested IQ modulators. Figure 6 compares a traditional nested IQ modulator structure with a simplified modulator using single-phase-modulator per polarization.

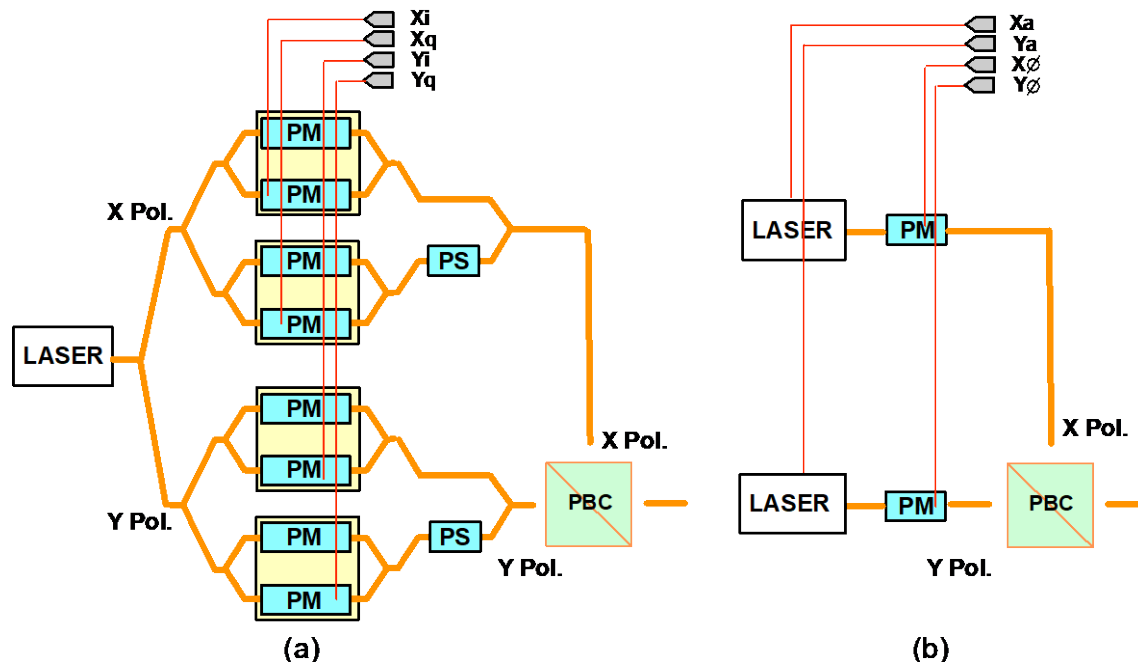

Figure 6 – Conventional IQ (a) and Simplified Optical Phase (b) Modulation Structures

This modulator alternative is simplified for a quadrature phase shift keying (QPSK) signal as no amplitude modulation drivers (X_a , Y_a) are needed. We verify the results by testing the performance of 12.5 GBaud polarization multiplexed PAM-4 signal, which is equivalent to 12.5 GBaud polarization multiplexed QPSK after phase domain modulation. Phase domain multilevel signal modulation and post-equalization is verified here with coherent detection. The results of a signal in different stages of receiver-side DSP process are shown in Figure 7. Clearly, obvious phase domain inter-symbol-phase interference (ISPI) exists, with large phase fluctuations on four QPSK phases. By comparing Figure 7 (d) and (e) or comparing Figure 7 (c) and (f), we can see significant improvements.

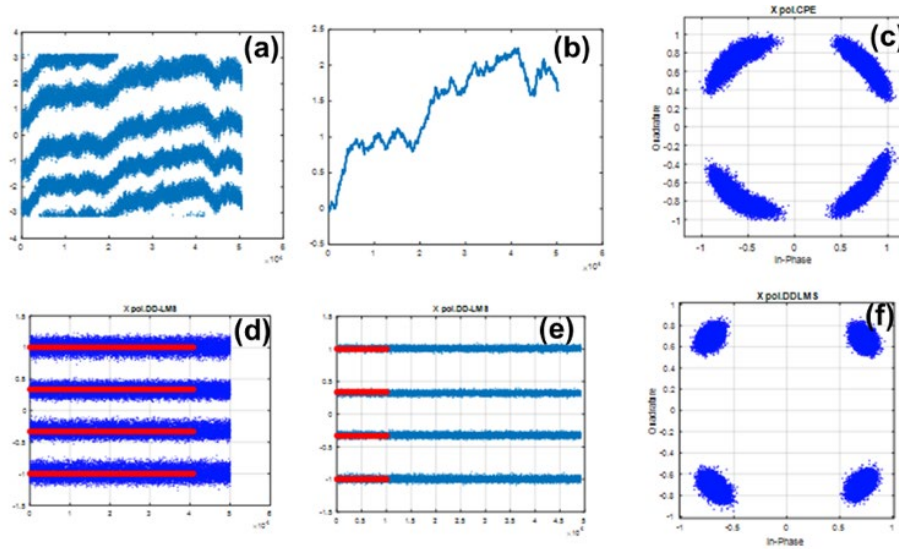

Figure 7 – Signal in Different Stages of Receiver-side DSP Process. (a) optical signal phase after frequency-offset estimation; (b) estimated optical signal phase noise; (c) QPSK signal constellation without phase domain equalization; (d) corresponding phase of QPSK signal in (c) mapped back to PAM-4 signals; (e) equalized PAM-4 signals after phase domain post-equalization; (f) QPSK signal constellation with phase domain equalization.

3.2. Simplified Carrier Phase Recovery (CPR)

In conventional CPR process, the independent phase estimation is performed for both polarization signals respectively. L-tap symbols are used for the center Symbol $S_{n+L/2}$ phase estimation based on 4th power Viterbi-Viterbi (VV) CPR or Blind phase search (BPS) algorithm as shown in Figure 8, where S_n is the n^{th} received symbol. As an example, for a QPSK signal with four phase states, the received complex symbols are first raised to the 4th power to remove modulation and make sure that only the phase noise is present. The $S_{n+L/2}$ is then added to N predecessors and successors to average the estimated phase. Because the phase varies over the range of 2π , the estimated phase must, therefore, be “unwrapped” to provide a continuous and unambiguous estimation of phase. After the phase “unwrapping”, the compensation of an estimated phase error is performed with respect to the received complex symbols.

In the simplified CPR process for the hardware-efficient DSP flow, two steps are proposed. phase noise estimation is firstly performed at only single polarization direction and then shared with the second polarization signals as shown in Figure 9. Data-aided or blind estimation methods is then used for the fixed phase rotation estimation & recovery of the second polarization signal. In this way, only one dynamic phase noise estimation is performed, which is time varying with high computation complexity.

Fixed phase rotation estimation is a one-time process and the computation complexity is negligible when compared to dynamic phase noise estimation.

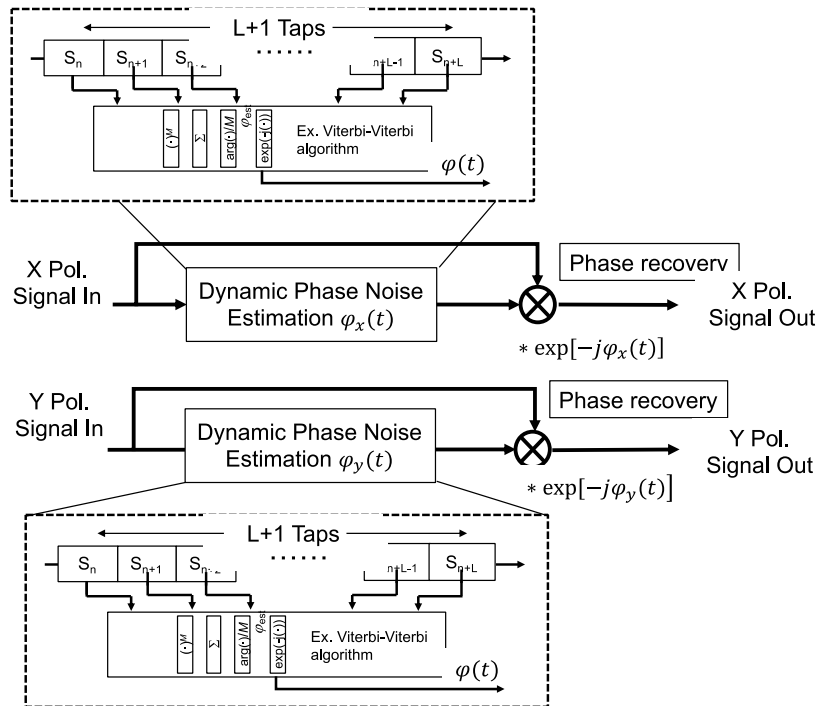

Figure 8 – Conventional CPR Process

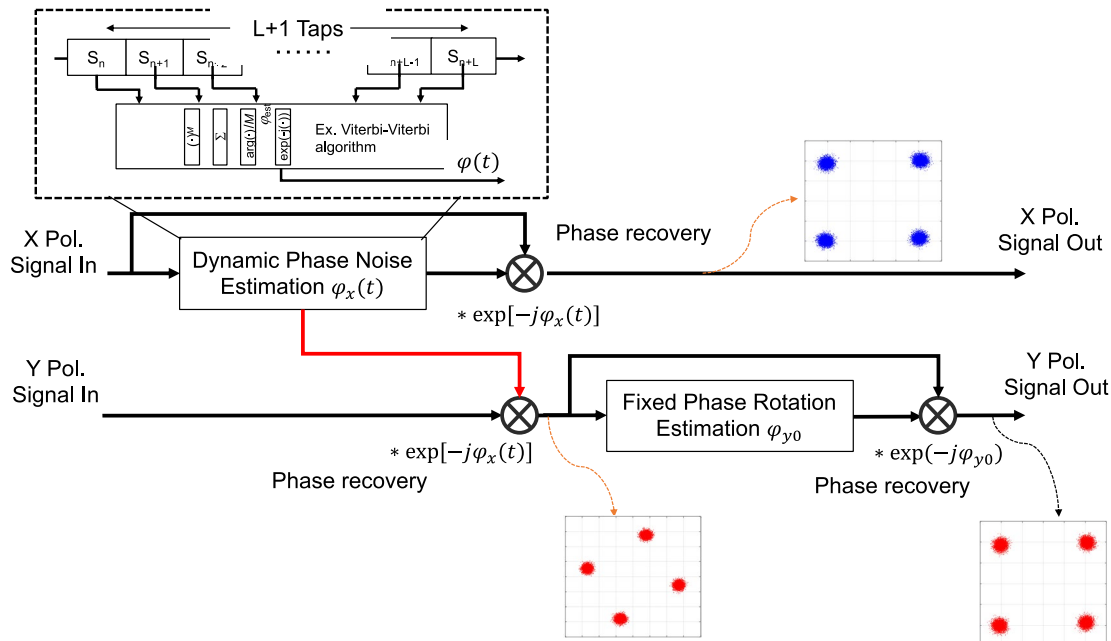

Figure 9 – Simplified CPR Process

Figure 10 shows the conventional and simplified CPR results. In the conventional algorithm (a), the independently estimated dynamic phase noise for X and Y polarization has the same phase evolution with a fixed phase offset. Since the independent phase noise from fiber nonlinearity is rather small at access distance, the phase noise in the two polarizations shows the same behavior except the fixed phase rotation. Figure 10 (b) shows the effectiveness of the simplified CRP process in the simplified DSP flow with the use of one polarization phase estimation result and fixed phase rotation for the other polarization.

Figure 10 – Phase Estimation Results for Two Polarizations

Figure 11 (a) shows BER performance with different fixed phase rotation estimation methods. It is clearly seen that training sequence (TS) and blind estimation have very similar performance in the condition of fixed receiver power at -38.3 dBm. It also shows that 64 symbols of TS or average window size shows the converged results for fixed phase rotation estimation. Figure 11(b) demonstrates the optical power sensitivity comparisons with conventional and proposed CPR methods for both QPSK and 16QAM signals. The results show the simplified method can apply for different modulation formats and no obvious performance degradation is observed by using fixed phase rotation estimation compared to conventional methods.

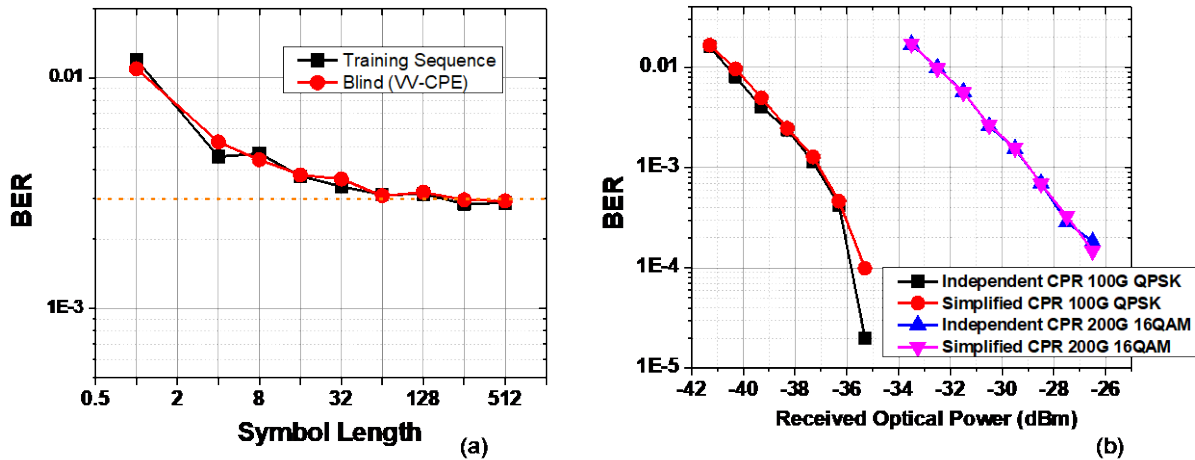

Figure 11 – BER Performance Comparisons

3.3. Preamble Design and Burst Signal Processing

One of the key challenges for CPON is the realization of upstream coherent burst-mode detection when coherent optics is brought to point-to-multipoint connection with a TDM fashion. Burst-mode coherent detection generally includes burst-mode linear amplification and burst mode DSP. Burst-mode amplification is required to deal with different signal power levels and enlarge the dynamic range. As considerable challenges are still associated with coherent receivers with burst-mode linear TIAs, optical burst-mode preamplification is an effective method of leveling burst signals before these signals are sent to coherent receivers via electrical, optical, or power control of local oscillator. Meanwhile, scheduler knowledge of which ONU is transmitting can also allow receiver to anticipate power level adjustment needed and ranging process can also be used to have the ONU pre-amplify Tx-burst so that it arrives at the OLT receiver at the desired level to alleviate some of the burden on the receiver.

Burst-mode DSP and an efficient preamble design at the receiver side are needed in addition to optical power control. The acquisition time for signal recovery at the coherent burst-mode receiver must be sufficiently short to improve the upstream efficiency. Specially designed preambles and fast DSPs have been reported. In pilot-aided time-domain estimation, a low-complexity widely linear compensation method is used to compensate for the IQ imbalance and burst-mode DSP based on precalculated finite impulse response (FIR) filter coefficients have also been demonstrated to shorten the acquisition time.

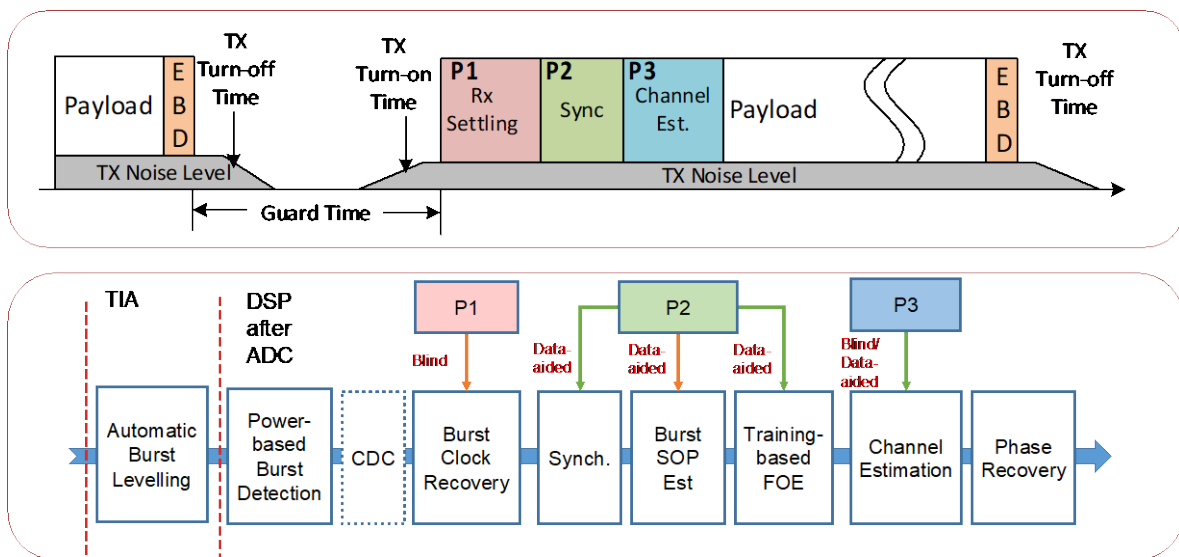

Figure 12 – Preamble Design and Coherent Burst Signal Processing

Figure 12 is a schematic showing the principle of the burst frame structure and upstream burst-mode signal recovery functions for a TDM CPON [10] with different synchronization patterns. Although the general concept is taken from the existing PON standards, most of the preamble patterns and related subfunctions are specially designed for dual polarization coherent bursts. Here, we consider the most complex case in which the optical signals are modulated and multiplexed on the phase, polarization, and amplitude. The proposed preamble consists of three sync patterns, P1, P2, and P3. Based on nearly equally distributed QPSK symbols, P1 is designed for receiver settling with burst-mode amplifications. P1 is also designed for burst clock recovery. P2 is designed for data-aided DSP synchronization functions, including frame synchronization, synchronization, and frequency synchronization (frequency offset estimation). In the design, 2 x N conjugate symmetric symbols are used to demonstrate the feasibility of efficient preamble design and signal processing, where three DSP functions share the same preamble to

reduce the overall preamble length. Based on low-order training symbols (e.g., QPSK symbols), P4 is designed for adaptive channel equalization. Based on the information of the state of polarizations (SOP) estimated by P2, the inverse of the Jones matrix can be utilized to reduce the convergence time of adaptive channel equalization. Finally, the payload process can be simplified using the information from the proposed preamble. High-order modulation formats can be used in the payload block. Finally, the order of these preamble patterns and burst mode DSP functions may differ from that shown in Figure 12, depending on the algorithms used.

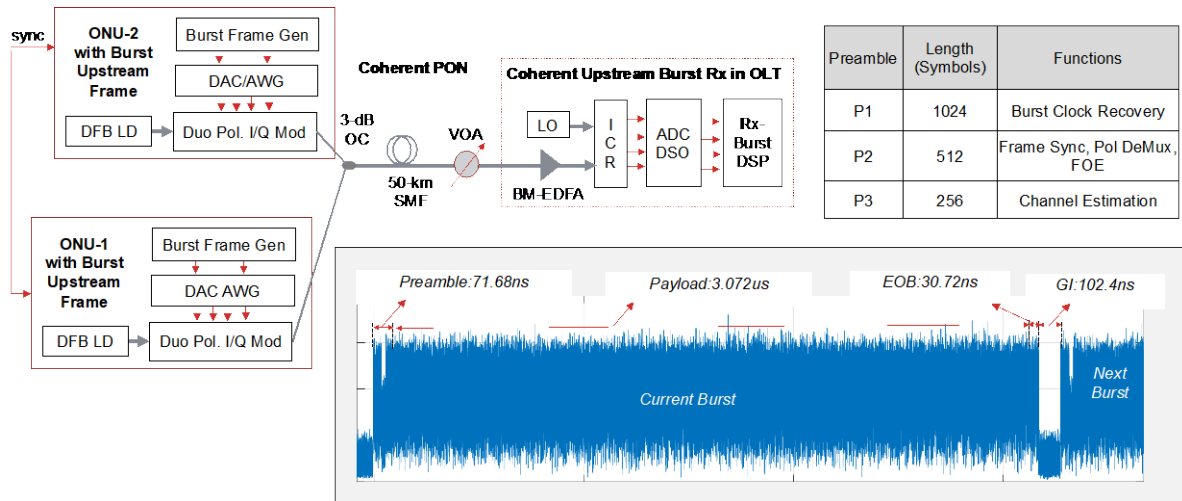

Figure 13 – Experimental Verifications for Coherent Burst System

Based on above preamble design and burst-mode DSP, we set up the experimental demonstration of coherent upstream burst detection in 100-Gb/s/λ TDM CPON, as shown in Figure 13. To evaluate the performance of upstream burst signal detection, two synchronized ONUs are running separately. At the ONU-side, the burst frames of 25-GBaud PDM-QPSK with the proposed preamble and structure as described in Figure 12, are generated by the 80-GSa/s arbitrary waveform generators (AWGs). Then the generated burst frames are fed into the dual-polarization I/Q modulators with four drivers for optical signal modulation. Here, we use a tunable DFB laser at 1550-nm wavelength with a linewidth of ~1-MHz as the laser source in each ONU. After modulation, the burst signals from ONU-1 are combined with a dummy signal from ONU-2 by a 3-dB optical coupler (OC). To avoid collision, the burst frames from two ONUs with same setup are staggered. Through the automatic bias-control and synchronization between two AWGs, the burst signal from one ONU is only coupled with the null signal from the other ONU.

The combined burst signals are then transmitted over 50-km single-mode fiber. The received optical power is controlled by a variable optical attenuator (VOA) for BER test. At the OLT-side, a burst-mode EDFA is used for signal pre-amplification. The pre-amplified signal is mixed with local oscillator (LO) in an integrated coherent receiver (ICR) for coherent detection. A tunable ECL at 1550m-nm is used as LO in OLT, and its linewidth is < 100-kHz. After coherent detection, the received signals are sampled by an 80-GSa/s scope and then processed via the offline burst-mode DSPs described in Figure 12. The detected power waveform of burst frame is shown in Figure 13 with the detailed configuration, and the summary of preamble unit length and functions is that P1, P2 and P3 have 1024, 512 and 256 symbols, respectively. Therefore, each burst frame contains a total preamble length of 71.68 ns (1792 symbols), a payload of 3.072μs, an end of burst (EOB) of 30.72 ns. A guard interval time of 102.4 ns is used to separate bursts. It is worth mentioning that the coherent preamble obtained is lower or comparable with preambles used by the different flavors of IM-DD PON, meaning that efficient preambles were achieved despite the dual polarization and IQ constellation complexity characterizing coherent transport.

4. Conclusion

This paper presents ITU-T and IEEE PON evolutions, the progress and limits of current intensity modulation and IM-DD PON technologies, and the major drivers and use cases for longer reach and higher split CPON. The high-level architectural requirements are discussed, such as the distributive optical taps for efficient power delivery, coexistence of generational PONs. This paper also provides the technology options to simplify the coherent OLT and ONU for cost reduction, and future PON upgrade strategies for different cable operators.

CableLabs[®] announced the launch of the CPON project in May 2021 toward the goal of future proofing cable's access architecture. The objective of the project is to initially develop specifications for 100G passive optical networks and devices that are multi-vendor interoperable, that coexist with existing infrastructure, and that can cost effectively be deployed at scale.

As reviewed in this paper, CPON demonstrates significant performance improvement, it can offer 10 times capacity compared to 10G PON and with the increase of 16 times in split ratio or 4 times in transmission distance, from 20km to 80km. Leveraging such capabilities and CPON synergies with existing HFC architectures, will allow CPON to significantly expand its capabilities beyond traditional residential deployment to support convergence needs at the network edge, from DAA aggregation, mobile x-haul, optical LAN, all the way to future fiber to the MDU and home.

It is worth mentioning the significant advantages that CPON brings beyond speed. Transitioning to coherent transport from IM-DD or analog optics results in a more efficient use of the optical wavelength spectrum. One can use one CPON channel instead of using ten 10 Gbps PON channels, which allow the operator to reclaim optical fiber spectrum just like they did years ago in the coaxial domain when transitioning from analog to digital video. Port reduction at the hub location is another key advantage when transitioning from 10 Gbps systems to 100 Gbps system as it reduces real estate in the router/switch and simplifies operation. The reach that CPON enables leads to pervasive all passive networks, forgoing the need in placing cabinets with repeaters to when link distances exceed 20 km and the operational overhead associated in maintaining and powering repeaters. The split and reach combinations possible with CPON results in great flexibility and homogeneity in the use of technology, meaning one technology that can be used for all services. CPON is a technology that is in a nascent stage with a lot of room to grow.

It is believed that CPON technologies can carry the cable industry for 20, 30, or 40 years into the future, just like DOCSIS has done since 1995!

Abbreviations

AN	aggregation node
b/s	bit per second

1. Introduction

The promise of 10G is emerging, as Full Duplex DOCSIS (FDX) and Extended Spectrum DOCSIS (ESD) solutions make their way through laboratory testing to field trials towards first market launches. DOCSIS 4.0 consists of these two complementary technologies aimed at dramatically increasing upstream capacity and, correspondingly, upload speeds that customers will enjoy.

The FDX option for DOCSIS 4.0 is based on use of spectrum in the 108 MHz-684 MHz band (or subset of the band) for both downstream and upstream. Intuitively, signals overlapping in frequency and time interfere with one another. However, FDX has two key innovations that prevent this. Echo Cancellation (EC) technology removes potential interference where possible. Interference that cannot be removed by EC is *avoided* by controlling transmission timing within the DOCSIS scheduler. FDX sizes up the network and creates groups of users – “Interference Groups”(IG) – that should not access the same chunk of spectrum at the same time. This knowledge is incorporated into algorithms for allocating downstream and upstream resources.

Because the scheduler’s job is to fairly and efficiently allocate time and frequency resources, the effect on traffic engineering arises. In this paper, a deep dive into the mathematical modeling and analysis, based on empirical data from real DOCSIS HSD systems, will be described. The analysis will show:

- How large can an IG be before it effects performance
- What are the implications to IG size and FDX service group size
- What are the relationships among common traffic engineering variables – bandwidth, speed, penetration of services and tiers, service groups size – with the IG element introduced
- How do the results impact network migration strategy

This pioneering analysis breaks new ground on traffic engineering of FDX systems, speaks to key aspects of N+x FDX systems, and promises to be a foundation for field implementation guidelines of DOCSIS 4.0 FDX.

2. DOCSIS 4.0 Full Duplex Overview

Figure 1 illustrates the essential spectrum goal of FDX– enabling significantly more upstream. More interestingly, these new FDX upstream bands (Red “FDX” in **Figure 1**) are also available for downstream! This is quite different than typical Frequency Domain Duplex (FDD) operation, the approach taken in DOCSIS 4.0 FDD. How can both downstream and upstream data exist in the same spectrum? There are two essential innovations in DOCSIS 4.0 that enable this.

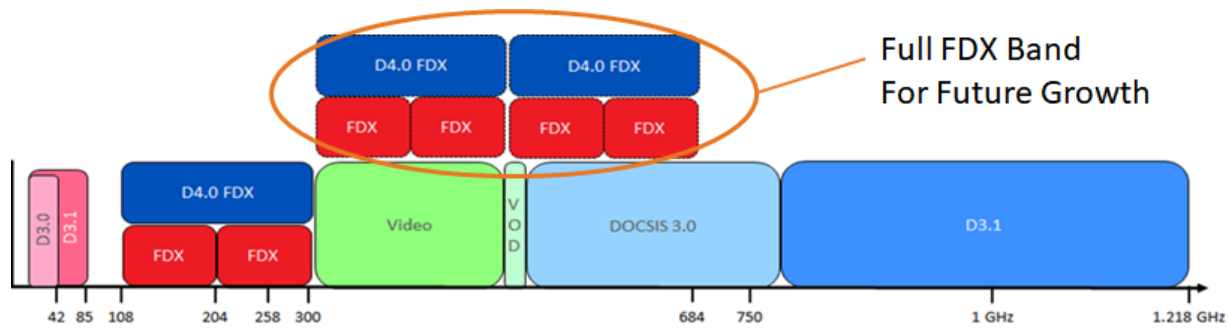

Figure 1 – Massive New Upstream Bandwidth by Sharing Downstream and Upstream in the Same Spectrum using DOCSIS 4.0 Full Duplex (FDX)

2.1. Key FDX Innovations

Although more upstream bandwidth is defined, it is the same 96 MHz OFDMA physical layer blocks that are defined in DOCSIS 3.1, except that the band over which they can operate is expanded. Thus, DOCSIS 4.0 leverages the power of the DOCSIS 3.1 PHY completely. Six additional 96 MHz blocks are added across the 108-684 MHz band, complementing an 85 MHz “mid-split” system.

Downstream and upstream can occupy the same band using a technology known as Echo Cancellation (EC). Echo Cancellation, in general, is a mature technology used in other telecom networks, such as xDSL and wireless. It has not yet been implemented in cable networks. The EC concept is very similar to those other applications, although the cable does introduce some new implementation challenges. EC is the first of the two critical innovations that power FDX.

The second key innovation is based on a fundamental architectural difference in cable systems compared to telco xDSL systems. Twisted pair telco networks are point-to-point connections from the DSL Access Multiplexer, or DSLAM, whereas HFC is a point-to-multipoint system. This logical architecture difference creates the need for another layer of innovation for FDX. This is the creation of Interference Groups (IGs) and Transmission Groups (TGs) for the scheduler to manage.

Figure 2 illustrates these innovations using a passive coaxial network (i.e. N+0) for simplicity. N+0 is NOT a requirement for FDX. In fact, one of the drivers for this paper is the evolution of FDX for N+x networks, whereas the DOCSIS 4.0 specification uses N+0 model types only as reference architectures. FDX-capable amplifiers will support FDX signals over N+x networks, allowing FDX to be implemented over a much wider swath of the footprint more quickly, and more of which is N+x than N+0. As we know from standard HFC networks, RF amplifier cascades impact end-of-line fidelity, and this is no different for FDX amplifiers. However, with amplifiers for FDX, an additional effect comes from the formation of IGs and TGs. As a result, an additional trade space created by N+x FDX networks are maximum speed tiers that can be supported for what amount of user penetration versus amplifier cascade depth. We will briefly discuss FDX amplifiers themselves in a subsequent section.

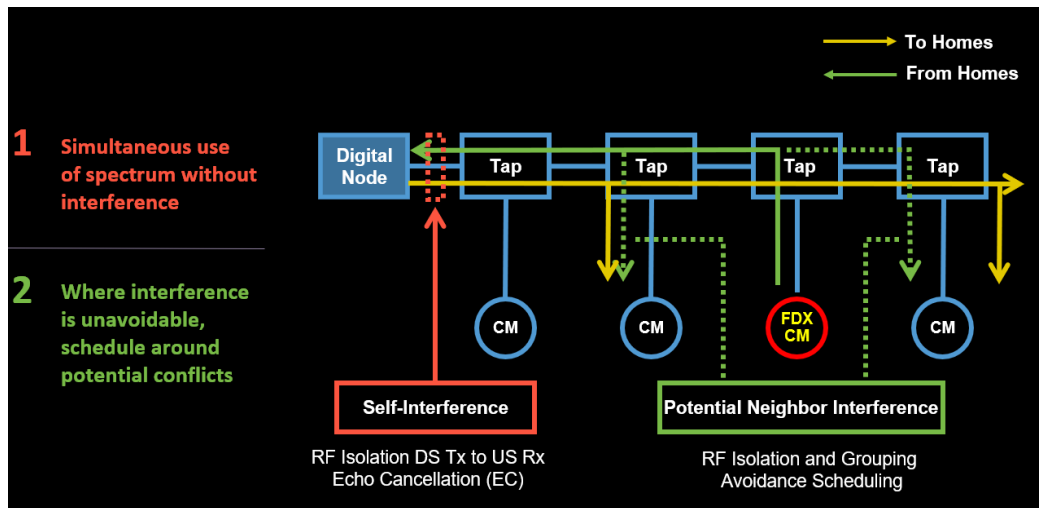

Figure 2 – Two Key New Innovations Power DOCSIS 4.0 FDX: Echo Cancellation and Interference Group / Transmission Group Formation

2.1.1. A Closer Look: Echo Cancellation

Referring to Figure 2, adding upstream signals at frequencies where downstream signals exist requires that the downstream signal be “subtracted” before the upstream (US) OFDMA receiver. This requires high RF isolation and strong EC of the much higher downstream signal that is reflected back into the US receiver. While the implementation details may be complex, the EC concept is a quite simple, and the digital signal processing (DSP) principles to build it are very mature. A simplified diagram illustrating the EC concept is shown in Figure 3.

The node downstream transmit signal will have some of its energy impose onto the US Rx simply through imperfect isolation characteristics of real hardware of an RPHY Node. It will also have some energy reflected back by imperfect RF interfaces as it travels down the coaxial plant, such as from the return loss of a tap, for example. These are the so-called “Echoes” that give the EC function its name. What is distinctive to EC for cable is the high cancellation required across a broad, multi-octave, bandwidth.

Figure 3 – Basic View of Echo Cancellation Concept

For more details describing Echo Cancellation and performance observed, please refer to [6][7][8][9][10].

2.1.2. A Closer Look: Interference Groups and Transmission Groups

As noted, the HFC network is a point-to-multipoint architecture. While an FDX modem knows its own upstream transmission, it cannot know that of his neighbor, and thereby has no way to “cancel” interference from a neighbor. It requires sufficient RF isolation among the homes sharing a coaxial RF segment to prevent FDX-band upstream users from interfering with a neighbor using that band for downstream. Unfortunately, RF isolation among homes cannot always be guaranteed to be high enough. Isolation relationships among homes are determined as part of FDX “sounding” process for DOCSIS 4.0 and DOCSIS 3.1 devices that support FDX-Light (aka FDX-L) functionality. A DOCSIS 3.1 CM that supports FDX-L becomes aware it is on an FDX-enabled network and can participate in the sounding process as a DS “measurer” device.

In situations without sufficient RF isolation, we instead call on the virtual CMTS (vCMTS) scheduler to avoid an interference scenario. Note that the vCMTS refers to the Comcast implementation of the CMTS function using commercial off-the-shelf servers hosting CMTS code and integrated with a DAA system based on a switched Ethernet architecture [7][8]. In an FDD system, the scheduler does not need to pay close attention to the relationship of downstream and upstream access to the coax. This changes in FDX. During FDX “sounding,” the FDX system determines these isolation relationships. Potentially interfering users are lumped into “Interference Groups,” or IGs. A logical set of IGs is called a Transmission Group (TG). Transmission Groups are created because not every IG needs to be treated independently – its overkill to do so, as we shall see later in this paper – and the vCMTS workload can be simplified by aggregating IGs into TGs. The scheduler assures that potentially interfering pairs are not accessing the same spectrum in the same time slot.

Because there are six OFDMA blocks, the vCMTS can service multiple IGs with uniform capacity and speeds by assigning different Resource Block Assignments (RBAs) to each IG. Figure 4 shows an example of how the 108-684 MHz FDX band might be allocated to simultaneously support a case with three TGs. These RBAs can adapt with time based on traffic and peak speed demand.

Note that the FDX band is not all of the DOCSIS spectrum available. Non-FDX DOCSIS 3.1 spectrum and DOCSIS 3.0 spectrum will also exist. Furthermore, not all of the FDX band needs to be assigned at all – more US bandwidth is allocated to FDX as peak upstream speed requirements increase.

Figure 4 – FDX Resource Block Assignment and Sample Band Allocation “States”

2.2. FDX-Capable Amplifiers

The FDX system specifications were written using the assumption of an N+0 network. However, as mentioned previously, FDX is not technically limited to an amplifier-free plant and the specification does not prevent it. In fact, shortly after the FDX specifications were completed, a CableLabs Study Group was formed to evaluate methods for implementing amplifiers that support FDX. The foundational EC

technology developed for the FDX RPD can be applied at any point in the network to manage overlapping spectrum, and this can include amplifiers. Of course, these are not traditional amplifiers, but a new class of device that includes digital signal processing (DSP).

An EC-based amplifier concept is shown in Figure 5. The nature of overlapping spectrum and gain in both directions creates a full-circle loop gain path in the FDX band. The EC must be capable of suppressing the FDX loop gain, such that the net gain around the path is < 0 dB across all frequencies to maintain a stable device. The EC must further be designed to act on the echo it is suppressing sufficiently that the aggregate residual echo noise, which becomes part of the amplifier's own noise floor, supports the US MER requirements effectively for DOCSIS 4.0, without introducing unacceptable MER degradation and subsequent loss of bandwidth efficiency.

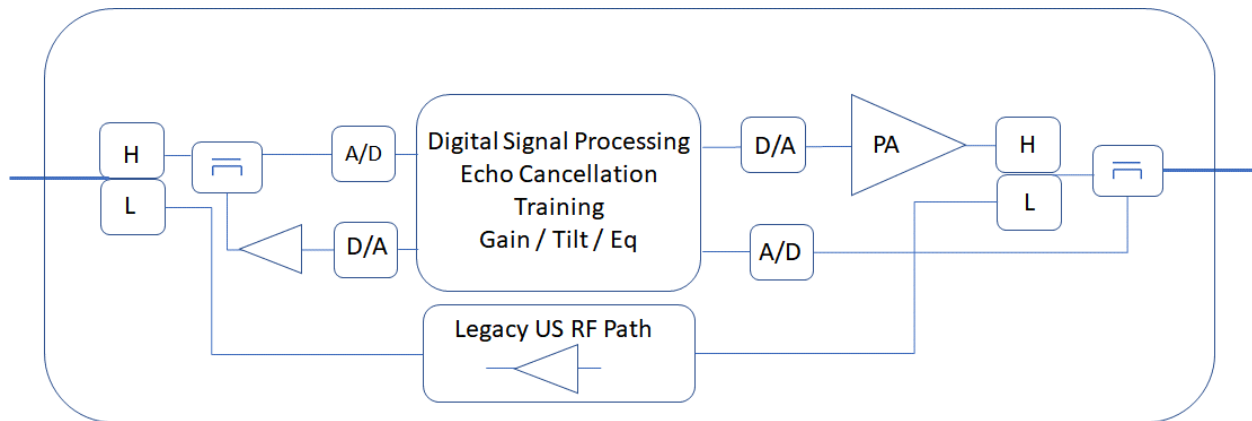

Figure 5 – Topology of a DSP-Based FDX Capable Amplifier

As noted previously, as an HFC amplifier cascade increases, noise contributions aggregate and the MER decreases. For the FDX amplifier, in the FDX band, there is an additional noise contributor in the form of residual echo. The amount of acceptable degradation due to the amplifier is a system engineering parameter that flows from performance specifications ultimately to the performance of the EC itself. A significant advantage for amplifier EC in comparison to an N+0 node output is that the levels on the DS Tx port are lower, and on the US Rx port higher. Thus, the DS to US level ratio is smaller, which is favorable for the EC.

While noise analysis is relatively straightforward for N+x with FDX, traffic engineering requires additional scrutiny due to the shared DS and US and the effect of amplifiers in expanding the size of an IG. Consider the N+1 system shown in Figure 6. When an amplifier is included, there is an expansion of Interference Group 4 (IG4) to the “south,” or home-facing, side of the amplifier. These users become part of the last IG of the tap string before the amplifier. This is because of the limited drop-to-output isolation characteristics of today's taps. This parameter can be optimized for high drop-to-output isolation, but until there was FDX to consider, there was no reason to drive more aggressive specifications for this parameter.

Figure 6 – Potential Interference Group (IG) Elongation due to an FDX Amplifier

3. FDX Traffic Engineering: An Operational Perspective

If we think about network segmentation triggers in current HFC networks, rules have been developed that link service group size, speeds, percent capacity utilization, and total capacity required. Then, with an awareness of device penetrations, this can be translated to DOCSIS 3.0 and DOCSIS 3.1 spectrum requirements and subsequently used to compare to thresholds that trigger a network augmentation.

Similar capacity-based analysis and empirical rule making will now apply to FDX, with one additional nuance. The FDX band, of course, can be allocated for both downstream and upstream. Infrequent bursts of peak speeds can therefore be called upon to service the downstream or the upstream, but they have a new shared resource dependency. The introduction of new terminology for FDX, in particular the terms “Interference Group” and “Transmission Group,” created an unfortunate aura of mystery around how the FDX band operates. This new terminology placed outsized significance on what turns out to be, from a traffic engineering point of view, a relatively benign, and certainly manageable phenomenon. What we have with FDX is a relatively modest “joint access” twist on HSD traffic engineering that we otherwise have been doing successfully for an independent downstream and independent upstream for decades.

Through these decades, operators have learned how to aggregate subscribers in a way that efficiently uses available capacity of the downstream and upstream while still delivering a high Quality of Experience (QoE) to the customer. Generally, operators have created empirically-based guidelines based on the key traffic engineering variables in play – capacity, service group size, HSD penetration, maximum speed, distribution of tiers, D3.1 and D3.0 mix, and also typically including some allowance baked in to account for a projected Compounded Annual Growth Rate (CAGR). Network augment rules have been developed over time to govern node splits, spectrum re-allocation, and device mix policies.

Instead of independent statistics of DS and of US, we now have a portion of the spectrum where resources are shared. However, we already have mature, reliable traffic models for downstream and upstream users! In either case – FDX or FDD – a set of users are sharing finite bandwidth and time resources, and the network design is deliberately NOT a non-blocking architecture, or it would be massively overdesigned. Users “compete” for the finite resources in the DS and in the US. The vCMTS makes decisions on packets sent DS and grants allocated US based on a set of QoE criteria determined empirically, as noted previously. Any individual user’s packets can be deferred for another’s *as part of*

normal CMTS operations – we just refer to it as *load balancing* and/or *fair scheduling*, and we developed rules and configuration settings for how to manage this effectively.

Again, for FDX, the only difference is there are users of DS and US both looking to access bandwidth and time resources, and the CMTS scheduler must accommodate them both. The mathematics and modeling of this joint access situation are in the sections to follow. They will underscore that an irrational “fear” of the Interference Group – seeking to minimize its size to a single Tap or two – was developed without any analysis or evidence to tell us just how big of a TG is too big. It just “felt” bad that US could interfere with DS unless we did something about it, that the two would both be looking to access resources, and one could be denied access in some mini-slot in deference to another. Of course, this happens ALL OF THE TIME in an independent DS or US!

A helpful *qualitative* way to think of the FDX band is to consider the DS users of the FDX band (D3.1+D4.0 CMs) as a service group (SG). Then, the US FDX band users can be considered a smaller set (smaller because D4.0 users < (D3.1 + D4.0) – and largely so for many years) of “new” users looking to, less frequently (because US utilization << DS utilization), access FDX band frequency and time resources. These FDX US “users” just happen to have the same MAC address and billing address of some of the DS users – which of course traffic engineering does not know nor care about. Because the upstream average and peak utilization is so much lower than downstream, and because the aggregate US traffic of a SG fits comfortably into the 85 MHz legacy band for many years of CAGR, except for brief, low-likelihood moments of peak speed bursts >300+Mbps, the FDX Band will be dominated by its use as a downstream channel. If the band was entirely dedicated to the upstream as it would be in an ultra-high split FDD system, it will be *idle* spectrum the vast majority of the time.

In summary, the DOCSIS 4.0 FDX Working Group (note – author’s included!) studied, in depth, the RF side of IGs and TGs, how to determine them, and incorporated it all into the specification. BUT – the working group did NOT do the math on practical implications of this phenomenon to the traffic engineering of the FDX band. We are now doing that Math! THE traffic engineering questions become:

- 1) How large can an IG be before there is an impact to the customer experience?
- 2) What service speed / IG size / spectrum rules exist when downstream and upstream traffic engineering become co-mingled in FDX?

These key questions are addressed in the traffic engineering analysis and modeling to follow. Before diving right into to answering these questions, however, we first take a step back to build up the foundation of burst traffic statistical behavior.

4. Network Capacity Planning

Determining the required amount of capacity needed for a service group (SG) is critical for providing customers with the appropriate quality of experience (QoE). Figure 7 shows an example of a SG upstream (US) capacity usage over a 16-minute window sampled at 1-second intervals. If an operator samples the bandwidth (BW) usage once every 16-minutes, then the purple line represents that average bandwidth for that measurement interval. This is a very useful datapoint but insufficient to determine the required capacity for the SG.

Sampling at 1-minute intervals would capture some of the variations, or ripples in the system but would still miss the many spikes which are individual modems bursting on top of the average BW. The gray line in the figure shows the high-water mark from 1-minute samples.

Figure 7 – Example of Upstream Capacity Usage

If an operator could sample at 1-second intervals or faster, then they could more closely determine the required SG capacity. The 1-second high-water mark is shown by the orange line. But sampling at these rates is not feasible in real systems, so another method is needed.

4.1. The “Basic” Traffic Engineering Formula

The CommScope (formerly ARRIS) team has been providing industry leading research in traffic engineering for many years which was most recently highlighted in [12]. The network capacity analysis in [12] provides an insight into how to calculate the SG capacity requirements. Previously, [4] introduced traffic engineering and QoE for broadband networks. From there, the paper develops a relatively simple traffic engineering formula for service groups which is easy to understand and useful for demonstrating basic network capacity components. Some additional references of note include [3],[5],[11],[13],[14], and [15].

The “Basic” formula shown below is a simple two-term equation. The first term ($N_{sub} * T_{avg}$) allocates bandwidth capacity to ensure that the aggregate average bandwidth generated by the N_{sub} subscribers can be adequately carried by the service group’s bandwidth capacity. The first term is viewed as the “DC component” of traffic that tends to exist as a continuous flow of traffic during the peak busy period. The growth rate of T_{avg} has seen much research. Some new revelations are discussed in [11].

“CLOONAN’S CLASSIC CAPACITY EQUATION” Traffic Engineering Formula:

$$C \geq (N_{sub} * T_{avg}) + (K * T_{max_max}) \quad (1)$$

where:

C is the required bandwidth capacity for the service group

N_{sub} is the total number of subscribers within the service group

T_{avg} is the average bandwidth consumed by a subscriber during the busy hour

K is the QoE constant (larger values of K yield higher QoE levels)...

where $0 \leq K \leq \text{infinity}$, but typically $1.0 \leq K \leq 1.2$

T_{max_max} is the highest Service Tier (i.e. T_{max}) offered by the MSO

There are obviously fluctuations that will occur (i.e. the “AC component” of traffic) which can force the instantaneous traffic levels to both fall below and rise above the DC traffic level. The second term ($K \cdot T_{\max_max}$) is added to increase the probability that all subscribers experience good QoE levels for most of the fluctuations that go above the DC traffic level.

The second term in the formula ($K \cdot T_{\max_max}$) has an adjustable parameter defined by the K value. This parameter allows the MSO to increase the K value and add bandwidth capacity headroom that helps provide better QoE to their subscribers within a service group. In addition, the entire second term is scaled to be proportional to the T_{\max_max} value, which is the maximum service tier being offered to subscribers.

In previous papers [1], found that a K value of ~1.0 yields acceptable and adequate QoE results. [4] provides simulation results that showed a value between $K=1.0$ and 1.2 provides good QoE results for a service group of 250 subscribers. Larger service groups (SGs) would need even larger values of K while very small SGs might use a K value near or less than 1.0.

4.2. The “Modified” Traffic Engineering Formula

Over time, it was discovered that the optimum value for K would vary based on all the inputs: N_{sub} , T_{avg} and T_{\max_max} . Some of these limitations were noted in [13] along with some refinements to the basic formula above. This resulted in the following which is still algebraically equivalent to the basic formula:

Modified “CLOONAN’S CLASSIC CAPACITY EQUATION” Traffic Engineering Formula:

$$C \geq (N_{sub} \cdot T_{avg}) + (K-1) \cdot T_{\max_max} + T_{\max_max} \quad (2)$$

The subtle change is that there are now three main components to the traffic engineering formula:

1. Peak Busy Period Average Consumption (i.e. $N_{sub} \cdot T_{avg}$)
2. Peak Busy Period Ripple (i.e. $(K-1) \cdot T_{\max_max}$)
3. Headroom for maximum Service Tier Burst (i.e. $1 \cdot T_{\max_max}$)

Figure 8 shows how the modified formula maps to the US capacity usage example given above. The basic formula might have used a value of $K=1.2$ in this example. This is now broken into a burst component equal to T_{\max_max} plus a ripple component that is estimated by $20\% \cdot T_{\max_max}$.

Figure 8 – Mapping Traffic Eng Formula to US Capacity Usage Example

Figure 9 – Network Capacity Example for 1G Service Tier

Figure 9 shows a network capacity example for an operator who wants to support a 1 Gbps downstream (DS) service tier on a SG with 150 subs and an average peak consumption of 3 Mbps per subscriber. This requires at least 1500 Mbps of SG capacity. This includes a ripple component of $5\% * T_{max_max}$ which is 50 Mbps. Note that in this example, the ripple component as a function of T_{max_max} is much smaller than the initial $K=1.2$ values because T_{max_max} is significantly higher.

The Peak Busy Period Average Consumption and maximum Service Tier Burst components are well known and easily obtained. Traffic engineering research has since focused on quantifying the Peak Busy Period Ripple component as it is impacted by all inputs, not just T_{max_max} .

4.3. Determining Service Group QoE based on Probabilities

It became apparent that quantifying the SG subscribers QoE needed to focus on the probabilities for SG capacity. And to predict behavior across different SGs with different parameters, a network capacity transmit model for individual subscribers was necessary.

4.3.1. Individual Subscriber Bandwidth Probabilities

Data was collected across an entire CMTS for multiple years during prime-time evening hours. Every packet was captured; associated with a particular modem and service tier; and timestamped down to a millisecond. Big data analytics was then used to find the patterns across the different types of subscribers.

It was discovered that all subs had very similar patterns. Figure 10 shows a very typical sequence that occurs frequently. Around 70% to 80% of internet traffic these days are video which pre-dominantly uses adaptive bit rate (ABR) encoding. The ABR streaming (#1 in figure) is a “grassy” region where traffic is limited by the video resolution (e.g. 5-10 Mbps). A second ABR starts later (#5 in figure) and begins with a burst to pre-fill its video buffers. This burst size is relatively small, limited by the video rate and buffer depth.

Figure 10 – Typical Subscriber Traffic Scenario

Sandwiched between these ABR streams is a file download. For a short instance, it may burst above the modem’s Tmax rate before the DOCSIS token bucket algorithms kick in to limit the transfer to its Tmax value. In today’s world, a 12 MB file download might represent a couple high resolution pictures or a PDF/Word/Powerpoint document. A modem with a 100 Mbps tier might download this in ~1 second while a 1 Gbps tier modem only needs 0.1 seconds.

The Big Data Analytics then determined the BW transmit probabilities for each identified type of subscriber using 1-second windows. It was found that using a window too fast (e.g. milliseconds) made it difficult or impossible to see the patterns while too slow (e.g. minutes) caused the bursts as shown above to be missed. Figure 11 shows the probability mass function (pmf) for a subscriber with a 1 Gbps tier and an average peak consumption of 3 Mbps. [note – the pmf is just a discrete version of the probability density function (pdf).]

Using the 12 MB file download example above, the 1G sub transfers 96 megabits in 0.1 seconds. Assuming the remainder of the 1-sec window is idle, then that burst would correspond to 96 megabits in a 1-sec window below even though the instantaneous rate is 1 Gbps.

Figure 11 – Single Sub BW DS Transmit Probabilities, 1G @ 3 Mbps, 1-sec windows

Being a log scale shows how quickly the probabilities drop for large bursts. Looking at the area under the curve >900 Mbps gives us a probability of 0.00114% which equates to this occurrence of a sustained burst >900 Mbps happening for 1 sec for every 24 peak period busy hours. With ~3 peak period busy hours per day, this means 1 sec for every 8 days.

The Big Data Analytics also found patterns as the Tavg and Tmax are varied from subscriber group to subscriber group. This allows subscriber behavior to be predicted for future Tavg and Tmax values. Figure 12 shows the pmf for a hypothetical user in 2030 with a 4G tier consuming 15 Mbps during peak. Not only does the “Tmax bump” get pushed to the right, but the probability tail gets pulled lower too. The probability of a burst >3600 Mbps is now an order of magnitude smaller at 0.000117%. This maps to 1 sec every 240 peak period hours which might only be 1 sec every 80 days.

Figure 12 – Single Sub BW DS Transmit Probabilities, 4G @ 15 Mbps, 1-sec windows

In the FDX Amplifier Working Group previously described, an example was given for probabilities for subs with a 1 Gbps speed tier and a 2 Mbps Tavg:

- Probability (a single random sub creates a DS burst $> (0.9 \cdot T_{max})$ in a 1-sec sample window) = $3.4e-6$ = 1 second out of every 3.4 days
- Probability (50 subs sharing BW create a single DS burst $> (0.9 \cdot T_{max})$ in a sample window) = $(3.4e-6) \cdot 50$ = 1 second out of 1.6 hours
- Probability (2 subs simultaneously create a DS burst $> 2 \cdot (0.9 \cdot T_{max})$ in a sample window) = $(3.4e-6)^2$ = 1 second out of 2743 years

As can be appreciated, these bursts to $>90\%$ of T_{max} are relatively rare.

4.3.2. Service Group Subscriber Bandwidth Probabilities

Once single subscriber BW pdf's were in place, it is then possible to create a SG BW pdf to analyze the behavior at the SG level. An example of the SG BW DS probabilities is shown in Figure 13.

This is the output of a Monte-Carlo simulation with 100K trials. It is a SG that consists of 128 subs, all of which have a 1G DS service tier. The Tavg = 15 Mbps which represents a time later this decade.

Figure 13 – Network Capacity Example for 1G Service Tier

Note the asymmetry in the curve – there is a much longer tail to the right. Various cumulative distribution function (CDF) probability thresholds are shown (i.e. 90%, 99%, 99.9%, 99.99%) to provide an insight as to the probability the SG BW hits different capacities.

The blue candlesticks in the figure show how the traffic engineering formula overlays the SG PDF. In this instance, the formula said 3,120 Mbps is required. Note that this is sufficient for ~99.5% of the peak busy period time. For the remaining 0.05% of the time, the buffers may be temporarily filled, and some latencies introduced. Note that 0.05% represents ~50 seconds out of every evening. For most of those 50 seconds, the delays should be insignificant and not noticed by users. This is normal network behavior and is why many users can share a single network pipe.

The remainder of the document uses these candlesticks often. Please keep in mind how low the probabilities are for their burst regions as shown above.

4.4. FDX Traffic Eng for Large SG with Overlapping Upstream + Downstream

The FDX Amp use case is leveraging existing plant and may contain many 100's of subscribers. When FDX was conceived, this was not envisioned as a viable use case. In the early days, it was thought that there would be significant overlap between the US and DS in the FDX band. This is shown in Figure 14.

The more that the DS and US peak period average consumption overlaps, then the more important it becomes to have multiple FDX transmission groups (TG).

Figure 14 – FDX Band as conceived, significant overlap, Multiple TG needed

What has subsequently come to light is that the multi-gigabit burst region is dominating our traffic engineering formula. This means that the burst region (i.e. T_{max_max}) is much larger than the consumption component (i.e. $N_{sub} * T_{avg}$). Figure 15, drawn to scale from one of our upcoming scenarios, shows how only the DS + US burst regions overlap in the FDX band. Most of the US traffic fits below 85 MHz while most of the DS traffic stays in the dedicated DS spectrum above 684 MHz.

Figure 15 – FDX Band as understood now, only burst overlap, Single TG needed

In one of our examples, the US stay below 85 MHz for 99.8% of the time and only needs to access the FDX band for 0.2% of the time. Meanwhile, the DS stays above 684 MHz for 99.9% of the time and only needs the FDX band for 0.1% of the time. So, the FDX band is basically providing the burst bandwidth (i.e. 5G DS, 4G US in this case) and the probabilities of US + DS bursts overlapping is microscopic.

There are certain SG capacity requirements that must be met in any system, whether it is FDX or not. These include:

1. $DS\ SG\ Capacity \geq N_{sub}(SG) * DS\ T_{avg} + DS\ T_{max_max} + DS\ Ripple$
2. $US\ SG\ Capacity \geq N_{sub}(SG) * US\ T_{avg} + US\ T_{max_max} + US\ Ripple$

These two traffic engineering (TE) conditions are shown pictorially in Figure 16.

Figure 16 – FDX Band Size – SG Limits

In an FDX world, that means that the DS capacity above 684 MHz plus the DS capacity in the FDX band must be sufficient to meet TE condition #1. This must be met, totally independent of US requirements. Also, the US capacity below 85 MHz plus the US capacity in the FDX band must be sufficient to meet TE condition #2. This must be met, totally independent of DS requirements. In this respect, an FDX network's capacity requirements is no different than any other network.

5. FDX Network Capacity Modeling for Large SG with FDX Amps

Business decisions about the timing and pace of introducing multi-gig symmetric speed tiers will govern the pace of the migration of the network. There is uncertainty in the timing of launching these new tiers, the pace at which they roll-out nationally, and in the traffic growth to anticipate what will have occurred by the time they are launched. Therefore, a range of spectrum scenarios and target speeds were teed up for evaluation to cover what today appears to be realistic representative situations for FDX launch and years into the future of its use.

5.1. FDX Use Case Overview

5.1.1. *Traffic Growth vs Time Considerations*

Table 1 identifies two traffic utilizations that can apply for four different growth scenarios based on CAGR assumptions. If the CAGR is 30% in 2023 and persists,, then, as shown in the table, an average downstream user at peak busy hour will consume approximately 7-8 Mbps downstream and 500 kbps upstream. That same DS/US ratio will also be approximately correct in 2026 if the CAGR is instead 15%.

Similarly, if the 30% or 15% persists through 2026 or 2029, the DS and US will be approximately 15 Mbps and 1 Mbps, respectively. Of course, the further out the model is taken, the more uncertain it is, as CAGR typically wobbles year-to-year. However, in recent years, with the exception of the COVID-induced spike which is still settling, residential CAGRs have dropped from the 50% range of the 2010 time frame through the low 30% range pre-COVID, and it continues to decline. The upstream had been flattening out, decreasing to the <15% range pre-COVID, and appears to is returning to that range.

With these utilization boundaries, we have run models to draw out the acceptable TG size for speed tiers ranging from 1 Gbps to 5 Gbps for US and DS. We have also added some potential higher speed DS projections for 6 Gbps and 7 Gbps. Note that the speeds possible have a dependency on how efficient the bandwidth can be used. The models therefore also show the TG threshold range as a function of achievable QAM format for DS and US. Minor variations of QAM efficiency are expected, just as they are in HFC, as RF amplifiers incrementally reduce DS and US signal fidelity (MER) at the respective receivers. These fidelity losses translate to relatively minor variations in capacity. For example, if 4096-QAM is unachievable, but 2048-QAM is, then the capacity loss is about 8.3%.

Table 1 – CAGR Effects on per-user Peak Busy Hour (pbh) Average Utilization

Near term (2023) w aggressive CAGR (30%) or longer term (2025) with modest CAGR (15%): **7 Mbps DS / 500 kbps US**

Longer term (2026) w aggressive CAGR (30%) or even longer term (2029) with modest CAGR (15%): **15 Mbps / 1 Mbps**

		Network Migration Plan Year								
			1	2	3	4	5	6	7	8
		2022	2023	2024	2025	2026	2027	2028	2029	
	CAGR %	Tavg								
DS	15	4.5	5.18	5.95	6.84	7.87	9.05	10.41	11.97	13.77
	20		5.40	6.48	7.78	9.33	11.20	13.44	16.12	19.35
	25		5.63	7.03	8.79	10.99	13.73	17.17	21.46	26.82
	30		5.85	7.61	9.89	12.85	16.71	21.72	28.24	36.71
US	15	0.3	0.35	0.40	0.46	0.52	0.60	0.69	0.80	0.92
	20		0.36	0.43	0.52	0.62	0.75	0.90	1.07	1.29
	25		0.38	0.47	0.59	0.73	0.92	1.14	1.43	1.79
	30		0.39	0.51	0.66	0.86	1.11	1.45	1.88	2.45

5.1.2. Spectrum Allocation Considerations

There is a time element to spectrum allocation as CAGR and new speed tiers – forcing functions for new blocks of spectrum that must be large enough to deliver the highest speed tier, with margin – require continuous maintenance of the channel maps. This has been an HFC story for decades: managing spectrum as HDTV took hold, alongside VOD and niche/specialized video channels grew even as HSD CAGR was consistently high. This ultimately led to the elimination of inefficient analog carriage altogether, as well as technologies such as Switched Digital Video (SDV) to perform the spectrum balancing act.

The contemporary version of this balancing act is DOCSIS 3.1 vs less than DOCSIS 3.1 devices. Operators are looking to add more spectrum that supports DOCSIS 3.1, to take advantage of the increased bandwidth efficiency (reminder note: DOCSIS 4.0 uses the same DS and US OFDM and OFDMA technology), and to reduce video single carrier QAM as channels move to IP delivery. The IP video Nirvana is removing single carrier QAM video altogether, but more realistically a long term scenario is reducing it to a small block that is sufficient to support the segment of the customer base that relies on this service.

Referring to Figure 18, five spectrum allocation cases are shown. The five are broken into two categories, near term (scenarios 1-3) and longer term (scenarios 4-5). Scenarios 1-3 will use as their peak busy hour average usage for DS and US as 7 Mbps and 500 kbps, respectively per the above. Scenarios 4 and 5 will use the peak busy hour average utilization for DS and US as 15 Mbps and 1 Mbps, respectively.

Scenario 3 is based on near term CAGR values, but presumes that an All-IP conversion has taken place – i.e. no video single carrier QAMs. This scenario is to serve more as a boundary, “what’s possible” scenario under these particular average DS and US utilizations. Scenario 5 is also an All-IP conversion, in a longer term and potentially practical time frame, for comparison, using the increased utilization that would occur with the CAGR values described in the model descriptions above

The near term scenarios 1 and 2 show a spectrum still heavily weighted by video single carrier QAM spectrum – 48 slots to be exact. There is also significant bandwidth set aside for DOCSIS 3.0 (168 MHz) to support the still large volume of D3.0-only modems in the network. While the balance is rapidly shifting, as of this writing, there are still more D3.0 modems in the network than D3.1 modems at Comcast.

Scenario 1 can be viewed as an initial launch scenario, supporting 2 Gbps symmetric speed. Scenario 2 provides an additional OFDMA block that enables 3 Gbps symmetric services. And again, scenario 3 is a “what if” under these lighter DS and US traffic loads.

Scenario 4 and 5 presume that significant harvesting of video single carrier QAM and D3.0 modems has taken place, and all or most of the spectrum is DOCSIS 3.1 enabled DS and the FDX US band is maximized to 684 MHz. In these longer term scenarios, access to higher symmetric speeds – 4 Gbps and 5 Gbps – is evaluated, as well as DS speeds above 5 Gbps. In the DS, there is more total spectrum to allocate – out to 1218 MHz – than in the DOCSIS 4.0 upstream.

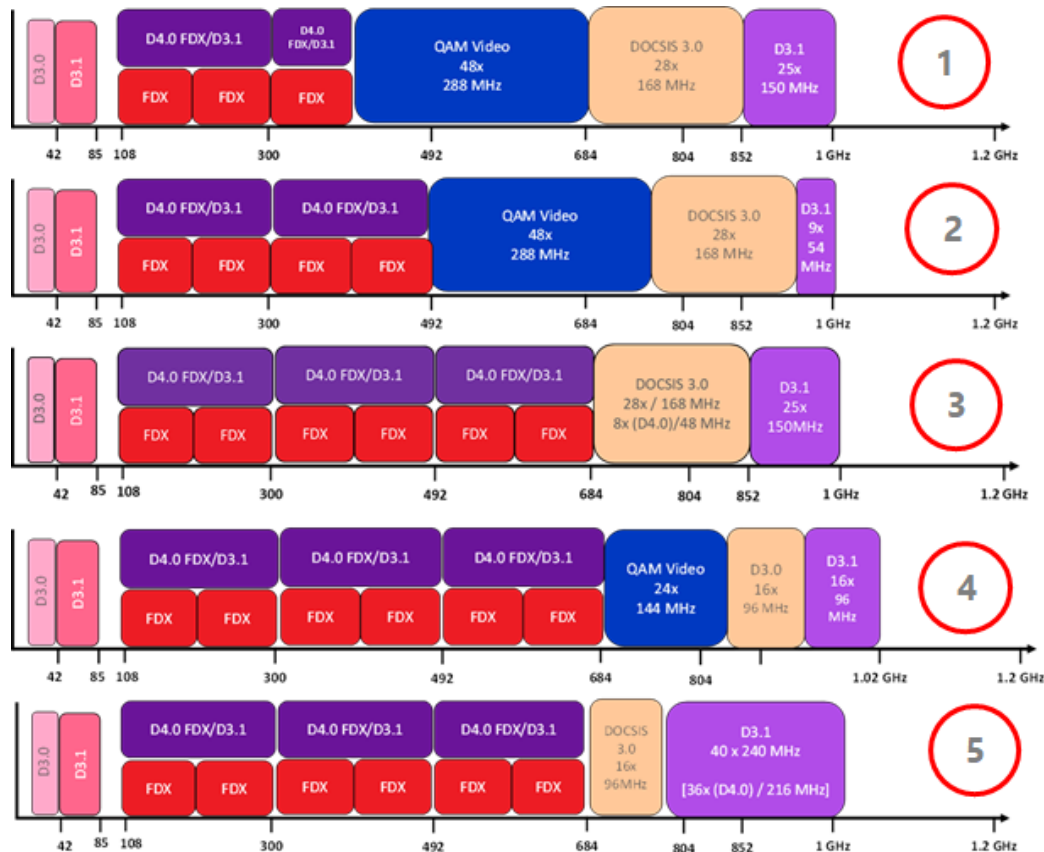

Figure 18 – Example Phases of Spectrum Migration vs Time

5.1.3. Network Capacity Modeling Assumptions

For our network capacity modeling, the following inputs were used in all scenarios:

- DS modulation = 4096-QAM for dedicated DS spectrum above FDX band
- Maximum DS frequency = 1002 MHz
 - Roll-off region not considered for this analysis, but could help
- DS modulation = 1024- to 4096-QAM inside the FDX band
- DS OFDM parameters: 1.25 usec Cyclic Prefix, 8K FFT
 - 4096-QAM => 9.70 bps/Hz

- 1024-QAM => 8.08 bps/Hz
- US fixed capacity below 85 MHz = 450 Mbps
 - Equates to 4 x 6.4 MHz SC-QAM + ~46 MHz OFDMA @ 1024-QAM
- US modulation = 64- to 1024-QAM inside the FDX band
- US OFDMA parameters: 1.25 usec Cyclic Prefix, 4K FFT
 - 1024-QAM => 7.70 bps/Hz
 - 256-QAM => 6.16 bps/Hz
 - 64-QAM => 4.62 bps/Hz
- SG sizes are varied from 32 to 384 subs
- Maximum service tier (Tmax_max) varied to fit up to 5G DS, 4G US
 - Every subscriber (i.e. 100%) takes the maximum service tier

5.2. FDX Use Case 1 – Nearer Term Years 2023-25

Case 1 assumes a DS Tavg = 7 Mbps with US Tavg = 0.5 Mbps. Three scenarios were considered: two with legacy video and one with 100% video over IP (IPTV) – meaning no QAM video carriers, all have been reclaimed for DOCSIS 3.1.

For our network capacity modeling, a SG CDF was created to allow us to determine the probability of various capacity thresholds. The 70th percentile point was used to effectively estimate the consumption (i.e. Nsub*Tavg) plus the ripple components.

Many folks are still familiar with the original traffic engineering formula using the K-value. To help relate our network capacity modeling results, Table 2 shows the effective K-value that would generate very similar results. As mentioned earlier, the optimum K-value varies with Nsub, Tavg and Tmax_max. The Tavg is fixed for Case 1, so the table shows the range of the other inputs.

For all US combinations, the service tier (Tmax_max) is >1,000 times larger than the Tavg. Thus, the effective K-value is extremely small, 1.025. For the DS, the Tmax_max to Tavg ratio isn't nearly as wide. For 4G & 5G tiers, the effective K-value is 1.05. For 3G tiers, the effective K-value is 1.05 until the SG size reaches 384 subs where it increases to 1.1. For 2G tiers, the effective K-value is 1.05 until the SG size reaches 256 subs where it increases to 1.1.

Table 2 – Effective K values used for Case 1

K-value Used	Original K		QoE modeling – Effective K			
Nsub/SG	DS	US	2G DS	3G DS	4G,5G DS	All US
32	1.2	1.2	1.05	1.05	1.05	1.025
64	1.2	1.2	1.05	1.05	1.05	1.025
128	1.2	1.2	1.05	1.05	1.05	1.025
256	-	-	1.1	1.05	1.05	1.025
384	-	-	1.1	1.1	1.05	1.025

5.2.1. Case 1 with 288 MHz Legacy Video, 396 MHz FDX Band

This scenario has 288 MHz of Legacy Video spectrum and the FDX band is limited to 108-396 MHz. This leaves DOCSIS with enough spectrum to fit 28 SC-QAM channels for D3.0/D3.1 modems plus 150 MHz OFDM channel for D3.1/D4.0 modems. These channels total ~2.5 Gbps of fixed DS capacity.

Figure 19 shows the DS BW Capacity required for several different T_{max_max} tiers. The Y-axis is the capacity in Mbps while the X-axis is a log scale of the number of subs in a SG (i.e. Nsub). The yellow curve shows the DS peak period average consumption (i.e. Nsub*T_{avg}). The various green curves show the maximum capacity required for various T_{max_max}, from 2G to 5G. Note that the burst plus ripple components is added to the average consumption.

The dashed lines show various key capacity marks. The lowest one is the SC-QAM capacity of 1.05 Gbps. This is the upper capacity limit for 3.0 modems. A separate calculation must be done to ensure the 3.0 pool does not exceed their capacity limit. The next blue dashed line shows the Fixed DS capacity limit of ~2.5 Gbps. As long as the DS peak period average consumption is less than this, then the US TG limit (i.e. TE condition #4) never kicks in. The figure highlights where Nsub*T_{avg} crosses this point at 358 subs. Above this point, the DS average consumption starts taking away usable FDX BW from the US.

The top 3 blue dashed lines show the total DS capacity available for the various FDX DS QAM modulations (i.e. 1024-, 2048-, 4096-QAM). The point where a green curve crosses the blue dashed line is the maximum number of subs that can be supported for that combination, i.e. TE condition #1.

This scenario supports:

- 2G DS tier to 375+ subs
- 3G DS tier to 240 subs @ 1024-QAM; 306 subs @ 4096-QAM
- 4G DS tier to 90 subs @ 1024-QAM; 157 subs @ 4096-QAM
- 5G DS tier does NOT fit

Figure 19 – Case 1 w Video, 396 MHz FDX – DS BW Capacity Limits

Figure 20 – Case 1 w Video, 396 MHz FDX – DS Spectrum Requirements

Figure 20 shows the DS spectrum requirements for each of the above combinations. Note – this includes both the DOCSIS DS spectrum and 288 MHz Legacy Video. This analysis assumes 1002 MHz is the top spectrum. If the roll-off for the 1 GHz is usable or the taps are upgraded to 1.2 GHz, then the figure also shows what can be achieved up to 1200 MHz. Even at 384 subs where Nsub*Tavg has overflowed into the FDX band, it only needs >96MHz of FDX BW <0.25% of the time.

To put the DS in context, here are examples of FDX band probability usage. A SG with 256 subs and a 4G DS tier will stay within the fixed DS BW outside FDX band for 98% of the time and only need some additional FDX BW for just 2% of the time.

The US SG limits (i.e. TE condition #2) are examined in Figure 21. Like the DS chart, the yellow curve depicts the US $N_{sub} \cdot T_{avg}$ while the various orange curves show the total US capacity required for various US tiers (1.5G – 2.5G). The red dashed line on the bottom shows the fixed US capacity of 450 Mbps below 85 MHz. Notice that the $N_{sub} \cdot T_{avg}$ component never crosses this line. This means that the DS TG limit (TE condition #3) will never kick in.

The three upper dashed lines show the total US capacity available for the various FDX US QAM modulations (i.e. 64-, 256-, 1024-QAM). The point where an orange curve crosses the blue dashed line is the maximum number of subs that can be supported for that combination, i.e. US TE condition #2 from above. As can be seen, each jump in modulation effectively allows an additional 0.5 Gbps to be added to T_{max_max} .

Figure 21 – Case 1 w Video, 396 MHz FDX – US BW Capacity Limits

Figure 22 – Case 1 w Video, 396 MHz FDX – US Spectrum Requirements

Figure 22 shows the US spectrum requirements. The upper red dashed line is showing the top of the usable FDX spectrum. This is nominally 396 MHz when the DS peak period consumption does not overflow into the FDX band. However, Figure 22 shows that this point occurs at 358 subs. That is why this red dashed line starts to drop as Nsub increases past this point.

This scenario supports:

- 1.5G US tier to ~370 subs @ 64-QAM; 400+ subs @ 256- or 1024-QAM
- 2G US tier to ~350 subs @ 256-QAM; 400+ subs @ 1024-QAM
- 2.5G US tier to ~210 subs @ 1024-QAM
- 3G & 4G US tier does NOT fit

To put the US in context, a SG with 256 subs and a 2G US tier will stay within 85 MHz BW outside FDX band for 98% of the time and only need some additional FDX BW for just 2% of the time.

5.2.2. Case 1 with 288 MHz Legacy Video, 492 MHz FDX Band

This scenario increases the FDX band by 96 MHz to 108-492 MHz at the expense of the top OFDM channel. This leaves DOCSIS with enough fixed spectrum above the FDX band to fit 28 SC-QAM channels for D3.0/D3.1 modems plus 54 MHz OFDM channel for D3.1/D4.0 modems. These channels total ~1.57 Gbps of fixed DS capacity. It also maintains 288 MHz of Legacy Video spectrum.

Figure 23 shows the DS BW Capacity required for several different Tmax_max tiers. The second blue dashed line shows the Fixed DS capacity limit has now dropped ~1.57 Gbps. This causes the US TG limit (i.e. TE condition #4) to kick in at 225 subs where Nsub*Tavg crosses this point. The DS average consumption starts taking away usable FDX BW from the US at a much lower point in this scenario.

The top 3 blue dashed lines show the total DS capacity available for the various FDX DS QAM modulations (i.e. 1024-, 2048-, 4096-QAM). This scenario supports:

- 2G DS tier to ~354 subs @ 1024-QAM; 400+ subs @ 2048- & 4096-QAM
- 3G DS tier to ~218 subs @ 1024-QAM; 306 subs @ 4096-QAM
- 4G DS tier to ~68 subs @ 1024-QAM; 157 subs @ 4096-QAM
- 5G DS tier does NOT fit

The DS 4096-QAM results are the same as before, while the DS 1024-QAM results are reduced from the previous scenario.

Figure 23 – Case 1 w Video, 492 MHz FDX – DS BW Capacity Limits

Figure 24 shows the DS spectrum requirements for each of the above combinations. Note – this includes both the DOCSIS DS spectrum and 288 MHz Legacy Video.

To put the DS in context, a SG with 128 subs and a 4G DS tier will stay within the fixed DS BW outside FDX band for 99% of the time and only need some additional FDX BW for just 1% of the time. Even at 256 subs where Nsub*Tavg has overflowed into the FDX band, it only needs >96MHz of FDX BW <5% of the time.

The US SG limits (i.e. TE condition #2) are examined in Figure 25. The various orange curves show the total US capacity required for various US tiers (1.5G – 3G). Like the previous scenario, each jump in modulation effectively allows an additional 0.5 Gbps to be added to Tmax_max.

Figure 24 – Case 1 w Video, 492 MHz FDX – DS Spectrum Requirements

Figure 25 – Case 1 w Video, 492 MHz FDX – US BW Capacity Limits

Figure 26 – Case 1 w Video, 492 MHz FDX – US Spectrum Requirements

Figure 26 shows the US spectrum requirements. The upper red dashed line is nominally 492 MHz until the DS peak period consumption overflows into the FDX band at 225 subs. The drop in usable US BW above 225 subs is the result of TE condition #4. As Nsub increases, the impact becomes greater.

This scenario supports:

- 1.5G US tier to ~360 subs @ 64-QAM; 400+ subs @ 256- or 1024-QAM
- 2G US tier to ~235 subs @ 64-QAM; ~340 subs @ 256-QAM
- 2.5G US tier to ~245 subs @ 256-QAM; 330 subs @ 1024-QAM
- 3G US tier to ~250 subs @ 1024-QAM
- 4G US tier does NOT fit

To put the US in context, a SG with 256 subs and a 2G US tier will stay within 85 MHz BW outside FDX band for 98% of the time and only need some additional FDX BW for just 2% of the time.

5.2.3. Case 1 with IPTV, no Legacy Video, 684 MHz FDX Band

In this scenario, 100% IPTV migration is reached which frees up the 288 MHz Legacy Video to be added to the DOCSIS BW pool. The FDX band is now a full 108-684 MHz while the fixed DS capacity above 684 MHz returns to 28 SC-QAM channels for 3.0/3.1 modems plus 150 MHz OFDM channel for D3.1/D4.0 modems. These channels total ~2.5 Gbps of fixed DS capacity.

Figure 27 shows the DS BW Capacity required for several different Tmax_max tiers. The second blue dashed line shows the Fixed DS capacity limit has now back up to ~2.5 Gbps. The US TG limit (i.e. TE condition #4) kicks in at 358 subs like the first scenario.

Notice that the top 3 blue dashed lines showing the total DS capacity available has increased significantly to 7-8 Gbps. The Case 1 IPTV scenario supports:

- 2G, 3G & 4G DS tier to 400+ subs @ all modulations
- 5G DS tier to ~272 subs @ 1024-QAM; 400+ subs @ 4096-QAM

Figure 28 shows the DS spectrum requirements for each of the above combinations. The probability of using the FDX band is the same as scenario 1 above. The US SG limits (i.e. TE condition #2) are examined in Figure 29. The various orange curves show the total US capacity required for various US tiers (2G – 4G). Figure 30 shows the US spectrum requirements. The Case 1 IPTV scenario supports:

- 2G US tier to 400+ subs @ all modulations
- 3G US tier to 400+ subs @ 256- & 1024-QAM
- 4G US tier to 400+ subs @ 1024-QAM

Figure 27 – Case 1 w IPTV, 684 MHz FDX – DS BW Capacity Limits

Figure 28 – Case 1 w IPTV, 684 MHz FDX – DS Spectrum Requirements

Figure 29 – Case 1 w IPTV, 684 MHz FDX – US BW Capacity Limits

Figure 30 – Case 1 w IPTV, 684 MHz FDX – US Spectrum Requirements

5.2.4. Probability of DS + US Overlapping Tails – Case 1

The analysis until now has focused on capacity requirements and how many subscribers can receive adequate service for a given configuration. Now let's take a closer look at the probabilities of a DS tail overlapping with an US tail in the shared FDX band. Again, this assumes this is one single large TG, so the US and DS need to timeshare any FDX channels they need to use.

Figure 31 is a complex chart showing the probabilities of spectrum usage for both US + DS CDF with 200 subs. Our model assumes that the US capacity fills from the lowest channel in the spectrum and increases to the right until it reaches the top of the FDX band. The DS capacity is the opposite where it fills from the top channel in the spectrum down to the left. The fixed DS capacity is completely used before the DS uses the FDX band.

The yellow curve on the left is the US 'CDF'. Technically, it is the (1 – CDF) function. It tells us the probability that the US will need MORE than that amount of spectrum. The curve crosses the red line (85MHz) at 0.2%. This means that 99.8% of the time, the US capacity remains completely within 85 MHz, and only 0.2% of the time does it even need to request FDX BW. That equates to only 20 seconds every evening!

The blue curve on the right is the DS 'CDF'. It tells us the probability that the DS will need spectrum below that point. The curve crosses the top of the FDX band (684MHz) at 0.1%. This means that 99.9% of the time, the DS capacity remains completely above 684 MHz, and only 0.1% of the time does it even need to request FDX BW. That equates to only 10 seconds every evening!

Figure 31 – Probability of DS + US Overlapping Tails – Case 1 IPTV, 200 subs

Figure 32 – Probability of DS + US Overlapping Tails – Case 1 IPTV, 200 subs (Log Scale)

To take a closer look at the overlapping tails, Figure 32 shows the same data but on a log scale. The US datapoint for 0.01% is at 128 MHz. What this means is that the US needs more than 20 MHz worth of capacity from the FDX band 0.01% of the time. For 20 MHz worth of capacity, the scheduler could assign this as 25% of a single 96 MHz FDX channel or as 4% of the entire FDX band. So, the US can still burst to the top of the FDX band, it is just that it is very infrequent and short bursts that shouldn't congest the system. In the rare event that the US does have a sustained burst (e.g. speed test once a month), the yellow dashed line at 599 MHz shows the US upper capacity limit based on the traffic engineering formula. The US will not exceed this BW point over a sustained period.

Looking at the DS CDF, the 0.01% datapoint is at 533 MHz. This means that 99.99% of the time, the DS BW needs are above this point and only 0.01% of the time does the DS need to go below this point. 533 MHz represents ~80% use of a single 192 MHz FDX DS channel or ~26% of the entire FDX band. The blue dashed line at 257 MHz represents the lowest spectrum BW point that the DS needs based on the traffic engineering formula (e.g. a speed test on top of normal traffic).

During the normal course of events, the probability of the US + DS tails overlapping is on the order of 1 second every 100+ years! Case 1 is the easier one, let's see how things change with Case 2.

5.3. FDX Use Case 2 – Longer Term Years 2026-29

Case 2 assumes a DS Tavg = 15 Mbps with US Tavg = 1 Mbps. Two scenarios were considered: one with legacy video and one with 100% IPTV.

Table 3 shows the effective K-value for Case 2. As mentioned earlier, the optimum K-value varies with Nsub, Tavg and Tmax_max. This table is identical to Table 1 except for the 3G DS tier. For 3G tiers, the effective K-value is 1.05 until the SG size reaches 256 subs where it increases to 1.1.

Table 3 – Effective K values used for Case 2

K-value Used	Original K		QoE modeling – Effective K			
Nsub/SG	DS	US	2G DS	3G DS	4G,5G DS	All US
32	1.2	1.2	1.05	1.05	1.05	1.025
64	1.2	1.2	1.05	1.05	1.05	1.025
128	1.2	1.2	1.05	1.05	1.05	1.025
256	-	-	1.1	1.1	1.05	1.025
384	-	-	1.1	1.1	1.05	1.025

5.3.1. Case 2 with 144 MHz Legacy Video, 684 MHz FDX

This scenario increases the FDX band to 684 MHz while Legacy Video shrinks to 144 MHz. This leaves DOCSIS with enough fixed spectrum above the FDX band to fit 16 SC-QAM channels for D3.0/D3.1 modems plus 96 MHz OFDM channel for D3.1/D4.0 modems. These channels total ~1.53 Gbps of fixed DS capacity.

Figure 33 shows the DS BW Capacity required for several different Tmax_max tiers. The second blue dashed line shows the Fixed DS capacity limit has now dropped ~1.53 Gbps. This causes the US TG limit (i.e. TE condition #4) to kick in at 102 subs where Nsub*Tavg crosses this point. The DS average consumption starts taking away usable FDX BW from the US at a much lower point in this scenario.

If the system is upgraded to 1218 MHz, then more than 200 MHz of OFDM capacity is added to the fixed DS capacity. See the lower purple dashed line in Figure 33. This moves the crossover point for TE condition #4 up to 242 subs.

The top 3 blue dashed lines show the total DS capacity available for the various FDX DS QAM modulations (i.e. 1024-, 2048-, 4096-QAM) up to 1002 MHz. This scenario supports:

- 2G DS tier to ~265 subs @ 1024-QAM; ~327 subs @ 4096-QAM
- 3G DS tier to ~200 subs @ 1024-QAM; ~260 subs @ 4096-QAM
- 4G DS tier to ~132 subs @ 1024-QAM; ~195 subs @ 4096-QAM
- 5G DS tier to ~62 subs @ 1024-QAM; ~125 subs @ 4096-QAM

Figure 33 – Case 2 w Video, 684 MHz FDX – DS BW Capacity Limits

Figure 34 shows the DS spectrum requirements for each of the above combinations. Note – this includes both the DOCSIS DS spectrum and 144 MHz Legacy Video.

To put the DS in context, a SG with 128 subs and a 4G DS tier will stay within the fixed DS BW plus one 192 MHz FDX band for 99.5% of the time and only need some additional FDX BW for just 0.5% of the time.

The US SG limits (i.e. TE condition #2) are examined in Figure 35. The various orange curves show the total US capacity required for various US tiers (2G – 4G). Each jump in modulation effectively allows an additional 1 Gbps to be added to Tmax_max. Note that the US Nsub*Tavg finally exceeds the 85 MHz BW beyond 450 subs which is much higher than the DS.

Figure 34 – Case 2 w Video, 684 MHz FDX – DS Spectrum Requirements

Figure 35 – Case 2 w Video, 684 MHz FDX – US BW Capacity Limits

Figure 36 – Case 2 w Video, 684 MHz FDX – US Spectrum Requirements

Figure 36 shows the US spectrum requirements. The upper red dashed line starts at 684 MHz until the DS peak period consumption overflows into the FDX band at 102 subs. The drop in usable US BW above 102 subs is the result of TE condition #4. As Nsub increases, the impact becomes greater. The slope is also steeper in Case 2 with the higher Tavq.

This scenario supports:

- 2G US tier to ~210 subs @ 64-QAM; ~265 subs @ 256-QAM; 310 subs @ 1024-QAM
- 3G US tier to ~175 subs @ 256-QAM; 225 subs @ 1024-QAM
- 4G US tier to ~150 subs @ 1024-QAM

TE condition #4 has now become the limiting factor in how many subs can be supported in a SG.

To put the US in context, a SG with 256 subs and a 2G US tier will stay within 85 MHz BW outside FDX band for 92% of the time and only need some additional FDX BW for just 8% of the time.

5.3.2. Case 2 with IPTV, no Legacy Video, 684 MHz FDX Band

Migrating to 100% IPTV frees up the 144 MHz Legacy Video which helps with the previous TE condition #4 limitations. The fixed DS capacity above 684 MHz is now 16 SC-QAM channels for 3.0/3.1 modems plus 240 MHz OFDM channel for 3.1/4.0 modems. These channels total ~2.93 Gbps of fixed DS capacity, almost double the previous scenario.

Figure 37 shows the DS BW Capacity required for several different Tmax_max tiers. The second blue dashed line shows the Fixed DS capacity limit has now back up to ~3 Gbps. The US TG limit (i.e. TE condition #4) now kicks in at 195 subs.

Notice that the top 3 blue dashed lines showing the total DS capacity available has increased significantly to 7.5-8.5 Gbps. The Case 2 IPTV scenario supports:

- 2G DS tier to ~353 subs @ 1024-QAM; 400+ subs @ 4096-QAM
- 3G DS tier to ~285 subs @ 1024-QAM; ~348 subs @ 4096-QAM
- 4G DS tier to ~225 subs @ 1024-QAM; ~287 subs @ 4096-QAM
- 5G DS tier to ~155 subs @ 1024-QAM; ~218 subs @ 4096-QAM

Figure 38 shows the DS spectrum requirements for each of the above combinations. The US SG limits (i.e. TE condition #2) are examined in Figure 39. The various orange curves show the total US capacity required for various US tiers (2G – 4G). Figure 40 shows the US spectrum requirements. The Case 2 IPTV scenario supports:

- 2G US tier to ~275 subs @ 64-QAM; ~325 subs @ 256-QAM; 350 subs @ 1024-QAM
- 3G US tier to ~250 subs @ 256-QAM; ~290 subs @ 1024-QAM
- 4G US tier to ~230 subs @ 1024-QAM

Figure 37 – Case 2 w IPTV, 684 MHz FDX – DS BW Capacity Limits

Figure 38 – Case 2 w IPTV, 684 MHz FDX – DS Spectrum Requirements

Figure 39 – Case 2 w IPTV, 684 MHz FDX – US BW Capacity Limits

Figure 40 – Case 2 w IPTV, 684 MHz FDX – US Spectrum Requirements

Figure 41 shows how three different service tier combinations map to spectrum using the candlesticks from the traffic engineering formula. The top example is a SG with 256 subs and 3G DS x 3G US tiers. Notice that the 3G US burst requires more spectrum than the DS 3G burst due to its lower modulation. This is a non-typical example of when US limits the DS from growing any further.

The middle example shows 256 subs with 4Gx2G tiers. The fully symmetric would not fit. As can be seen, there is still some headroom in both US + DS for additional Tav growth. The bottom example shows 128 subs with 5Gx4G tiers with headroom.

Figure 41 – Case 2 w IPTV, 684 MHz FDX – Various Service Tier Examples

5.3.3. Probability of DS + US Overlapping Tails – Case 2

As seen in the Case 2 scenarios with increased Tavg, the DS capacity needs more and more of the FDX BW. Figure 42 looks at the Case 2 IPTV probabilities of spectrum usage for both US + DS CDF for 200 subs.

As before, the yellow curve on the left is the US ‘CDF’. For Case 2, the curve crosses the red line (85MHz) at ~3%. This means that 97% of the time, the US capacity remains completely within 85 MHz, and ~3% of the time it needs to request FDX BW.

The blue curve on the right is the DS ‘CDF’. The DS curve crosses the top of the FDX band (684MHz) at ~50%. This means that 50% of the time, the DS capacity remains completely above 684 MHz, while 50% of the time it will need to request FDX BW. A much different situation than Case 1!

Figure 42 – Probability of DS + US Overlapping Tails – Case 2 IPTV, 200 subs

To take a closer look at the overlapping tails, Figure 43 shows the same data but on a log scale. The US datapoint for 0.01% is at 160 MHz. What this means is that the US needs more than 52 MHz worth of capacity from the FDX band just 0.01% of the time. For 52 MHz worth of capacity, the scheduler could assign this as 55% of a single 96 MHz FDX channel or 9% of the entire FDX band. Even in Case 2, the US can still burst to the top of the FDX band, it is just that it is very infrequent and short bursts that shouldn't congest the system. In the rare event that the US does have a sustained burst (e.g. speed test once a month), the yellow dashed line at 615 MHz shows the upper capacity limit based on the traffic engineering formula. The US will not exceed this BW point over a sustained period.

Looking at the DS CDF, it crosses 492 MHz just above 0.1%. This means that 99.9% of the time, the DS BW needs are above this point (i.e. DS Fixed spectrum + a single 192 MHz FDX DS channel) and only 0.1% of the time does the DS need to go below this point into a 2nd &/or 3rd FDX DS channel. The blue dashed line at 135 MHz represents the lowest spectrum BW point that the DS needs based on the traffic engineering formula (e.g. a speed test on top of normal traffic).

Figure 43 – Probability of DS + US Overlapping Tails – Case 2 IPTV, 200 subs (Log Scale)

While the probabilities of the US + DS tails overlapping becomes infinitesimal, the operator still needs to engineer the system for that instance when one modem does burst to its maximum (e.g. speed test). The worst case happens when the US bursts to its maximum, which is the yellow dashed line at 615 MHz. At this point, the US is completely consuming 108-492 MHz FDX band and needs 64% of the 492-684 MHz FDX channel (and 36% is available for DS BW). The critical question then becomes how much is the DS overlapping this?

To answer that, look to see where the blue DS curve intersects with US max at 615 MHz. The DS CDF intersects at the 5% point on its curve. This means that 95% of the time, the DS stays above this BW point, and everyone has sufficient capacity. However, 5% of the time there is a BW conflict with the DS overlapping the US Tmax_max burst. But how big is it? Breaking the 5% window into segments shows:

- US burst gets 4000+ Mbps for 95% of time
- US burst gets 3840-4000 Mbps for 2% of time
- US burst gets 3615-3840 Mbps for 2% of time
- US burst gets 3450-3615 Mbps for 0.5% of time
- US burst gets 3270-3450Mbps for 0.25% of time
- US burst gets <3270 Mbps for 0.25% of time

The impact of this contention is minimal. On average, it will reduce the US 4G burst by <0.5%. Just adding a small amount of over-provisioning into Tmax_max will easily compensate for this slight shortfall.

6. Results Summary

As we noted at the outset and have shown herein, traffic analysis of the FDX band is tractable using known statistical methods, tools, and empirical data. We have gone onto significant depth explaining the statistical foundation of burst traffic, the empirical basis of these statistics, describing modeling scenarios used to create operational guidelines, and creating parametric curves that quantify the relationships among bandwidth allocated, speeds, bandwidth efficiency, and transmission group sizes.

The foundational principle enabling large transmission group sizes is that, because of the statistical characteristics of real traffic, networks are able to be oversubscribed – meaning that many customers can effectively share capacity that is a number less than the sum of their individual peak usage needs. This has been the case for decades. As the peak speeds to average utilization skew to larger ratios in the Gigabit speed era, we see that the higher the peak burst, the increasingly infrequently it occurs. Years of evidence from broadband service delivery have been used to generate probability distributions that describe the traffic behavior, and which are leveraged and extrapolated to predict the expected performance in these models, and in particular how that applies to the dual-use FDX band.

The consolidated results are shown in Table 4. Results show that large TGs can be supported without loss of QoE. Furthermore, the TG sizes align well with what are current node sizes and service groups sizes that will result from network augments that are already part of the Comcast HFC upgrade plan.

As a point of context, the average size of a fiber node today is 350 hp and getting smaller. As nodes get split during DAA network upgrades, they are roughly halved – or become approximately 175 hhp. Adjusting then for residential penetration, these numbers would represent a service group of subscribers of about 200 and 100, respectively – very well aligned to the values in Table 4. *This suggests that, with proper spectrum management, and even under aggressive CAGR, N+x FDX – including with elongated TG – will comfortably multi-gig symmetrical speeds well within today's network architecture and expectations of future augments.*

Table 4 – TG Size Summary: Spectrum Scenarios and Speeds

	Scenario	2G / 2G	3G / 3G	4G / 4G	
Near Term	1	>350	306 / X	157 / X	
	2	>400	250	157 / X	
	3	> 400	>400	>400	
Longer Term	4	310	225	150	
	5	350	290	230	

*4k-QAM DS / 1k-QAM US

5 Gbps DS @ TG Size = 218
6 Gbps DS @ TG Size ~ 125
7 Gbps DS @ TG Size ~ 60

7. Conclusion

Traffic engineering of the HFC network has been at the root of our success deploying HSD services cost-effectively, and without over-engineering the network. The industry has decades of successful deployment experience. Over time, operators have developed mature empirically-based statistical models of DS and US. This has translated into robust processes for operating and augmenting the network in the face of DS and US CAGR and continually increasing speeds tiers. The essential relationships of capacity supply vs peak speed and user demand have led to predictable thresholds for configuring service groups. These same learnings can be applied to traffic engineering the FDX band.

However, we have even more tools, and more powerful ones, at our disposal today to manage capacity. Utilization data can be captured and delivered to the cloud on a service-group-by-service group basis. With algorithms to crunch the localized data and traffic trends, extremely granular, and thereby more efficient, cost-effective, and targeted migration planning can take place. On top of this, because there are now decades of aggregate traffic data history, the empirical data can be used confidently to create probability distributions using classical goodness-of-fit tools of statistical analysis and pattern recognition theory. Once these are crystallized into mathematical expressions, we have the foundation to quantifiably predict burst characteristics sliced and diced into durations and size, and use these to guide business decisions. The modeling exercise described in this paper is an outcome of this process.

From a traffic engineering perspective, an FDX US population represents a small number of less aggressive “users” looking to infrequently access frequency and time resources in a specific band that is managed jointly by the vCMTS. Similar to independent DS and US criteria, thresholds can be quantified for TG size versus peak speeds (for a fixed set of assumptions on CAGR, total capacity, penetration, BW efficiency). Infrequent (statistically) peak bursts and DS Avg BW >> US Avg BW means the FDX Band’s RBAs will be deployed as DS blocks the vast majority of the time.

By contrast, if a large chunk of the coaxial spectrum such as 5-204 MHz, 5-300 MHz, 5-396 MHz, etc., is dedicated to upstream traffic, it will be *idle* the vast majority of the time. Furthermore, for the increasingly high “ultra-high split” options, while this high-quality spectrum mostly idles as an outlet for a very occasional US burst, the approach will force more downstream into the least predictable and never before activated part of the coaxial spectrum above 1 GHz, and only *after* all of the taps and passives have been upgraded.

Traffic analysis of the FDX bandwidth has shown that

- 1) The initial intuitive instinct to minimize the size of an Interference Group turns out, in practice, to be evidentially unfounded.
- 2) Large TGs can be supported while maintaining customer QoE, similar to how oversubscription models have worked for operators for decades of broadband services.
- 3) The TG sizes determined for the multi-gigabit symmetric speed tiers of interest align well with current node sizing and the expected network augments in the Comcast upgrade plan in the years ahead.
- 4) Capacity, speed, penetration, and TG relationships can be used, as they are similarly used today, to provide guidance to network operators’ network augmentation and business (speed) planning

With these findings, and with the innovative development of FDX amplifiers already in the works and showing promise, the industry can now feel confident that multi-gigabit symmetrical speeds can quickly be enabled in their existing N+x HFC deployments, founded on a deep understanding of the practical realities of burst traffic engineering and how it applies in the FDX band.

1. Abstract

London Underground or the ‘Tube’ began as a modest steam rail system over 150 years back and is now a sprawling transit system transporting over 5 million people daily. Similarly, Comcast began modestly but today has a large and growing optical footprint with fiber getting deeper into the network often leading to challenging underground fiber construction in the neighborhoods. Just as generations of Tube engineers innovated on their predecessors’ plans deep underground and grew their rail network, Comcasters innovate on critical infrastructure built by our cable predecessors and provide higher capacity to match current demands and future needs.

In this paper, we report on the use of innovative technology that enables us to use existing underground critical infrastructure and make fiber deployments in the neighborhoods simple, cost effective and minimally customer impacting. Cable companies have been laying underground RF cables inside conduits, in vast sections of cable builds since the mid 1990s. This process, called Cable in Conduit (CiC) has a fraction of the conduit occupied by the RF cable with a contiguous empty space in the conduit. Recently, fiber manufacturers have come out with ‘micro-fiber’ cable that bundles of up to 72 optical fibers occupying a diameter of only a few millimeters. This new fiber cable bundle is supple, affords tight bend radius and has good tensile strength. With existing rod-rope-pull equipment this micro-fiber can now be deployed within the existing conduit alongside the RF Cable cost-effectively, quickly and with minimal impact on the customer experience, all without the need for trenching or boring.

The paper describes details of trial activities on CiC in one of our divisions and the economics of this technology. Skillful use of this technology and innovative optical systems being developed bring fiber to the last active, simplify other architectures such as Full Duplex (FDX), improve performance and capacity overall and help propel new optical architectures such as Switch on a Pole/Pedestal (SOAP). Since this technology provides large fiber counts at RF tap locations very close to our customers, it provides great long-term opportunities to span the last few meters and reach customer homes (FTTH) when needed.

2. Introduction

As the largest broadband company in the US, Comcast serves millions of customers and businesses coast to coast. All of this is the result of a large optical network that spans core, metro and access layers as illustrated below [1].

Figure 1 – Comcast Network at a Glance

While the Core and Metro layers are all-optical circuits interconnected by ROADMs fed by large routers, the access layer comprises hybrid fiber and coaxial (HFC) cable network, some fiber to the home (FTTH) all optical networks and wavelength specific all optical very high-speed commercial connections. While the HFC and FTTH networks serve primarily residential customers and small-medium business customers, the commercial optical networks primarily serve 1, 10 or 100Gbps commercial enterprises with Metro Ethernet and cell tower back haul and 5G front-mid and backhaul links. Very often the HFC, FTTH and Commercial services are carried in the same fiber sheath, and over time could share the same access fiber. Over the years, Comcast has innovated on its access plant and through node splits and network expansion, driven fiber deeper into the network. In this context Cable in Conduit could be a valuable additional tool assisting in the fiber journey.

3. What is CiC?

At this point, Comcast has an almost equal share of aerial and underground plant overall. Due to varied plant practices many regions out West have a predominantly underground plant while in the Northeast a predominantly aerial plant exists, although there is an admixture of underground (UG) and aerial (AR) per node across the country. When new fiber is deployed, AR plant can more easily be converted to fiber since the infrastructure of overlaying fiber over coax cable is fairly well known and there is a high degree of infrastructure reuse. Such is today not the case however when underground fiber has to be deployed. Deploying UG fiber is a cumbersome process that requires digging up the streets or front and back lawns and is generally much more time consuming and much more expensive than of AR fiber deployment.

While both AR and UG plant require permitting and traffic management the nature of AR permits are of weight studies of additional cables being strung, but of underground are much more complicated and time consuming due to the need of non-interference between cable, telephone, power and natural gas infrastructure that is also buried below ground.

And so, it would seem that if a solution could be found for reuse of UG cable infrastructure, both the cost of fiber deployment as well as the time of fiber deployment would come down significantly. Furthermore, if such a solution were easy to deploy and in use in some way, it would immensely aid in pushing fiber deeper and accelerate our fiber journey by providing an additional high-speed lane. Such is the case with a technique that Comcast has started using called Cable in Conduit (CiC) also called sometimes internally called fiber override in the neighborhood.

3.1. The Basics

In a large portion of the Comcast UG cable plant West of the Mississippi built after around 1985~1990, the RF cable was laid inside of a conduit, and the RF cable then surfaces to pedestals containing amplifiers and nodes, hence our name for this approach “Cable in Conduit” (CiC). While the prevalence of CiC is high in the West due to the already high UG plant there, there are areas in Central and the Northeast divisions that are also CiC based. But a fair amount of Cable plant and particularly some of the older plant across the country is what is directly buried (DB) several feet under the ground and the RF Cable surfaces to taps and pedestals. Accordingly, we have three types of plant AR, CiC and DB that together describe the total Comcast RF plant today.

Figure 2 – Cable in Conduit and Direct Bury Cable [2] (Comcast)

The picture above illustrates CiC and DB underground plants. Here, we have shown DB as a larger hardline cable, while CiC a slimmer hardline cable contained within a conduit. With the above illustration, it is easy to see that the skinnier the cable and larger the conduit, the easier it might have been to sneak the cable into the conduit and surface it at required intervals to service pedestals that hold taps, amplifiers and passives.

Figure 3 – Illustrating pedestals in the neighborhood

The picture above illustrates various pedestals and enclosures that interconnect RF cables. These are roughly about 100ft to 250ft in distance. The pedestal on the left is the tap enclosure typically in the front lawn of homes, a San Pellegrino can is shown next to it for an indication of its size. A handhole from the local telephone utility is shown along-side it, sometimes Comcast itself may have handholes nearby as well. The middle pedestal is a bullet type enclosure that sometimes may contain RF amplifiers, a fire hydrant (in need of some paint work) is shown along-side of it for size comparison. The one on the right is a pedestal that might hold a node. In each case if CiC is the mode of deployment, the cable comes out of the conduit from each side and connected at two ends to appropriate devices.

3.1. Pervasiveness of CiC

In previous sections, how pervasive CiC could be in Comcast plant. To get a feel for it in real terms, we elected to check this out across the West division. We analyzed all the nodes in West and looked at their plant composition. This would include all hardline cabling in AR and UG plants, but NOT any of the drop cables. Drop cables connect homes to tap ports on the RF plant and are of varying lengths, but crucially these could be AR, DB or CiC.

Figure 4 – Illustrating the West Division Plant Composition

Comcast plant is a conglomeration of many acquisitions over the years and the relentless growth fueled by node splits and plant extensions. While documentation of hardline fiber plant necessarily follows the original plant, plant extensions generally follow modern guidelines. Presented above is the plant composition of the entire West division. One can see that the AR plant is only around 38% of the total while the remaining 62% of the plant is in UG. Around 25% of the total plant is clearly marked as CiC, but 37% of the plant is a mixture of CiC and Direct Bury, with no easy way of demarcating the builds. This is somewhat an artefact of the aforementioned acquisitions that results in a loss of clarity.

Still the results are quite revealing. In general, labor costs for fiber construction dominate over the cost of individual fiber costs. And UG fiber construction cost per foot is about 10 times the cost of AR construction. This is not surprising, as already mentioned, the labor cost of trenching and boring along with the more involved permitting and traffic control costs dominate over the more AR plant construction costs. So in that context, the total construction cost here could have been $0.38x + 0.62 \times 10x = 6.58x$. As will be shown later, the CiC process brings down the cost of construction in UG plant by around 7 to 10 times less than current UG deployment and bringing the CiC costs closer to AR deployments. In this context, the total cost of construction would have been $0.38x + 0.25x + 0.37 \times 10x = 4.33x$. This is a 34% reduction in construction cost overall! For construction budgets running into billions of dollars and spread out over years, these types of savings are quite impressive.

We would also stress again the importance of the time to upgrade types savings - using an existing duct infrastructure as compared to new trenching/directional boring construction in underground areas, and would also note that reentering the existing duct requires fewer permits, less traffic control and less restoration to the areas resulting in lower downtime and better customer experience.

3.1. The Fiber Journey ... Underground and in the Air

In previous papers [3,4] we have discussed that a move towards all fiber network across the country is a journey with multiple rest stops and not a single one-off event. And this is more so because of many

interesting developments in technology that enable the industry to serve customer bandwidth needs without an exclusive move to all-fiber solutions at once. Recent 10G industry moves help unlock RF cable potential via efficient and bi-directional use of RF spectrum and are of critical importance to our customers.

A point to note here is that each extra step in driving fiber deeper towards the customer has a force multiplying effect. Driving fiber to a node (which is N+x or N+0) is easier than driving fiber to the last active (FTLA), which in turn is easier than driving fiber to the curb (FTTC), which is easier than driving fiber to the home (FTTH).

By way of clarification, while N+0 and FTLA both have no actives save the nodes in the plant, but a crucial difference between the two is that N+0 reimagines the RF plant and with optimum node placement and RF modifications achieves the elimination of actives. In the FTLA however, the entire RF plant remains as before including the node and amplifier locations. By connecting up the nodes and each amplifier via optical fibers, each of the amplifiers is upgraded to a node (or a mini-node) and serves the existing homes attached to the said amplifier. FTTC entails running fiber to the current tap location and terminating it in micro-nodes and using existing RF drop cables to home, whereas FTTH requires an all-fiber circuit to the home and terminating it in analog or digital customer premise equipment (CPE).

As mentioned before, Comcast plant is today AR and UG, so a move towards deeper fiber should accommodate both plant types, else the end result cannot be accomplished. So, there is a need to optimize UG construction so that the entire process of fiber deployment become simple cost effective and predictable.

4. CiC Parameters

In this section, we define some important parameters that explain the CiC and discuss the ways in which CiC is implemented. In the picture below, the orange ring represents the conduit. The black circle on the left indicates the RF cable ensconced in the conduit when the UG plant was laid out originally. One can see here that there is an empty space in the conduit not utilized by the RF cable that might be big enough to accommodate an extra cable comprising optical fibers.

For many years, on short sections of conduit, folks sometimes SST fiber bundles. These SSTs were rectangular shaped stiff fiber build that held just 12 fibers. The peculiar geometry of the bundle and very limited fiber counts made it difficult and less attractive to consider this for a wider deployment. Recently, there has been a slew of development in so called micro-fibers that enable up to 72 count fibers in a diameter of just ~4.5mm! The middle picture above shows how such a fiber would look relative to the RF Cable. To compare these micro-fibers to what is generally used in AR plant the armored cable has a 48 count fiber with a total diameter of ~11.7mm. As can be seen, the wider the conduit and smaller the cables, the easier it is to accommodate within the conduit.

Of course, Comcast plant changes from place to place, but for purposes of discussion, we have considered here a 0.625in Coax in 1-1/4 Conduit for a good portion of our analysis and trial. For these conditions, the conduit inner diameter is ~1.4in, while the Coax outer diameter is ~0.85in.

4.1. Linear and Area Fill Ratios

In the left picture, the ratio of RF cable outer diameter to the conduit inner diameter is called the linear fill ratio (LFR) while the ratio of the respective cross-sectional areas is the area fill ratio (AFR). In the above example, the LFR is ~61%, while the AFR is ~37%. What this means is that with the cable in the conduit, the conduit still has an empty space that can accommodate an appropriately small fiber cable inside of

itself in addition to the existing RF cable. The smaller the LFR and AFR, the easier it is to get additional cables in. As the LFR and AFR grow, the accommodating space becomes smaller and friction and geometry start acting up and limit the addition of additional cables into the conduit.

Figure 5 – Illustrating CiC Linear and Area Fill Ratios for various cables

Consider the right picture above, where we are looking the typical conduit trying to accommodate an RF Cable along with a ~11.7mm armored 48 count cable. The LFR here which is the sum of the two cable diameters relative to the conduit inner diameter is 94%, while the AFR which here is the ration of the sum of the cross-sectional areas of the two cables relative to the inner cross-sectional area of the conduit is 48%. So, while there is a bunch of space (52%) in the conduit, it is not possible to pull or push the armored cable thru the conduit while also the RF cable rides the same conduit. The friction of the two cables is too much, some of it with the conduit walls, others thru the RF Cable itself. If on the other hand, one considers a ~5mm micro cable, the LFR is 76% and the AFR is 39%, which is considerably better

4.1. Micro-Fiber Details

Recent developments in micro-fiber technology have enables CiC. Previously only SST fibers accomodating just 12 fibers were in use, today these cables can accomodate 72 or mode fibers. Typically these fibers have a core strength memembr in the middle and 6 tubes arranged around it. Each tube contains 12 SMF fibers. Therefore a typical micro-fiber can have upto 72 fibers. There are options that may provide more or less fibers depending upon the geometry and population of fibers in the cable. Many of the micro-fibers have a rip cords on the side that enable easier peeling of the cable to expose required fibers. The entire 72 fibers with 200um buffer along with all cabling has an outer diamter of just 4.5mm and is an impressive achievement. In case of the standard 250um buffer with all cladding requires a 5.5mm buffer. Both these fibers have a 200lbs/ft pull and crush strength. Another type of 72 count fiber cable with tensile and pull strength that rivals traditional 48 count armored cable at 600lbs/ft is now available with 9.1mm diameter as compared to the 11.7mm of the standard cable.

4.2. Fiber Strength and Micro-ducting

It should be easy to see from the above section that lower fill ratios help in CiC deployments, but in broad terms, the fibers are pulled thru the conduit. Such pulling of micro fibers could result in fiber breakage in which case it will reset the entire CiC process on a bad path since it will end up needing a large amount of fiber splices in tight spots and significantly increase deployment time. So to prevent that we select lower

fill ratios, but also fibers which have a sufficient pull or tensile strength. A fiber of 600lbs/ft of pull strength should be able to handle most of the pulling encountered in the CiC deployment. In addition to the pull strength, we will also need to have good crush strength. This crush strength is super important for AR deployment generally so that the fiber can handle the periodic wiring holds on the fiber. But crush strength is important even in CiC in case where the CiC integrity is less than optimal or in case of tight bends and dents that might form over time. Typical crush strength ranges from 200 to 600 lbs/ft. The armored cable for example has a crush strength of 600lbs/ft, while the micro-fiber has a 200lbs/ft.

This is where the idea of micro-duct comes as an additional tool in simplifying CiC. Micro-ducts which are typically 8mm outer diameter and 6mm inner diameter are a bigger than the micro-fibers with LFR of 84% and AFR of 42% and with the same tensile strength as the micro-fiber. At first glance it appears to be not that great of a bargain in using micro-duct with its higher FRs without any consequent increase in tensile strength. But the main reason this is so useful is that the micro-duct does not have any fiber of its own, so pulling the micro-duct and having it break while inconvenient is not a show stopper. One could repair the micro-duct and continue one with micro duct deployment. For this reason, one can tolerate a higher FR in the case of a micro-duct. Once the duct is installed, the 4.5mm micro-fiber itself may be very easily blown in, this time without any extraordinary effort and risk of fiber breakage in installation. Incidentally, one could use the arrive at the FRs for a micro-fiber in a micro-duct which itself is inside a conduit with an RF cable in it already. These FRs for the micro-duct referred to above are an LFR of 75% and AFR of 56%.

Table 1 – Table of Basic Attributes and Ratios [5,6,7]

Construction Description	ID Conduit/ Duct (in)	OD 0.625 in RF Cable (in)	OD micro-fiber / micro-duct (in)	LFR micro-fiber / micro-duct	AFR micro-fiber / micro-duct	Pull Strength micro-fiber / micro-duct (lbs)	Crush Strength micro-fiber / micro-duct (lbs/in)	Bend Radius micro-fiber / micro-duct (in)	Weight micro-fiber / micro-duct (lbs/ft)
GC Basic with just RF Cable	1.4	0.85		61%	37%				
+ 11.7mm 48ct armored fiber (for comparison only)	1.4	0.85	0.46	94%	48%	600	125	4.6	80
+ Rodder (for initial install support only)	1.4	0.85	0.38	88%	44%				
+ 8.5mm/6.0mm micro-duct	1.4	0.85	0.33	84%	42%	100	125	3.3	18
+ mXT 4.5mm 72ct micro-fiber in micro-duct						200	30	3.3	30
+ mXT 5.4mm 72ct micro-fiber in micro-duct						200	30	3.3	35
+ LMHD 9.1mm 72ct micro-fiber Only	1.4	0.85	0.36	86%	43%	600	125	5.0	44

Above, we have summarized several options (we thank Duraline, Corning and AFL) and FRs for each of the options, again the smaller the FRs, the better is the outcome for CiC. It is however critical to remember that there are many more conduits of various diameters and different micro-ducts and micro-fibers available and a table including many more possible combinations might be needed as we proceed more into CiC. Note here that although all the optical fibers illustrated here are from Corning, the are micro-fiber cables and micro-ducts could be from multiple manufacturers.

Although standard techniques exist for AR construction, the use of micro-fibers and micro-ducts can still be extended there if needs be. For starters, micro-fibers weigh a lot less than traditional armored fibers, so with sufficient strength micro-fibers, either by themselves or in micro-ducts these fibers may find spots in AR construction. We see from the above table that traditional armored cable suitable for AR lash might weigh ~80lbs/kft but an equivalent micro-fiber or micro-duct and micro-fiber combination might be just half of the equivalent weight. This reduced weight will also be useful while seeking permits for AR construction.

As an aside, ‘squirrel chew’ the issue of pesky rodents determined to sharpen their teeth is a well known issue in construction. The ability to deter rodents will be a prime consideration ! Armored cable has long

been important for this effort, but so also the use of non-toxic bittering agents in the fiber cabling and micro-duct construction to deter squirrel chew would be helpful.

5. CiC in a Green Sandbox – The Control Trial

With the above understanding, Comcast and our partners decided to try CiC out in an outdoors trial location. Our microfiber partner Corning and micro-duct partner Duraline together elected to test out the CiC concept at the Corning Green Acres facility. Our many thanks to the partners and their dedication to see this work amongst the pandemic restrictions. This is an impressive outdoor underground plant laid out in a grid fashion over several acres. This facility has handholes with conduits connecting them up, and several of these conduits are the 1-1/4 sized. In addition, several of these conduits also have cables that are similar to the 0.625in RF Cable. As such a trial in this location could mimic Comcast plant.

Presented below is a grid diagram of the plant we had, on the left is the way we began with CiC on the first day, across 5 sections of plant of various lengths, the second day is represented by the middle picture where we installed CiC in 3 sections and on the third day we installed 2 sections with CiC. Each day we tested different concepts, and cumulatively we had tested our ability to install a single micro-fiber, two micro fibers and micro fiber installation in a micro-duct. At the same time important questions about slack, bend radius were answered, as we questions about the total thruput of CiC per day with a crew of 4 installers. All installations were manual installations, and towards the end of the trial, several mechanized versions of installations were discussed. These are described in detail next.

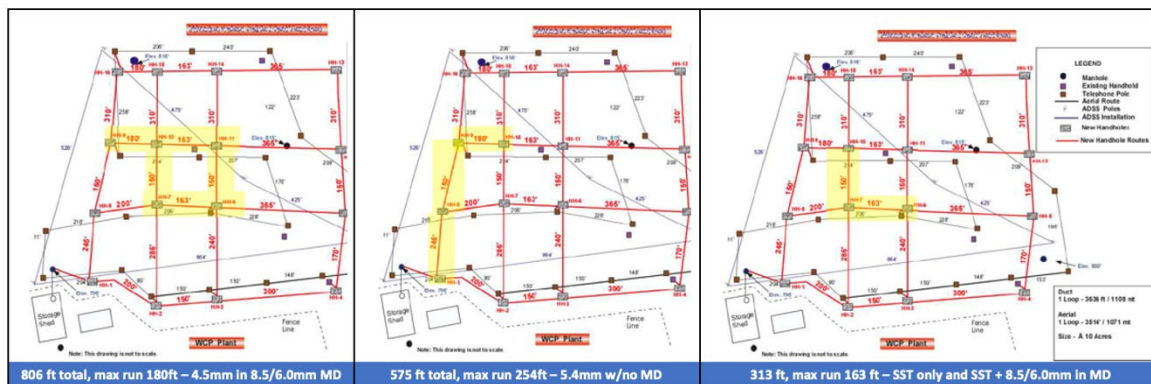

Figure 6 – Controlled trial: Day 1, 2 and 3

5.1. Basics of CiC Deployment

The basics of CiC deployment begin with selection of the RF Cable present and micro-fiber or micro-duct to be installed based on the FRs described earlier. Once that is done, a strong fiber glass “Rodder” of a diameter bigger than the micro-fiber or the micro-duct is inserted in the conduit. A nard bullet is affixed to the start of the rodder and is then pushed into the conduit until it surfaces at the other end of the conduit which may be 125 to 200 ft away. In doing so, the RF cable has been gently pushed aside and a continuous passageway has been opened inside the conduit.

At the surfaced end of the conduit, a cable pulling sock is attached to the rodder and the other end of the sock grabs on to the micro-duct or micro-fiber. The rodder is then pulled back the same way it went in, but at the other end, the micro-fiber or the micro-duct is then surfaced and thus the first phase of installation completed. This installation process is called the rod-and-rope method. During the many installations of the CiC, the Corning Green Acres trial clearly showed that re-entering the CIC using the rod-and-rope method was a viable solution.

Figure 7 – Illustrating the Rod-and-Rope process and blowing fiber into the installed micro-duct

The fiber or the duct is slacked and the next section is then begun. In practice one could go rather long distance fairly quickly if regular opportunity for surfacing the rodder are available. Notice that in this whole process, we never really had any reason to dig up the ground. Once the requisite length is reached, and if a micro-duct is used the fiber is simply blown in for the whole length, thus completing the process.

Figure 8 – Finished micro-fiber and micro-duct installed

The figure above shows the installed micro-fiber on the left and the installed micro-duct on the right.

5.2. Identified Challenges

In general, factors to consider for successful CiC include distance of the conduit system and the spacing between the handholes, the age of the system, condition of the conduit and blocks or damages, condition of the pedestal and space available around, terrain of the build and its proneness to rocks, elevation and ice. While none of these on their own are showstoppers, it is wise to prepare countermeasures ahead of time.

Most of the rodders also have a tonal strip, one that enables the exact path of the rodder to be known from above ground using tone detection equipment. So if the rodder is stuck or unable to proceed further, the exact spot of may be dug up and the conduit unblocked and the procedure continued. This is a way to precisely dig up only a small spot and limit impact. In our trials and tests we did not encounter this specific obstacle.

5.1. The Power Touch vs. the Human Touch

With a crew of 4 we spanned around 1700 ft of CiC spread over 10 sections, yielding an average of 170ft/section although, there was a section that was 245ft long. Based on these we estimate that a 200ft of CiC could be spanned by a crew of 4 within 20-65 minutes depending upon specific challenges. Rodding could be accomplished between a minimum of 10 to 40 minutes depending upon the conduit, pulling back the fiber our duct could be between 5 to 20 minutes and creating a fiber slack before proceeding to the next rod-and-rope could be about 5 minutes and if a micro-duct was used, blowing the fiber into it would be less than 5 minutes, but this last process is done after the micro-duct is installed thru all the sections.

We note here that if fiber is to be taken out of the micro-fiber cable, appropriate splice enclosures that can handle splices and the associated slack must be considered. In addition a good fiber management strategy should be adopted, one where tube colors and individual fiber colors in the tubes must be used as identifiers. The time associated with that process is part of node/network commissioning and not included here.

With this in mind a 4700-5000 ft of CiC could potentially be installed in one day with an 8 member crew. This is an important observation as the regular plant for an average sized node is about a mile (or 5200ft), and if it were in a planned development then that node could be fiberized to FTTC within a day in ideal conditions. Note here that there is no disruption of services as the fiber installation procedure has no impact on RF and power signals running on the cables.

There are power tools that could help the rodding and pulling process and all such equipment along with the fiber blower could be accommodated on a standard pickup truck, thus improving mobility and alleviating traffic concerns.

6. The CiC Trial out West

A decision was made to take the learnings gained from controlled testing that already had occurred and deploy it in an existing network. The market in the Denver area and the home of Comcast West Division office was selected as a suitable location. This market was selected as it has had a planned community with continual growth each year over the last thirty plus years. An important factor in performing this trial in the real world is determining where CiC has been deployed if mapping information did not capture conduit usage.

6.1. Locating the Trial

We were able to check neighborhoods by age of houses and using local knowledge of when CiC began widespread usage. Although CiC had been introduced in the 1980's the adoption amongst the multiple MSOs that existed at that time varied. There were variations of adoptions within the geographic areas of MSOs as well that affect what areas can be targeted for fiber override of existing conduit. After a couple attempts, we found consistent CiC usage in neighborhoods built after the year 2000. We did not go further in this area to narrow down what year CiC became prevalent but that information can be useful for particular geographic areas.

6.2. Dividing the Trial

For the field trial we decided to expand slightly over the controlled trial and push the application to gain additional data. Three different approaches were taken that are shown in the two pictures below that would give us additional data.

Location #1 what we called the outside left was an express run which would push the distance between each pedestal. Our plan here was to use the microduct being placed by rod and rope technique to establish the path for a final blow in of fiber.

Location #1 down the middle met the spacing consistent with what had been done in the controlled trial but here we would use a micro fiber with traditional six hundred pound pull strength. For deployment we would use rod and rope technique with no conduit, directly pulling the fiber in over the existing conduit.

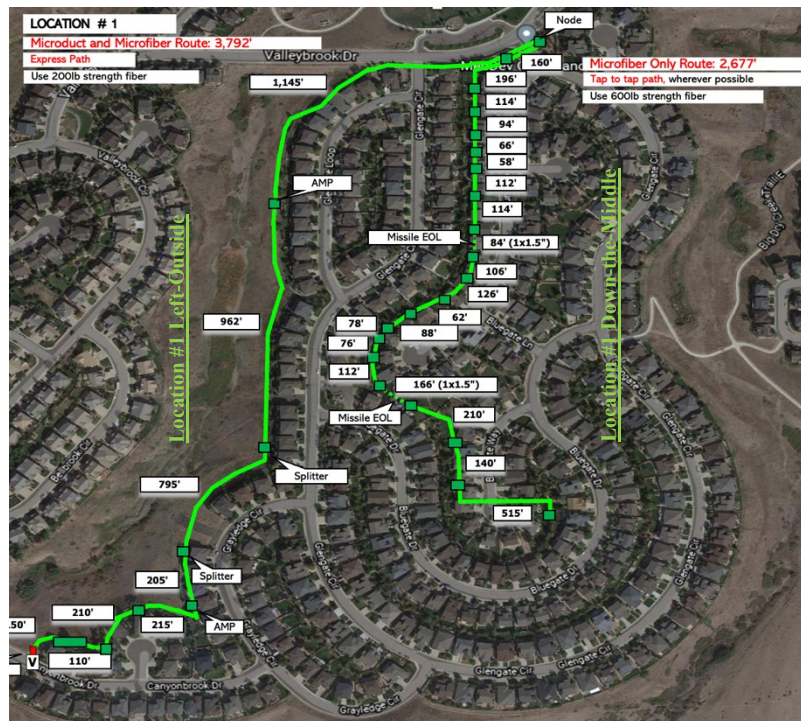

Figure 9 – Location #1 with “Left-Outside” and “Down-the-Middle”

Location #2 most fit what had been done in the controlled area and this was used to validate the lessons from the controlled trial. Pedestal distances were what we considered normal, the rod and rope technique was used to pull in micro duct to prepare for blowing in of fiber.

Figure 10 - Location #2 Real World Comcast trial matching the Control Trial

In each case, appropriate amounts of slack were rolled in into as part of construction. An important part of the trial was also the ability to identify fibers apart from RF cables. While this might look like a trivial part of the trial, getting this right is important to prevent needless fiber cuts by well-meaning techs out and about as they troubleshoot the RF plant. Some identification techniques work better than others and were incorporated in the builds.

Figure 11 – Location # 2 Left: Blowing of fiber, Right: Conduit spliced in ped for blowing continuity

Figure 12 – Location #1 down the middle direct pull of micro fiber with 600 pound pull strength

6.1. Trial Highlights

- No damaged conduit encountered in 7,924ft of CiC deployment
- Max length of conduit that can functionally be overridden is around 250ft (before rising above ground) this was determined in location #1 outside left. For distances longer than 250ft Rodder either became stuck or the micro-duct broke with too much pull force exerted on it
- 600-pound pull strength fiber is handled like BAU fiber today does not require any micro duct placement. We did experience scrapping of jacket making footage readings difficult from the jacket. Note that the 600-pound pull strength can be lashed in aerial plant like existing fiber (but this cable does not have armor)
- 200-pound pull strength fiber will require micro duct placement. Business Partners require additional skills and installation equipment not common to CATV construction. 200-pound pull strength cannot be placed aerially without micro duct, requires additional processes
- Both types of fiber cables can be successfully placed but must be operationalized for proper deployment
- Preliminary indications confirmed the significant reduction in cost indicated earlier relative to regular underground trench and bore in this location. Therefore cost savings can be substantial and time to deployment can be substantially decreased as well

6.2. Operational Considerations

- A new Statement of Work would likely be required to operationalize CiC across the footprint. This is because the amount of fiber that can be deployed and the speed of deployment are both different than for standard UG construction. From a strategic point of view, a new SOW focusing on CiC would also reduce conflict of interests within the builder community and help focus on CiC when that is better or regular construction when that is the only option available
- If smaller pedestals are in deployment, the CiC construction process and slack preparation would be longer and potentially impact construction costs. At this trial we encountered a number of smaller pedestals and considered upgrading them along the way
- Storage length and placement in each pedestal needs to be specified and documented. Identification of fiber vs. Coax needs to be vividly documented. Appropriate training material for maintenance and fulfillment teams would need to be developed

The technique of CiC fiber override has been introduced within Comcast as an option for local construction groups to use. This does require them to work with their business partner (contractor) to ensure they are properly prepared to execute this technique with adequately trained staff. Fiber override is not a one size fits all but the trial has proven that this is a viable technique which becomes another arrow in the quiver for the construction crews to use.

6.3. Fiber Portfolio

In other papers in this conference, we have presented on Hollow Core Fibers [8], this is a new type of fiber that enables light to be guided in a hollow core as opposed to the standard light being guided in solid core fibers. As light travels much faster (300,000km/s) in air than in glass (200,000km/s), there is a fundamentally large reduction in latency. This helps in important latency sensitive applications such as high frequency trading and 5G. In this context, CiC could play a major role in helping roll out fiber in UG plant. Recall that most micro-fibers have 6 tubes within with 12 fibers each in each tube. In this case, one or more tubes could be dedicated to hollow core fibers while others are for standard fiber and a portfolio of fibers may be installed when the conduit is re-entered. This type of innovative deployments may help overall to bring fiber to the neighborhood where high-capacity latency sensitive endpoints may be located.

7. Conclusions

In this paper, we reported on the use of innovative technology that enables us to use existing underground critical infrastructure and make fiber deployments in the neighborhoods simple, cost effective and minimally customer impacting. With innovations in fiber cabling and availability of higher count fibers, the ability to reuse existing conduit infrastructure opens up quicker ways of deploying fiber, all without the need for trenching or boring. As our own trials show, skillful use of this technology when combined with innovative optical systems could bring fiber to the curb (FTTC) and support the industry's 10G efforts and provide great long-term opportunities to span the last few meters and reach customer homes (FTTH) when needed.

Abbreviations

AFR	Area Fill Ratio
AR	Aerial
bps	bits per second
CiC	Cable in Conduit
DB	Direct Bury
FDX	Full Duplex
FEC	forward error correction
FTLA	Fiber to the Last Active
FTTC	Fiber to the Curb
FTTH	Fiber to the Home
HCF	Hollow core fiber
Hz	hertz
K	kelvin
LFR	Linear Fill Ratio
SCTE	Society of Cable Telecommunications Engineers
SOAP	Switch on a Pole
UG	Underground

1. Introduction

As Software Defined Networking (SDN) and Network Functions Virtualization (NFV) have become modern approaches to quickly deliver and offer network services such as SD-WAN, Security and other value-added services using service chains. Declarative & model driven orchestration technologies like TOSCA has become the fabric to develop Network Automation platform to manage lifecycle of these network service applications and build an ecosystem for multiple vendors to participate & integrate with their VNF solutions.

Comcast architecture leverages several information models and orchestration tools including TOSCA and YANG to enable complete life cycle management of SDN and NFV functionalities and to configure physical and virtual devices that comprise an end-to-end service.

The paper describes how TOSCA is being used to describe orchestration between resources across complex end to end service(s) such as SD-WAN and Cloud Security. Demonstrate the capabilities of TOSCA like substitution/service decomposition for vendor abstraction to realize some of the VNF's, interface and life cycle operations used for the implementation aspects, requirement, capability types, node referencing features, define and visualize end-to-end service as a topology graph of inter-connected nodes and to navigate across connected services.

YANG is a data modeling language used to describe the device configuration. Device/network configuration properties are modeled as YANG. The syntax and semantic constraints and capabilities offered by YANG are made use of during service validation and activation.

2. Overview

At a high level, for Comcast use cases, Service life cycle management comprise of one or more of the following.

- 1) Staging/provisioning the base configuration for the network devices
- 2) Amend changes to the configuration.
- 3) View service configurations
- 4) Updates service configuration.
- 5) Add/Remove features to the services
- 6) Upgrade/Downgrade of services
- 7) Monitoring the health of services and corrective actions in case of service degrade and/or disruption.

This paper will focus on the model-based service management platform. The platform provides APIs for some of the service life cycle management functionalities. The platform is a middleware layer that interacts with OSS/BSS systems northbound and Network Layer, VNF Managers, Vendor specific EMS/NMS systems southbound.

The paper highlights how TOSCA model and Service Orchestrator enables to support service life cycle management functionalities for different domains such as SD-WAN, Security, Wireless etc.

3. Service Model (TOSCA)

OASIS TOSCA is an orchestration language for automating Service Lifecycle Management. Service designers use TOSCA to create Service Templates that contain, model-based descriptions of services, platforms, infrastructure, and data components, along with their relationships, requirements, capabilities,

and configurations. The TOSCA model optionally supports service-specific orchestration and lifecycle management directives and operational policies that operate on these models. TOSCA model assumes a runtime environment (an “orchestrator”) in which service models are processed with the goal of orchestrating the service and managing service lifecycles.

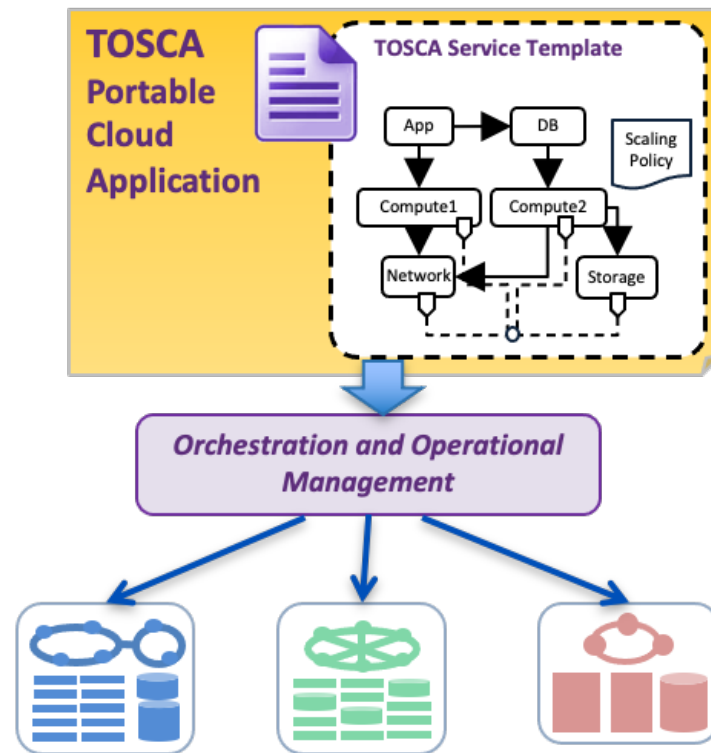

Figure 1 - What is TOSCA

3.1. Why TOSCA

TOSCA provides several features for the automation of service life cycle management via declarative directives. The following tables provide a high-level comparison of declarative versus imperative architecture.

Table 1 – Declarative versus Imperative Architecture

Declarative Architecture	Imperative Architecture
Arbitrary number of levels of recursion	Fixed number of layers
Federation built-in: North-south and east-west interfaces are the same	Federation must be added-on: North-south and east-west interfaces are different
Flexible resource layer: no architectural distinction between resources and services; resources are	Inflexible resources layer: distinction between resource layer and services layer is baked into the architecture

Declarative Architecture	Imperative Architecture
accessed as services, and services can be exposed as resources	
Identical DSL at each level in the recursion	Layer-specific APIs
Identical orchestration functionality at each level in the recursion	Layer-specific orchestration functionality
Interface implementations based on Domain-Specific Language (DSL)	Interface implementations based on APIs
Interface paradigm based on negotiation (request/response) and delegation	Interface paradigm based on management (higher layers control lower layers)
Organizing construct: recursive decomposition	Organizing construct: static layering

3.2. TOSCA Features

The following are some of the high-level features offered by TOSCA. These features are used as part of the service life cycle management.

- TOSCA Specification and TOSCA profiles. Profiles come with pre-defined type definitions.
- Ability to define type definitions (Node Types, Datatypes, Requirements, Interfaces, Capabilities, Artifacts etc.)
- Standard Interface & Lifecycle Operations - create / configure / start / stop / delete
- Custom Interfaces and Operations (Modify, Upgrade)
- Declarative workflows based on node relationships and capabilities
- Service Topology Template (Service inputs and outputs, Service components/nodes and their relationships)
- Substitution Mapping / Service Decomposition
- Node reference via node filter
- Package TOSCA models as a CSAR

3.3. Use of TOSCA and Yang

In certain use cases, there is a need to use multiple modeling languages for example, YANG. In such scenarios, the properties needed for the orchestration functionalities are modeled as TOSCA type definitions. The core feature configurations are modeled in YANG. The device configuration YANG model is parsed and represented as JSON schema and packaged as part of the CSAR. This allows the service orchestrator and implementation to validate input JSON data for the feature configurations against the schema at run time.

3.4. TOSCA Meta Model Phases

TOSCA Meta-Modeling Constructs support all phases of the service lifecycle

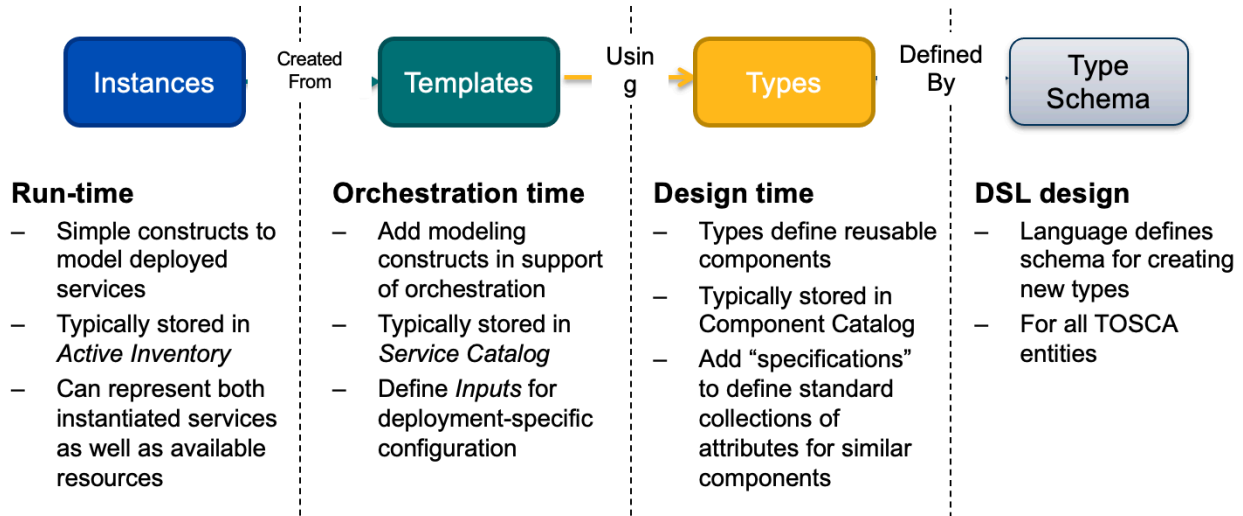

Figure 2 - TOSCA Meta Model Phases

3.5. TOSCA Object Model

Following is the TOSCA Object Model UML

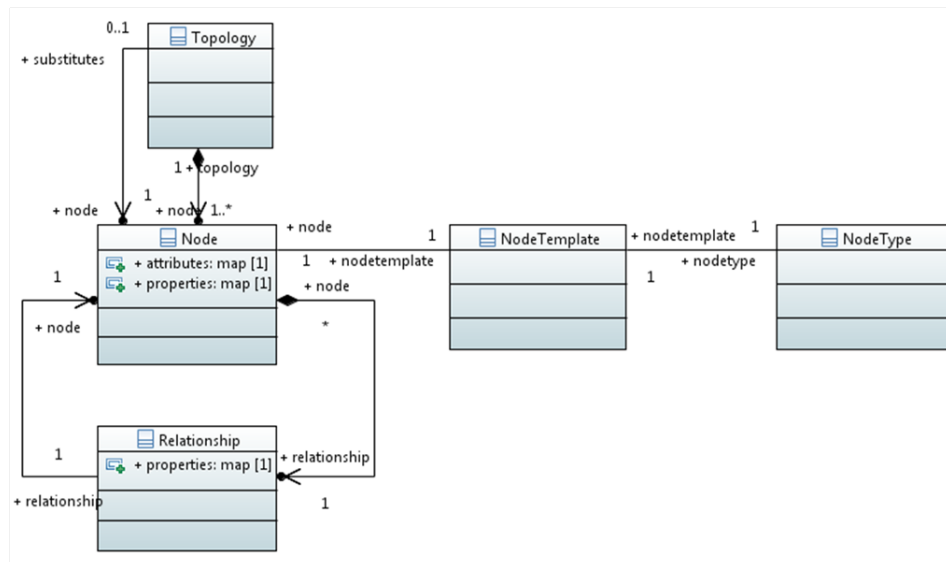

Figure 3 - TOSCA Object Model

4. Service Orchestration

4.1. Challenges with Service Life Cycle Management

The following lists some of the high-level challenges with regards to managing services.

- Service Model – How much to model/when not to model, Vendor specific versus Vendor agnostic, mix/match of model technologies (for example, TOSCA, YANG, SNMP, CLI etc.)
- Handing out of automation changes (Manage out of band changes and synchronization)
- Source of Truth – Network versus Automation System. This is critical in scenarios where out of band changes happen and the automation system does not have the capability to sync with the network.
- Rollbacks in case of failures – Automated versus Manual
- Managing service dependencies – Impact of a service change to another dependent service (Ripple effect)
- Service Upgrades – Model upgrade resulting in service instance(s) upgrades, Defect fixes, new feature rollouts etc.

4.2. Platform Goals

Software platform to unify and automate service lifecycle management functionalities via model driven (TOSCA for orchestration and YANG for configuration) architecture. The platform.

The platform offers capabilities to onboard models, provision/deploy/update services for different domains such as SD-WAN, Security, WIFI etc.

- A software platform to unify and automate complete service lifecycle
- Leverages Model driven Service Automation Language: TOSCA & YANG for configuration.
- Onboarding, Provisioning, Deployment, Monitoring
- Orchestrate multiple services (e.g., SD-WAN, Security, VNFs, other)
- Orchestrate hybrid environments – physical, multiple clouds and on premise
- Modeling and Service design tools
- Dynamic traffic steering and service chaining
- Active Inventory and Service Topology
- Southbound vendor specific implementations
- Enable us to define and implement business logic and functional logic independently

Figure 4 – Functional Architecture of Service Orchestrator

4.3. Service and Function Model Definition (Design)

Network Services and Network Functions are designed by creating TOSCA topology templates from which services can be instantiated and managed.

Service design involves the following steps:

- Defining set of type definitions (Data types, Node types, Relationship types and Capability types etc.). Reuse and/or enhance existing type definitions and add new type definitions.
- Define the topology template that represents the service as a topology of interconnected service components, relationships between the service components
- Define inputs that need to be provided at deployment time
- Define outputs that are expected to be returned upon successful service operation
- Provide implementation details (Plans/Workflows/Scripts references) for the life cycle operations (create, update, delete, upgrade, etc.) of the service components.
- Package as a cloud service archive (CSAR).

4.4. Service and Function Onboarding

The service packaged as a CSAR should be onboarded to the Service Orchestrator catalog repository. Service orchestrator validates (syntax and semantics) the CSAR and store in the catalog repository. Multiple versions of the CSAR can be onboarded.

4.5. Orchestration (Runtime)

At runtime, service(s) can be instantiated using the onboarded service CSAR. The service inputs as defined in the CSAR should be provided as part of service instantiation.

Service orchestrator performs validation of the inputs, invoke the implementations, and create service instances in the instance repository. Internally, TOSCA service orchestrator does the required substitutions, resolves references (matching requirements and capabilities) to the service components and resources. The service instance is a graph of service components nodes connected via relationships.

5. UseCases

5.1. SD-WAN

SD-WAN is an overlay service configured over the underlay infrastructure. Comcast offers physical/virtual CPEs in which SD-WAN is configured. CPEs are configured via VNF Manager. VNF Manager offers REST APIs. Configurations are staged at the VNF Manager and later committed to the CPEs (2 step process). SD-WAN logically modeled as 4 services. Services are linked. Information shared across services to enable configuration. For example, WAN Interface information, CPE details exposed by uCPE Service to VPN Site service. VPN information exposed by VPN Service to VPN Site Service.

Vendor VNF Manager modeled as a node type and node instance in the service (Not as a separate service/resource). Service Referencing (Orchestrator implementation extension, like the node referencing in TOSCA) feature used to link services and share information across services.

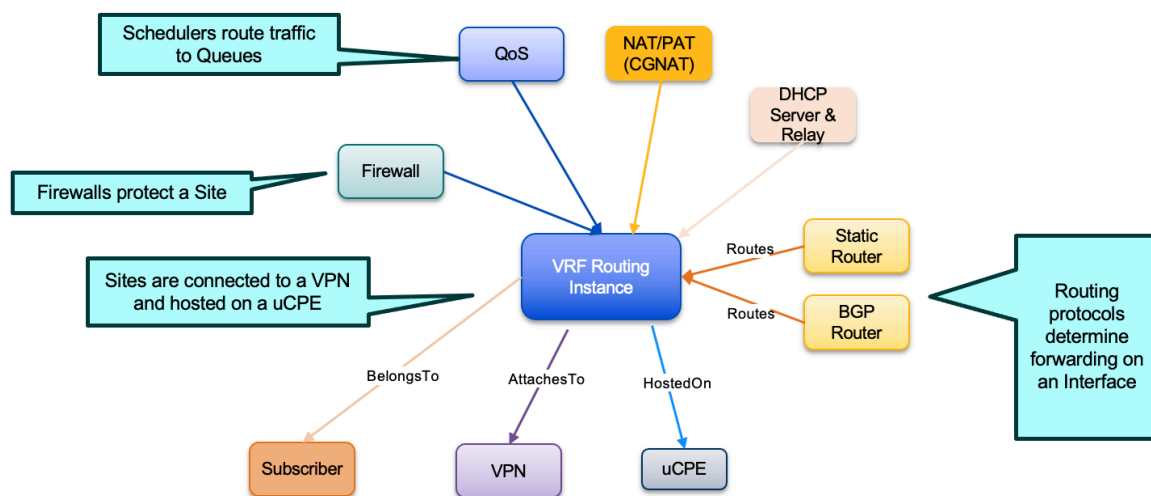

Figure 5 – SDWAN VPN Site Service (Sample)

The following are some high-level configurations represented as JSON type.

- Interface (LAN & WAN Interfaces) Configuration
- Routing Configuration (BGP, Static Routes etc.)
- DHCP Server & relay
- Class of Service
- CGNAT
- Firewall
- Traffic Steering Rules/Policies
- Custom Services & URL Filter Definitions

SD-WAN VPN Site Service Topology Template (Snippet only)

Following topology template snippet for a service component/node in a topology template. The sample highlights the node requirements and the life cycle operations of the service component (create, delete, upgrade) and the implementation references.

      inputs:
        ## Omitted for clarity
```

5.2. Firewall

Vendor agnostic models are defined as abstract models. The goal of abstraction is to avoid making technology/product decisions at design time. The abstract models will be decomposed (model decomposition feature of TOSCA/Service orchestrator) at runtime to vendor specific implementations.

Figure 6 - Firewall Vendor Abstraction

Figure 7 - Firewall Vendor Substitution

Substitution and Service decomposition - One Node instance substituted with a single node / set of nodes defined in the substituting topology template. In the above example, Firewall node substituted with Vendor A Firewall Template containing 4 nodes.

6. Conclusion

This paper highlighted how TOSCA as a modeling language and the TOSCA features combined with a service orchestrator simplifies the deployment of services for different domains.

The type definitions in TOSCA model simplifies the application to perform the validations. The service orchestrator combines all the node dependencies and generates the declarative workflow for the service minimizing the need to deal with dependencies in the application.

The service orchestrator enables to provide implementations for the supported life cycle interfaces and operations and is abstracted from the domain TOSCA models. In addition, it offers the flexibility to provide multiple implementations for a given model (Plug & Play).

1 Introduction

1.1 Executive Summary

CableLabs developed a simulations engine intended to estimate a set of Key Performance Indicators (KPIs), concerning the user experience for Fixed Wireless Access (FWA), when estimated across a cluster of cells. This simulations engine is further used to provide input data for the FWA economics performance analysis tool. The Economics Analysis Methodology is presented in a companion paper.

The Technical Performance Analysis discusses the impact of different limitations upon the cell coverage:

- The support of frequency reuse 1, when smart arrays are employed. More specifically how could the network load impact upon victim cell coverage, could be controlled by dynamically controlling the base station (BS) array vertical down-tilt angle.
- The interfering cell network load impact upon the victim cell user throughput (T_{put}), indicating a network load in the 50% range or less, may be optimal to avoid significant cell throughput degradation.
- BS antenna height (h_{BS}) of 30m and 60m were analyzed, pointing to: i) a higher network interference impact when the frequency is decreased; ii) a lower network interference impact for the outdoor-to-indoor (O2I) case vs. the outdoor scenario; and iii) a very low or close to the noise floor outdoor 6.4GHz network interference.
- The impact of fading and loss mechanisms upon outdoor and O2I propagation is further analyzed. The results show that the main contributor to outdoors increased path loss is the small-scale fading, as long as the O2I fading is kept in check (CPE positioned close to the outer wall closest to the victim BS).
- The uplink (UL) link Budget limitations, pointing to i) downlink (DL) and UL coverage are in the same range for $h_{BS}=30m$ (3.7GHz) due the increased DL interference (MobEdge=2000m), ii) 2.6GHz coverage is slightly larger than the 3.7GHz, however the difference between the two is minimal due to the larger network interference impact on the 2.6GHz system, iii) the O2I UL coverage is more reduced vs. DL, due to reduced O2I DL interference and the reduced indoor CPE antenna gain vs. outdoor CPE gain,

The key results concerning cell coverage and user throughput are discussed from different angles:

- The outdoor coverage may extend beyond the serving cell edge, due to the highly directive outdoor CPE antennas.
- 2.6GHz line-of-sight (LOS) coverage is smaller than the 3.7GHz one ($h_{BS}=30m$ and 60m), due to the higher network interference impact.
 - Non-LOS (NLOS) becomes the dominant propagation mechanism, since the network interference is greatly reduced in NLOS conditions. Overall, the 2.6GHz composite coverage is NLOS driven being higher than the similar 3.7GHz coverage.
- The network interference ($h_{BS}=30m$) is higher than corresponding to $h_{BS}=60m$ for the 2.6GHz, due to the smaller cell radius selected for this case (MobEdge =2000m).
- The outdoor 6.4GHz cell edge is limited by the lower BS effective isotropic radiated power (EIRP) of 36dBm.
- Providing NR in Unlicensed Spectrum (NR-U) services in unlicensed 6 GHz spectrum may require a densified network.

- The O2I cell edge is UL limited, due to the additional UL path losses, caused by the O2I loss, the indoor CPE being required to either i) have a higher conducted RF power and/or ii) use a directive antenna array with a higher gain vs. an omni antenna.
- For 3.7GHz, $h_{BS}=60\text{m}$, outdoor case, all scenarios exceeding a service availability >97% are impacted by an UL asymmetric link budget.
- As the probability of achieving a particular radio link throughput (i.e. service availability) is increased to 99%, cell coverage is reduced.
- A FWA network planning targeting 95% service availability backed by 50% network load may be an optimal trade-off.

The paper is organized as follows:

- Section 2 introduces the analysis methodology and the simulations assumptions.
- Section 3 presents the main results.
- Section 3.1 discusses the limiting factors driving to a sub-optimal coverage.
- Section 3.2 summarizes the key results characterizing the user coverage and overall cell coverage, the coverage for FWA throughput thresholds.
- Section 4 summarizes the main findings of this analysis.

1.2 Wireless Spectrum Intended for Rural FWA Applications

FWA provides broadband service in areas where wired solutions are not prevalent or as a competitive alternative to wired broadband. One key performance factor is the optimization of wireless coverage for high throughput services. While earlier FWA implementations were hampered by spectrum and other technology implementations, 5G maximizes the potential FWA performance by employing channel bandwidths up to 100MHz (sub-7GHz) and up to 400MHz (24 – 52GHz spectra).

We identified the following spectra with channel bandwidth allocations in excess of 60MHz, which could be suitable for FWA in North America and Europe, following related spectrum auctions.

Table 1 – Bands Available at 2.6, 3.7 and 6.4 GHz for FWA Services

Frequency [MHz]	Band	Common Name	Max Channel BW [MHz] [4]	Market	Comments
2500 – 2696	n41	BRS	100	USA	
3550 – 3700	n48	CBRS	100	USA	
3450 – 3650 3650 – 3980	n77 Canada		100	Canada	
3300 – 4200	n77 global		100	Global	except USA and Canada
3450 – 3550 3700 – 3890	n77 USA	C-band	100	USA	
5925 – 7125	n96	6GHz	100 80	Regional USA, Canada	
5925 – 6425	n102		100 80	EU	

2 Analysis Tools and Assumptions

Throughout the paper we use the generic term BS for 5G BS (gNB).

2.1 Analysis Methodology

Our FWA coverage analysis is based on a simulation engine developed by CableLabs. This engine was designed to support an economics analysis based on the technical performance of a large-scale cluster of 5G of cells.

2.1.1 Simulations Engine Block Diagram

The simulations engine block diagram is presented (Figure 1). Within the simulation engine the System Level Simulator (SLS) module evaluates radio performance for unmodulated signals over a large number of iterations (Monte Carlo simulation). The SLS generates statistical results of aggregated interference across a cluster of 19 cells arranged in 2 rings surrounding the cell of interest. The 5G New Radio (NR) Link Level Simulator (LLS) simulates 3GPP compliant waveforms targeting the 5G NR performance in a simulated network environment including the network interference predicted by the SLS. The CPE/BS antenna pattern array block generates suitable BS and CPE antenna array patterns. The antenna arrays are critical for supporting frequency reuse (FR) 1 across the radio network by optimizing the link budget component.

The economics analysis block estimates the economic feasibility of the 5G FWA O2I and service delivery network under consideration, based on a set of technical KPIs. This paper focuses on the technical simulation consists of SLS, LLS and antenna characteristics. A companion SCTE Cable-Tec Expo 2022 paper presents the economics analysis.

The functionality of the component blocks is explained in sections 2.1.2 to 2.1.5.

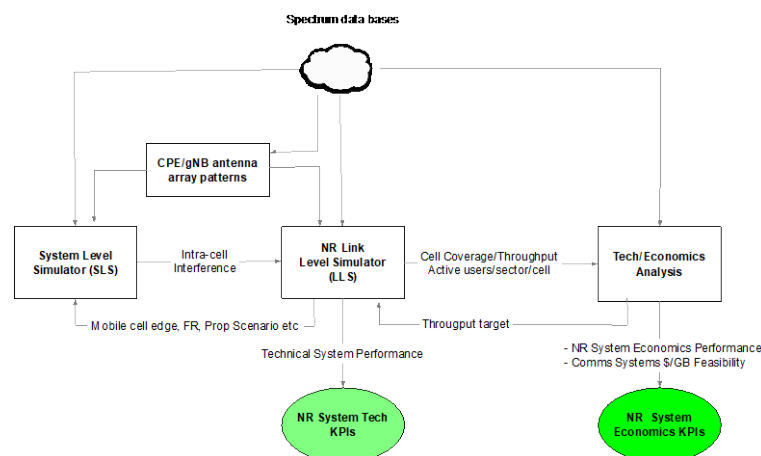

Figure 1. Block Diagram of the FWA NR Techno-Economics Performance Simulator.

2.1.2 CPE/BS Antenna Array Patterns

The CPE/BS antenna array patterns are critical for SLS and NR LLS to calculate the link budget in an interference rich environment, for both the victim path and interference paths in both DL/UL. The spectra used for this analysis are n41 (central frequency 2.6GHz), n77 (central frequency 3.7GHz) and n96

(central frequency 6.4GHz). For each of these bands, a number of antenna array parameters are estimated (Table 2, Table 3, Table 4). A selection of plots summarizing the performance of these arrays is presented in section 7.2.

An antenna array manufacturer may further optimize the electrical performance of the arrays described below. In this context, the performance of these array should be considered as readily achievable.

Table 2. CPE/BS arrays. Summary of the Main Configuration Parameters

	Array Type	Array of Subarrays	Subarray Size	Antenna Element Type	Vertical Electrical Tilt [°]	Estimated Mechanical Size L×W [mm]
CPE Indoor Antenna	UCA	4×1	1×4	Omni	0	
CPE Outdoor Antenna	URA	1×1	2×8×2	Cross-Dipole	0	400×150
BS	URA	4×1	4×4×2	Cross-Dipole	-15	

Table 3. Summary of the CPE Array Performance Parameters

	Max Gain [dBi]	Azimuth (Beam) HPBW [°]	Elevation HPBW [°]	Estimated Mechanical Size L×W [mm]
Indoor Antenna	8.2	360	10 ⁰	58x58x158 (cylinder)
Outdoor Antenna 2.6GHz	16.0	16	53	
Outdoor Antenna 3.7GHz	17	16	52	400×150
Outdoor Antenna 6.4GHz	17.1	16	52	400×80

Table 4. Summary of the BS Array Performance Parameters

	Max Gain [dBi]	Azimuth (Beam) HPBW [°]	Elevation HPBW [°]	Estimated Array Mechanical Size L×W [mm]
2.6GHz	15.6	29	32	
3.7GHz	16.4	29	30	800×200
6.4GHz	16.5	29	28	480×120

2.1.3 System Level Simulator

The SLS is 3GPP compliant in terms of cell topology [1] and propagation models [2]. As shown in Figure 2, the SLS's topology consists of 19 sites, with the serving BS (#1) in the center and two rings of interfering BS (#2 – #19). The assumed cell Radii are presented in Table 5, where inter-site distance (ISD) is calculated as:

$$ISD = \sqrt{3} \times Radius \quad \text{Equation 1}$$

For this analysis a three sectors per cell topology was assumed. All cells use a frequency reuse 1 (FR1). This topology allows each cell to employ the maximum channel bandwidth (BW), 100MHz for n41 and n77, 80MHz for n96, but triggering a significant intra-network interference for some scenarios. Adjacent

channel interference is ignored since is much weaker than co-channel interference. The BS and victim CPE employ the antenna patterns presented in section 7.2. For this paper, we conducted a comparative analysis on multiple scenarios, exercising $h_{BS}=30$ and 60m, outdoor and O2I scenarios for 2.6, 3.7 and 6.4GHz frequencies. While the analysis summarizes results for both $h_{BS}=60$ m and $h_{BS}=30$ m, for the sake of brevity, the authors chose to minimize the amount of simulations plots concerning $h_{BS}=30$ m.

Figure 2. Example of the 19 Cells Topology Used by SLS.

The related cell radius and ISD are presented in Table 5.

Table 5. Assumed cell radius (MobEdge) and ISD for $h_{BS}=30$ m and 60m

h_{BS} [m]	Cell radius (MobEdge) [m]	ISD [m]
30	2000	3464
60	4000	6928

SLS is a Monte Carlo simulation technique that runs a large number of iterations (e.g., 100,000 for each scenario analyzed) to output statistical results. For each iteration, a random CPE location is generated inside the serving cell. Distance, relative azimuth and elevation angles between the CPE and each of the 19 BS sites are calculated to estimate path loss, antenna gain, shadowing loss, small-scale fading, and O2I wall penetration loss for both the serving link and interference links. The distributions of these parameters are generated by the Monte Carlo simulation, based on which the service availability (e.g., 95% or 99%) is derived.

Network load is another variable given that not all radio resource blocks are fully allocated for all BSs at all times. For example, if the network load is set to 25%, each of the interfering cells and the victim cell have a 25% probability to transmit in each SLS iteration. All bands under consideration are time division duplex (TDD) bands. We assume TDD sync is enforced among BS s to avoid DL-to-UL and UL-to-DL interference. In this paper, we focus only on the aggressor-to-victim DL-DL interference from the aggressor BS to the victim CPE. Another internal study (not discussed here) indicated that UE to UE and UE to BS interference are negligible, even when TDD aligned.

The cell scenarios modeled in this paper are based on 3GPP channel models [2] as defined by the rural macro (RMA) environment. A random LOS probability is assigned for each SLS iteration, then the path loss, shadowing and fading are calculated for this probability of LOS or NLOS conditions. A Ricean K -

factor of 12 dB is used to generate small-scale fading in the LOS condition and small-scale fading Rayleigh distribution in NLOS conditions. The O2I wall loss is also based on the 3GPP model [2] following a Gaussian distribution for a residential home (wood outer wall, regular glass windows, with a glass/wall ratio of 0.3) centered on a mean value of 9.3 dB and standard deviation of 4.4 dB [2].

The calculation of interference power level and aggregated interference is presented in [12]. The aggregated network interference is further used by the NR LLS to estimate the signal-to-interference-plus-noise ratio (SINR) for the target victim CPE. Shadowing (large-scale fading), small-scale fading, and O2I loss variables for the signal link are also provided to the NR LLS to quantify service availability.

2.1.4 Link Level Simulator

The NR LLS is a Matlab-based simulator, developed in compliance with relevant recommendations from the 3GPP [2], [3], [4], [5], [6], [7], ITU [8], [9], [10] and TIA [11] targeting the behavior of a 5G waveform when subject to a target propagation environment and for a given geography, propagation model and system interference impact.

The LLS outputs the following technical performance KPIs.

- Dynamic DL/UL SINR, predicting the DL/UL link budget asymmetry per path length unit.
- User throughput versus path length for LOS, NLOS and composite propagation.
- DL user spectral efficiency (SE) versus path length as a function of NR Rel-16 link adaptation.
- DL received signal level (RSL) versus path length.
- BS array EIRP vs. path length and vertical tilt angle.
- Victim fade margin and system interference impact (based on the SLS inputs).
- 50, 100, 300 Mbps (configurable) and mobile cell edge coverage service availability.
- Coverage and user throughput vs. BS array vertical tilt angle.
- Coverage and user throughput vs. network load.
- Network interference power vs. BS EIRP or BS array tilt angle or network load etc.

2.1.4.1 LLS Methodology

The analysis methodology employs the following steps.

The PathLoss is calculated based on:

$$PathLoss(f, path, BS, CPE, environment) = PropagationLoss + prctile\{Shadowing + AtmosphericConditions, Outage\}$$

Equation 2

where:

PropagationLoss is a function of (distance, frequency), including BS Height, CPE height, CPE Outdoor/O2I scenario and clutter;

prctile function calculates the additional link fade margin for the target availability

Shadowing outdoor large-scale fading modeled by a Gaussian distribution (sigma scenario, mean path loss) and

AtmosphericConditions additional path loss caused by rain fading, water vapor fading and gaseous fading. For a path length <5 km below 10 GHz, the impact of atmospheric conditions upon the PathLoss may be negligible. More details about the environmental factors methodology upon the PathLoss could be found in [12].

The link SINR is calculated based on:

$$SINR = RSL - prctile\{LargeScaleFading + SmallScaleFading + ShadowingO2I + Interference(NetworkLoad) - WallLoss(sigmaO2I, MeanLoss)\} - NF + 10 \times \log_{10}(OS) \quad \text{Equation 3}$$

where

NF CPE noise figure (it includes the CPE modulation implementation losses);

OS Oversampling ratio (CPE PHY). Though the oversampling is effective on improving the SINR for noise-limited environments, it may have a limited capability on interference limited ones.

SmallScaleFading Modeled as the Rayleigh distribution for NLOS (Rice distribution with low K factor available is optional);

ShadowingO2I Modeled by a normal distribution {meanWallLoss, sigmaO2I}; Mean(WallLoss) is the mean outer wall penetration loss (O2I only), as a function of wall material, glass to wall area ratio, and glass material.

Interference(Outage, NetLoad) Network interference plus noise floor as a function of link outage probability and network load. The (System) Interference is calculated by the SLS for given outage, MobileCellEdge, and CPE/ BS antenna geometries.

The CodingRate function calculates the LDPC coding rate and the QAM modulation order as a function of SINR, based on the QAM256 modulation and coding scheme (MCS) table.

$$[MCS_{coding}, MCS_{qam}] = CodingRate(SINR) \quad \text{Equation 4}$$

where

MCS_{qam} QAM order for the target distance, subject to link adaptation,

MCS_{coding} MCS coding rate for the target distance, subject to link adaptation.

Spectral Efficiency is defined as:

$$SpectralEfficiency = MCS_{qam} \times MCS_{coding} \quad \text{Equation 5}$$

The User Throughput ($UserTput$) is calculated as follows:

$$UserTput(distance) = MCS_{coding} \times MCS_{qam} \times PRB \times (TDD_DL_sym - DMRS - ControlSym) \times MIMO \times Slots \times Subframes \times Frames \quad \text{Equation 6}$$

where

MCS_{coding} Emulates the link adaptation as a function of the SINR degradation by calculating the LDPC user coding rate,

MCS_{qam} Emulates the link adaptation as a function of the SINR degradation by calculating the QAM modulation order,

PRB The number of Physical Resource Blocks per slot,

TDD_DL_sym Chosen as 12 symbols/slot (TDD ratio 12:1:1), maximizing the DL output,

DMRS Selected as 1 symbol/slot,

ControlSym The number of control symbols per slot,

MIMO DL MIMO rank. MIMO performance in O2I propagation environments may be subject to degraded performance under severe multipath conditions due to the large amplitude imbalance between the different Rx air layers reaching the antenna receiver.

Slots 2^μ , where μ =numerology order: SCS= $\mu \times 15\text{kHz}$, where $\mu=1, 2, 3, 4$ (NR Rel 15-17)

Subframes Number of subframes/frame:10/frame

Frames Number of frames per second (10/s).

The overall BS User Throughput ($DLUserTput$) is based on:

$$DLUserTput = UserTput \times Beams \times Sectors \quad \text{Equation 7}$$

where

$UserTput$ User throughput data (it excludes the control and signaling data)

$Beams$ beams/sector and

$Sectors$ sectors/cell.

All the above steps are repeated three times to calculate above parameters for LOS, NLOS and composite (LOS/NLOS) for UMi, UMa, or RMa scenarios (only the RMa scenario considered for this analysis). The above functions are calculated for every meter of the path length, supporting high accuracy plots.

2.1.5 Economics Performance Simulator

This paper focuses on the technical performance parameters of mid-band spectrum. A companion strategy brief looks at the potential competitive implications of FWA services, based on main KPI of the Technical Performance Analysis (e.g., household (CPE) distribution per coverage as a function of path length to the BS). The analysis estimates how much capacity can be created by cell area under a range of assumptions. Using data from CableLabs' quarterly bandwidth usage report, the analysis forecasts future peak broadband demand per average household, factors household density for the areas of interest and estimates what percentage of FWA subscribers can be supported from a market penetration perspective.

2.2 Assumptions

There is a large set of assumptions backing the Key Performance Results, presented in this paper. All simulations results presented in this paper are based on this set of assumptions. These assumptions are grouped in the following categories:

- System and cell simulations assumptions (see Table 16)
- BS and CPE simulations assumptions (see Table 17)
- Atmospheric/environment conditions assumptions (see Table 18)
- CPE/ BS arrays summary of the main configuration parameters (see Table 2)
- Summary of the CPE array performance parameters (see Table 3)
- Summary of the BS array performance parameters (see Table 4)

Samples of BS and CPE arrays performance plots (3.7GHz) are presented in Figure 15 and Figure 16.

3 Key Results

The key performance parameters (coverage, throughput) are impacted by a series of other parameters. The following sub-sections analyze the impact of these parameters upon coverage and user/cell throughput. All throughput values presented hereby, represent user throughput only, the signaling and control data being de-embedded.

3.1 Sensitivity Analysis for Key Inputs

We analyze different cell coverage limitations, due to different factors.

Table 6. Cell Coverage Limitations

Sub-section	Parameter	Frequency (GHz)	BS antenna tilt	Network load	h_{BS} (m)	Cell radius (m)	O2I	Service availability
3.1.1	BS antenna tilt	3.7	0° vs. -15° vs. -21°	50%	60	4000	Outdoor CPE	95%
3.1.2	Network load	3.7	-15°	25% vs. 50% vs. 75%	60	4000	Outdoor CPE	95%
3.1.3	BS antenna height	2.6, 3.7 and 6.4	-15°	50%	30 vs. 60	2000/4000	Indoor/outdoor CPE	95%
3.1.4	Fading and O2I Loss	3.7	-15°	50%	30/60	2000/4000	Indoor CPE	95% and 99%
3.1.5	DL/UL	3.7	-15°	50%	30/60	2000/4000	Indoor/outdoor CPE	95%

3.1.1 BS Antenna Down Tilt

BS antenna array's performance is critical for controlling the radiated interference across the neighboring cells. Dependent on BS array performance, the network operator may enable or not frequency reuse 1. Frequency reuse is the number of times the same RF channel (frequency) is reused throughout the network. The most efficient spectrum utilization occurs when the same frequency is reused across the entire network, frequency reuse 1 being the most efficient one.

These simulations highlight the impact of vertical tilt upon frequency reuse 1 in a 5G network. We chose 3 vertical tilts: 0° (along the horizon), -15° (-3dB along the horizon) and -21° (equivalent to -6dB in the H direction), for a 3.7GHz 4×4×2 sub-array, grouped in 4×1 subarrays (2×2 subarray configuration).

Figure 3 is based on BS antenna array's ability to steer the beams vertically by electrical means, rather than mechanical ones (e.g., LTE case).

For the particular scenario simulated, the effective radiated power vs. the horizon is max EIRP ($V_{tilt}=0^\circ$), -2.5dB ($V_{tilt}=-15^\circ$) and -5 dB ($V_{tilt}=-21^\circ$). This EIRP reduction is further compounded, during the

simulations process with the path loss, system interference and different fading mechanisms for the propagation scenarios under consideration. Unlike a mechanically controlled vertical tilt, such an antenna array could accommodate dynamic tilt factors, dependent on the network load, potentially alleviating the impact of interference.

The related impact upon the system interference (assuming all BS antennas are tilted by the same angle) and the cell user throughput/coverage are presented in Figure 4. The impact of horizontal beam steering upon the network interference is not discussed in this paper.

Figure 3. BS Antenna Tilt Impact upon EIRP Distribution vs. Elevation Angle (Reference Boresight Horizontal Direction), 3.7GHz ($h_{BS}=60m$).

The related DL SINR degradation, for Path Length=2000m and 4000m (Cell Mobile Edge), network load is presented in Figure 4.

Figure 4 Vtilt impact upon system interference and the related user throughput degradation as a function of Elevation Vtilt=0°/-15°/-21° ($h_{BS}=60m$, outdoor scenario, NetLoad=50%, **95% Service Availability, 3.7GHz).**

Table 7. Vtilt Impact upon Network Interference and DL Cell Throughput, referenced to the horizontal direction, (3.7GHz, Mobile Cell Edge=4000m, NetLoad=50%, 95% Service Availability)

Vtilt Variation		Network Interference Variation		DL Cell Throughput Variation	
Vtilt	Gain Variation [dB]	Interference Power [dBm]	Degradation [dB]	Tput [Gbps]	Degradation [%]
0	-6	-57.8	3.7	4.3	0
-15°	-3	-59.5	2	4.3	0
-21°	0	-61.5	0	3.6	15.2

Observations:

- Due to the higher directivity of the outdoor CPE array, one beam's coverage could extend into the adjacent cell, though exceeding the target MobEdge (e.g., 4000m for the modeled case).
- No significant cell throughput degradation on the MobEdge (4000m, $h_{BS}=60m$), when the BS array is tilted from 0° down to -15°.
- The effective user throughput degradation when the BS array is tilted down to -21° from 0°, is 0.63% (24 users per cell) or 15.2% for the entire cell.
- Frequency Reuse 1 could be effectively implemented.
- The DL SINR gets improved by ~2dB when the BS antenna tilt gets tilted by 21°. A sharper vertical beam would reduce even more the network interference power radiated towards a victim cell, thus improving the victim user's SINR and related throughput. As a consequence, a larger subarray vertical size should be used in order to optimize even more FR1 coverage (e.g., 4 subarrays each subarray being 8×4×2 antenna elements, amounting to a 16×8×2 array).
- If the BS antenna's tilt is controlled dynamically, as a function of the network load, the system interference and subsequently the cell coverage and user throughput could be optimized.

3.1.2 Network Load

The impact of network load upon the cell performance in terms of cell (user data) throughput is analyzed, while holding BS Vtilt constant (-15°). We compare the cell throughput and the CDF of the network interference for NetLoad=25%, 50% and 75%, see Figure 5. The quantitative results are summarized in Table 8.

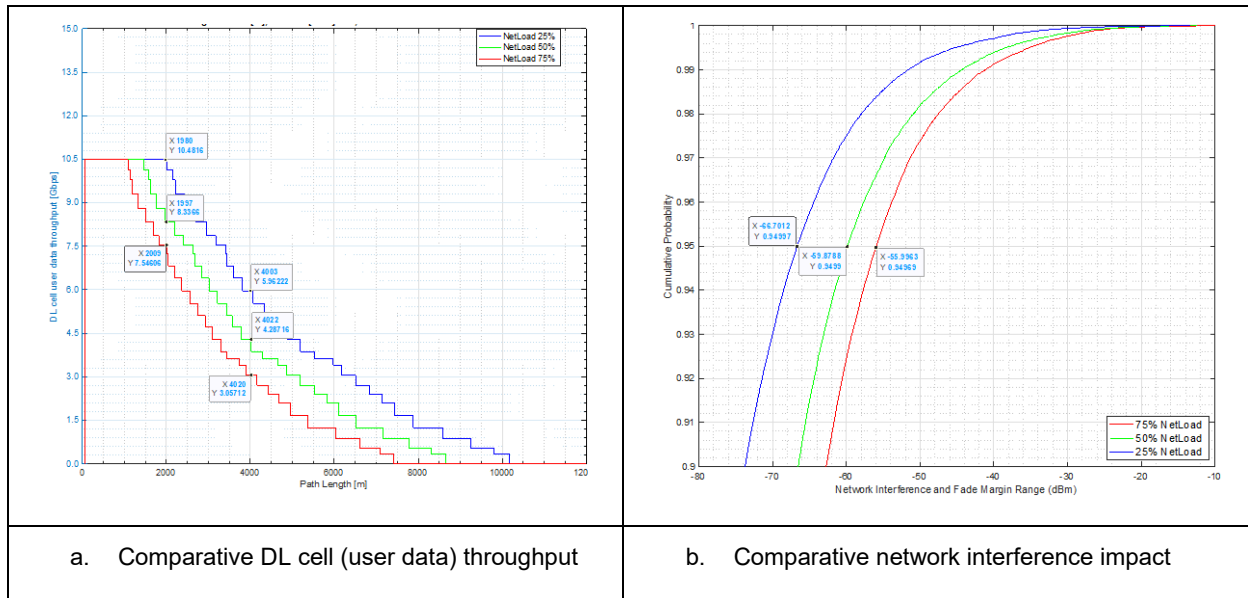

Figure 5. Comparative network interference impact upon (a) DL User Data Throughput and (b) Network Interference (expressed as CDF), impact for 25%, 50% and 75% network load (Outdoor scenario, 95% Service Availability, $h_{BS}=60m$, 3.7GHz)

Table 8. NetLoad impact upon overall cell radius (user data only), for $h_{BS}=30m$ (MobEdge=2000m) and $h_{BS}=60m$ (MobEdge=4000m).

	Cell Radius=2000m		Cell Radius=4000m (DL edge)	
NetLoad	Cell Tput [Mbps]	Variation	Cell Tput [Mbps]	Variation
25%	10481	0%	5962	0%
50%	8336	-21.5%	4278	-28.3%
75%	7540	-28.1%	3057	-48.8%

Observations:

- Cell throughput gets degraded by 48.8% ($h_{BS}=60m$, MobEdge=4000m) and by 28.1% ($h_{BS}=30m$, MobEdge=2000m), when NetLoad is increased from 25% up to 75% on the cell radius.
- The higher is the netload, the lower is the cell coverage and user/cell throughput.
- The coverage and throughput degradation caused by the increased network load highlights the significance of steering 5G antenna arrays, dynamically updating Vtilt as a function of network load, across a cluster of cells accordingly.

3.1.3 BS Antenna Height

The network interference impact caused by low and high BS antenna heights ($h_{BS}=30m$ and $h_{BS}=60m$), outdoor and O2I scenarios, for the 3 frequencies of interest (2.6, 3.7 and 6.4GHz) is analyzed. Summary results are presented in Figure 6. The quantitative results are summarized in Table 9.

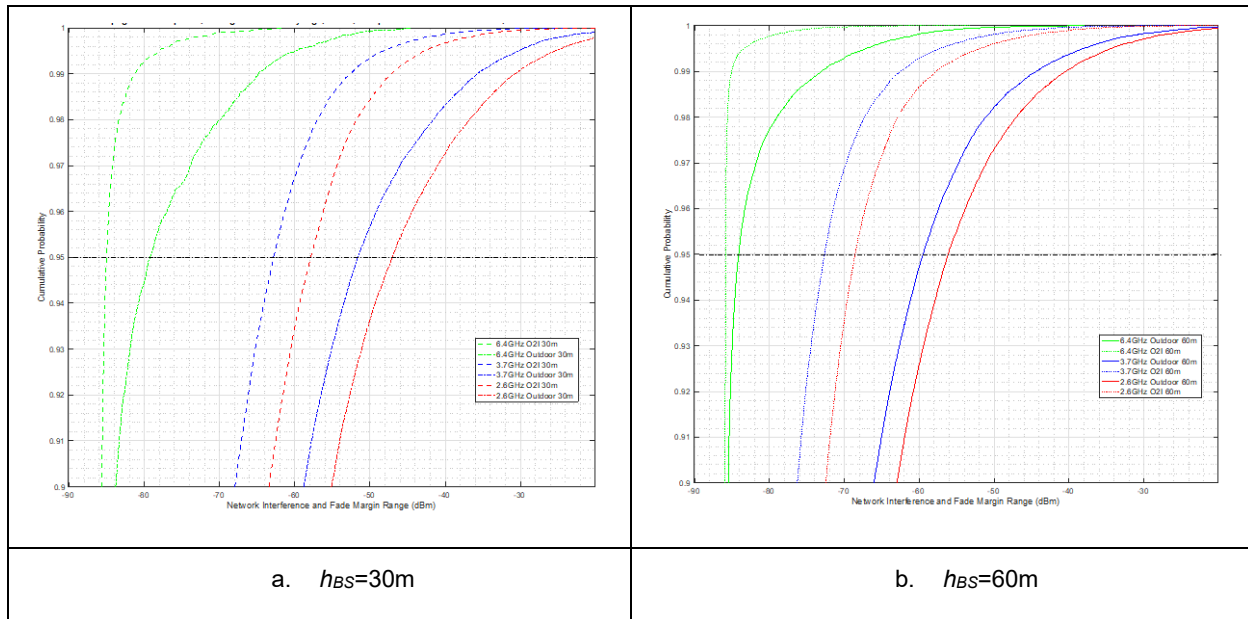

Figure 6. Comparative network interference impact for outdoor and O2I scenarios (network load 50%, 95% service availability, $V_{tilt}=-15^\circ$, 2.6, 3.7 and 6.4GHz), $h_{BS}=30m$ and 60m.

Table 9. Comparative BS antenna impact upon network interference power impact upon victim cell (2.6, 3.7 and 6.4 GHz).

	$h_{BS}=30m$		$h_{BS}=60m$		Degradation	
Central Frequency	Outdoor	O2I	Outdoor	O2I	Outdoor	O2I
2.6 GHz (ChBW=100MHz)	-47.2	-58	-56.3	-68.6	9.1	10.6
3.7 GHz (ChBW=100MHz)	-51.8	-62.9	-60	-72.8	8.3	9.9
6.4 GHz (ChBW=80MHz)	-79.5	-85	-84.2	-85.8	4.7	0.8

Observations:

- Mobile Cell Edge of 2000m is chosen for $h_{BS}=30m$, which triggers a higher network interference impact upon the victim cell than $h_{BS}=60m$ (MobEdge 4000m). DL SINR is degraded as follows, when remote head (RH) height is reduced from $h_{BS}=60m$ down to $h_{BS}=30m$:
 - Outdoor scenario: 9dB (2.6GHz), 8.3dB (3.7GHz) and 4.7dB (6.4GHz).
 - O2I scenario: 10.6dB (2.6GHz), 9.9 (3.7GHz) and 0.8dB (6.4GHz).
- The 2.6GHz system is subject to the highest network interference, among all considered scenarios, due to the lowest propagation losses vs. 3.7 and 6.4GHz cases.
- The outdoor 6.4 GHz system operates as a quasi interference free system, due to the lower EIRP density: 27dBm/10MHz vs. 50dBm/10MHz (2.6 and 3.7GHz).
- The network interference for the O2I case is lower than for the outdoor one, due to the additional O2I propagation fading impact.

3.1.4 Small-Scale, Large-Scale Fading and O2I Loss

The O2I propagation is subject to 3 different types of fading mechanisms:

- Large-scale fading, also known as shadowing

- The propagation delay is larger than the coherence time of the channel, hence the resulting received amplitude and phase are quasi constant. This type of fading is mainly caused by obstruction of the main path (e.g., shadowing, path loss).
- Small-scale fading
 - This is due to the multipath components in the propagation channel. The multipath arrived at the receiver can be constructive or destructive depending on the phase of each multipath, which cause the signal strength variation.
 - The small-scale Fading was modeled by a Rice distribution ($K=12$ dB) for LOS conditions and by a Rayleigh distribution for NLOS conditions.
- O2I loss is a Gaussian distribution centered on the mean value of the outer wall. It was assumed that the indoor CPE is positioned 1m behind the closest outer wall to the serving BS. The O2I fading does not apply for the outdoor scenario.

It should be noted that the Doppler spread fading, affecting mobile communications, doesn't impact FWA propagation.

All these three fading/loss mechanisms are modeled by three different distributions, which are summed up statistically, following 100,000 random victim CPE locations. The cumulative loss is further calculated by applying CDF function for the target service availability. The three distributions presented above are exemplified for O2I propagation ($h_{BS}=30m$ and $h_{BS}=60m$).

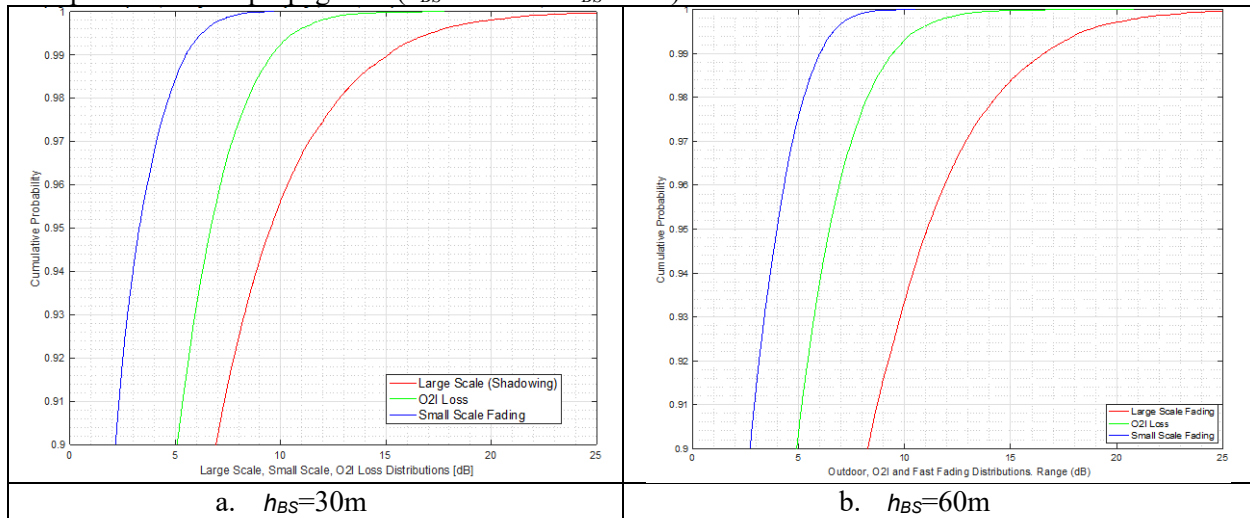

Figure 7. CDFs of Large-Scale, Small-Scale and O2I fading, for an O2I Propagation Scenario ($h_{BS}=30m$ and $h_{BS}=60m$)

The following table summarizes the quantitative analysis. The channel is more likely in LOS condition with the smaller cell radius with 30m BS height. Thus, the large-scale and small-scale fading at 30m h_{BS} are relative smaller than that at 60m h_{BS} .

Table 10. The Link Budget Penalty Caused by Different Types of Fading Encountered by O2I Propagation ($h_{BS}=30m$ and 60m)

	$h_{BS}=30m$			$h_{BS}=60m$		
Service Availability	Large-scale fading (Shading)	Small-scale Fading	O2I loss (dB)	Large-scale fading (Shading)	Small-scale Fading	O2I loss (dB)
95%	9.4	3.3	6.7	11.0	6.4	6.4

99%	15.3	5.5	9.6	14.3	5.2	9.4
-----	------	-----	-----	------	-----	-----

Observations:

- Large Scale (shadowing component) fading has the strongest impact among the three mechanisms analyzed, due to the NLOS propagation (Rayleigh type fading).
- The higher is the desired service availability, the higher is the composite fading impact upon the link budget.
- The O2I Loss could become the driving factor of the composite fading if the CPE is placed deep inside the house (vs. the outer wall facing the BS) and/or other construction materials used for the outer wall.
- FWA could use a lower target service availability (e.g., 95%):
 - Even for a higher service availability, the user experience impact may not be noticeable, as long as the user may not use the highest achievable allocated user data rate.

3.1.5 DL SINR and UL SINR

UL link budget is another coverage limiting factor. Usually the CPE/UE has a lower EIRP than the BS, driving to an asymmetrical link budget. This could cause coverage limitations, limited by the UL lowest MCS connection. In this section we examine the UL SNR impact upon the Cell Edge (MobEdge).

Firstly, we compare DL SINR and UL SNR for outdoor and O2I scenarios (3.7GHz, $h_{BS}=60m$), as presented in Figure 8. The max throughput is achieved for SINR=25.5dB (0.925 coding rate and QAM256), while the minimum throughput (cell edge conditions) is achieved for SINR=-4.5dB (0.117 coding rate and QPSK). It should be noted that the network planners may use a higher min MCS, for cell edge calculations, allowing cell overlapping in order to support seamless mobile handover between adjacent cells, however for FWA this may not be required.

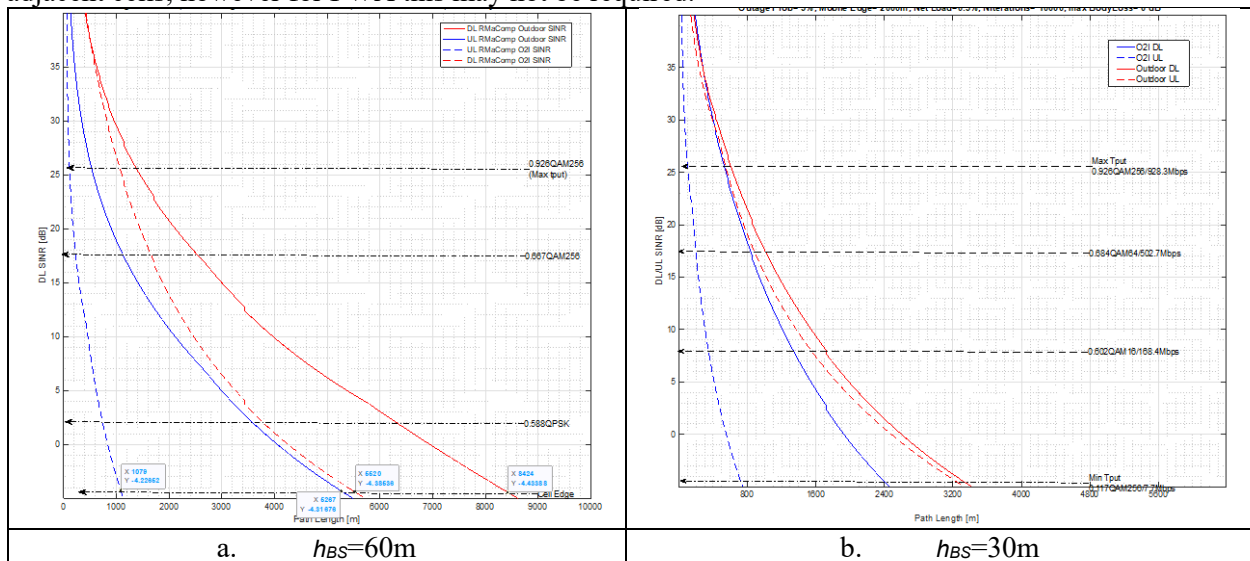

Figure 8. Comparative DL and UL SINR for Outdoor and O2I Scenarios (3.7GHz), $h_{BS}=60m$ vs. $h_{BS}=30m$

The coverage reduction (referenced to cell edge) is summarized in the following table. The cell coverage reduction is calculated against the respective MobEdge (for $h_{BS}=60m$ and $h_{BS}=30m$).

Table 11. Coverage and coverage reduction due to asymmetrical link budget (3.7GHz, $h_{BS}=60m$, 95% service availability, NetLoad=50%)

	$h_{BS}=30m$ (MobEdge=2000m)			$h_{BS}=60m$ (MobEdge=4000m)		
	Min(DL SINR)	Min(UL SINR)	Coverage reduction (%)	Min(DL SINR)	Min(UL SINR)	Coverage reduction (%)
Outdoor	3559m	3268m	16%	8424m	4316m	0%
O2I	2400m	720m	91%	5520m	1079m	92.8%

Observations:

- DL coverage is larger than the UL one for 3.7GHz, low and high RH height scenarios.
- Outdoor DL and UL coverage are in the same range for $h_{BS}=30m$ (3.7GHz) due the increased DL interference (MobEdge=2000m).
- The O2I UL coverage is more reduced vs. DL, due to reduced O2I DL interference and the reduced indoor CPE antenna gain vs. outdoor CPE gain.

We run the same analysis, comparing the cell coverage due to the UL link budget asymmetry, for different frequencies, as shown in Figure 9.

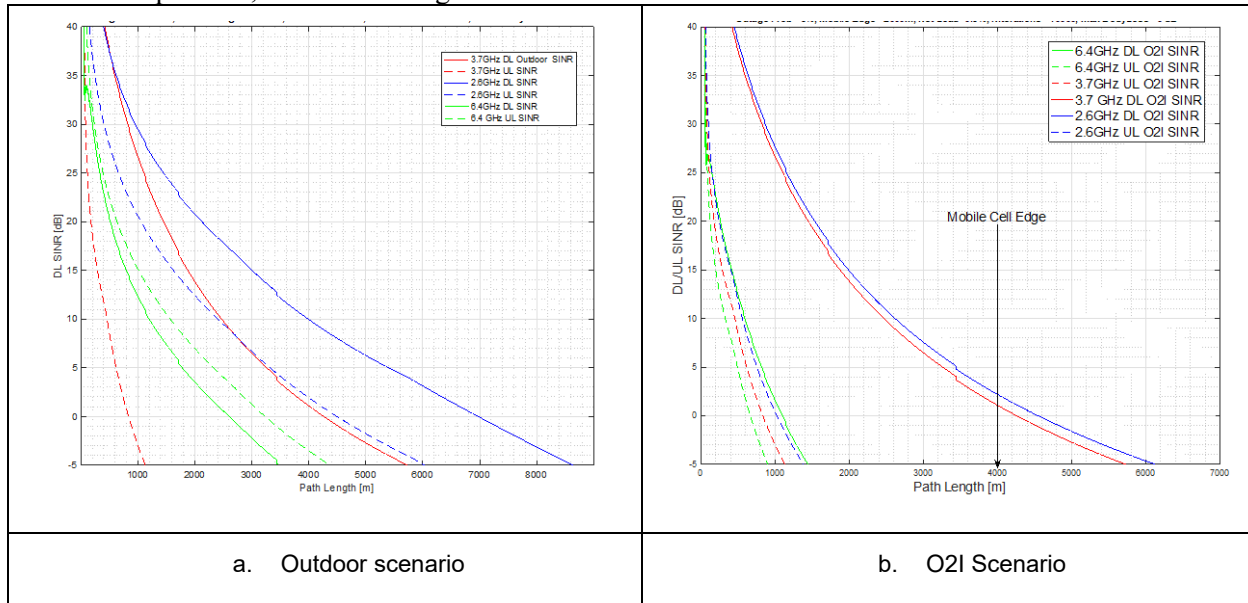

Figure 9. Comparative DL and UL SNR Degradation 2.6GHz vs. 3.7GHz vs. 6.4GHz, for Outdoor and O2I Scenarios (95% service availability, $h_{BS}=60m$).

Observations:

- The outdoor 2.6GHz coverage (both DL and UL) is slightly larger than the 3.7GHz.
- The DL interference limits the cell coverage for 6.4GHz (outdoor case), due to the close DL/UL EIRP difference (6dB) and increased UL coverage.
- The O2I coverage is severely limited by the UL coverage (poor UL link budget due to the additional O2I Loss).

3.2 Cell Coverage

The user data throughput is limited by the factors presented in section 3.1 and determined by the assumptions employed for this analysis:

- Subcarrier spacing=30kHz for all three frequencies
- 2000 slots/frame
- 4 beams/sector
- 3 sectors/cell
- 2 users/beam
- MIMO 2×2

The relationship between total user throughput and user throughput:

$$\text{CellThroughput} = \text{BeamsSector} * \text{Sector/Cell} * \text{User/Beam} * \text{UserThrupughput}.$$

Equation 8

where $\text{BeamsSector} * \frac{\text{Sector}}{\text{Cell}} * \frac{\text{User}}{\text{Beam}} = 24$. The DL comparative cell and user throughput for 2.6, 3.7 and 6.4GHz with 60m h_{BS} are analyzed.

3.2.1 Cell and User (Data) Throughput

The cell and user throughput plots are presented in Figure 10 (outdoor/O2I h_{BS} =60m). All throughput values represent user data (control and signaling data have been de-embedded).

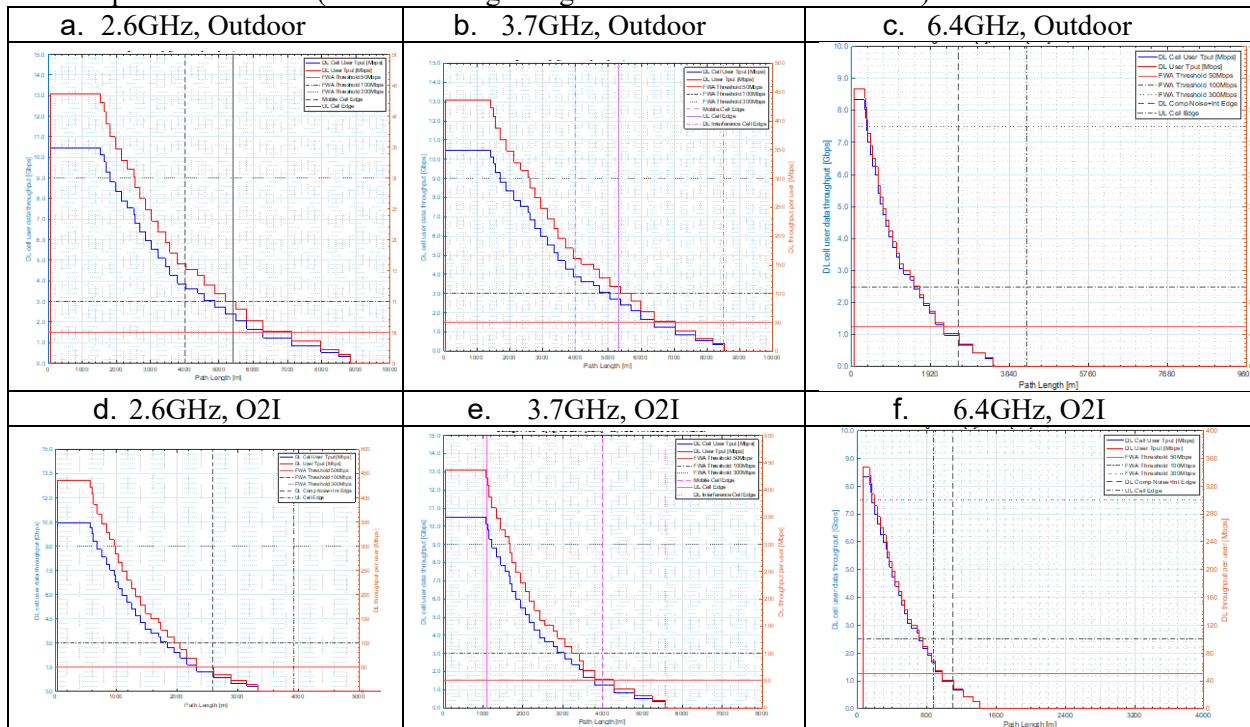

Figure 10. Comparative Cell (User Data) and Throughput per User (User Data Only), 2.6, 3.7 and 6.4 GHz, for h_{BS} =60m Outdoor and O2I Scenarios¹

It should be noted:

- DL cell edge accounts for the DL system interference
- The throughput jagged plots are generated by the link adaptation algorithm (QAM-256 MCS table).
- The UL System interference is minimal due to the lower CPE EIRP and lower CPE antenna height (increased obstruction probability).

¹ Network Load 50%, 95% service availability, VTilt=-15°

Similar plot shapes are obtained for all scenarios under consideration (30 and 60m, outdoor and O2I, 2.6, 3.7 and 6.4GHz). For the sake of brevity, we present the summarized data in Table 12 and Table 13, the limiting cell edge being highlighted. We analyze the limitations imposed on the cell edge by the following factors:

- DL cell edge, propagation and different fading and loss mechanisms limitations.
- Mobile cell edge (MobEdge) defined initially by the network planner (e.g., 2000m for $h_{BS}=30m$).
- UL cell edge limited by the asymmetrical link budget (DL driven).

There are 3 different cell edges. The relationship between them:

$$RealCellEdge = \min(DLCellEdge, MobEdge, ULCellEdge)$$

Equation 9

Table 12. Cell Coverage $h_{BS}=30m$ (95% Service Availability, NetLoad=50%, Vtilt=-15°)

Frequency [GHz]	Outdoor				O2I			
	DL Edge	MobCellEdge	UL Edge	Real Edge	DL Edge	MobCellEdge	UL Edge	Real Edge
2.6	3276	2000	3917	2000	2125	2000	1198	1198
3.7	3331	2000	3244	2000	2402	2000	723	723
6.4	1694	2000	2832	1694	1048	2000	560	560

Table 13. Cell Coverage $h_{BS}=60m$ (95% Service Availability, NetLoad=50%, Vtilt=-15°)

Frequency [GHz]	Outdoor				O2I			
	DL Edge	MobEdge	UL Edge	Real Edge	DL Edge	MobEdge	UL Edge	Real Edge
2.6	8846	4000	6398	4000	6002	4000	1344	1344
3.7	8461	4000	5339	4000	5572	4000	1097	1097
6.4	3436	4000	4249	3436	1395	4000	847	847

Observations:

- DL outdoor coverage is limited by the mobile cell edge (2.6 and 3.7GHz).
 - The network planner may allow a larger MobEdge than initially predicted
- DL outdoor 6.4GHz coverage is limited by the limited DL EIRP (36dBm)
- The O2I coverage is limited by UL cell edge, for all frequencies
 - The O2I coverage may require a higher CPE EIRP.
- While it may be expected to see a larger coverage for the 2.7GHz vs. the 3.7GHz case, the lower frequency advantage is partly offset by:
 - The higher interference impacting both the signal and network interference, but since $SINR=SNR-I$, the SINR impact may not be straightforward. A graphical explanation is provided in Figure 11 ($h_{BS}=60m$):

Figure 11. Comparative LOS, NLOS and Composite SINR and Tput, 2.6 3.7GHz²

We define

$$RealCellEdge = \min\{DLInterferenceEdge, ULEdge, MobCellEdge\}$$

Equation 2

Observations ($h_{BS}=60m$, $h_{BS}=30m^3$)

- 2.6GHz LOS coverage is smaller than the 3.7GHz one (both $h_{BS}=30m$ and $60m$), due to the higher network interference impact.
- NLOS becomes the dominant propagation mechanism because of the network interference is greatly reduced in NLOS conditions, 2.6GHz gets a larger RMa NLOS and RMa composite coverage. Overall, the 2.6GHz overall composite coverage is higher than the 3.7GHz one.
- The network interference ($h_{BS}=30m$) is higher for the 2.6GHz, due to the selected MobEdge (2000m).
- The outdoor 6.4GHz RealCellEdge is limited by the lower BS EIRP (36dBm).
 - The unlicensed 6GHz spectrum regulatory regulations restricts $\max(EIRP)=36dBm$.
- Providing NR-U services in unlicensed 6 GHz spectrum may require a densified network.
- The O2I cell edge is UL limited, due to the additional UL path losses, incurred due to the O2I loss. Under these assumptions, the indoor CPE is required either:
 - i) have a higher conducted RF power and/or
 - ii) use a directive antenna array with a higher gain vs. an omni antenna.

However, it should be noted that increasing the indoor CPE EIRP may also increase the indoor multipath, which may require a different analysis.

3.2.2 50, 100 and 300Mbps Coverage

We considered the 50, 100 and 300Mbps as three different traffic tiers for FWA services. We modeled the related coverage for these tiers, for 3.7 and 6.4GHz, outdoor and O2I scenarios. We also model the impact of different service availability rates upon coverage. The outdoor 3.7 and 6.4GHz coverage vs. service availability is plotted with and without UL limitation (Figure 12), for both $h_{BS}=30m$ and $60m$.

Observations:

² 95% service availability, 50% network load, 60 m h_{BS} .

³ Related plots available.

- Providing a higher target user rate availability (e.g., 99%) for outdoor 3.7GHz (same applies to 2.6GHz) a progressive coverage reduction may occur. The higher the target the service availability, the higher are the propagation losses and the shorter is the coverage.
- The higher the target user throughput (e.g., 300Mbps), the smaller is the related coverage.

The coverage reduction between 95% and 99% service availability is summarized in Table 14.

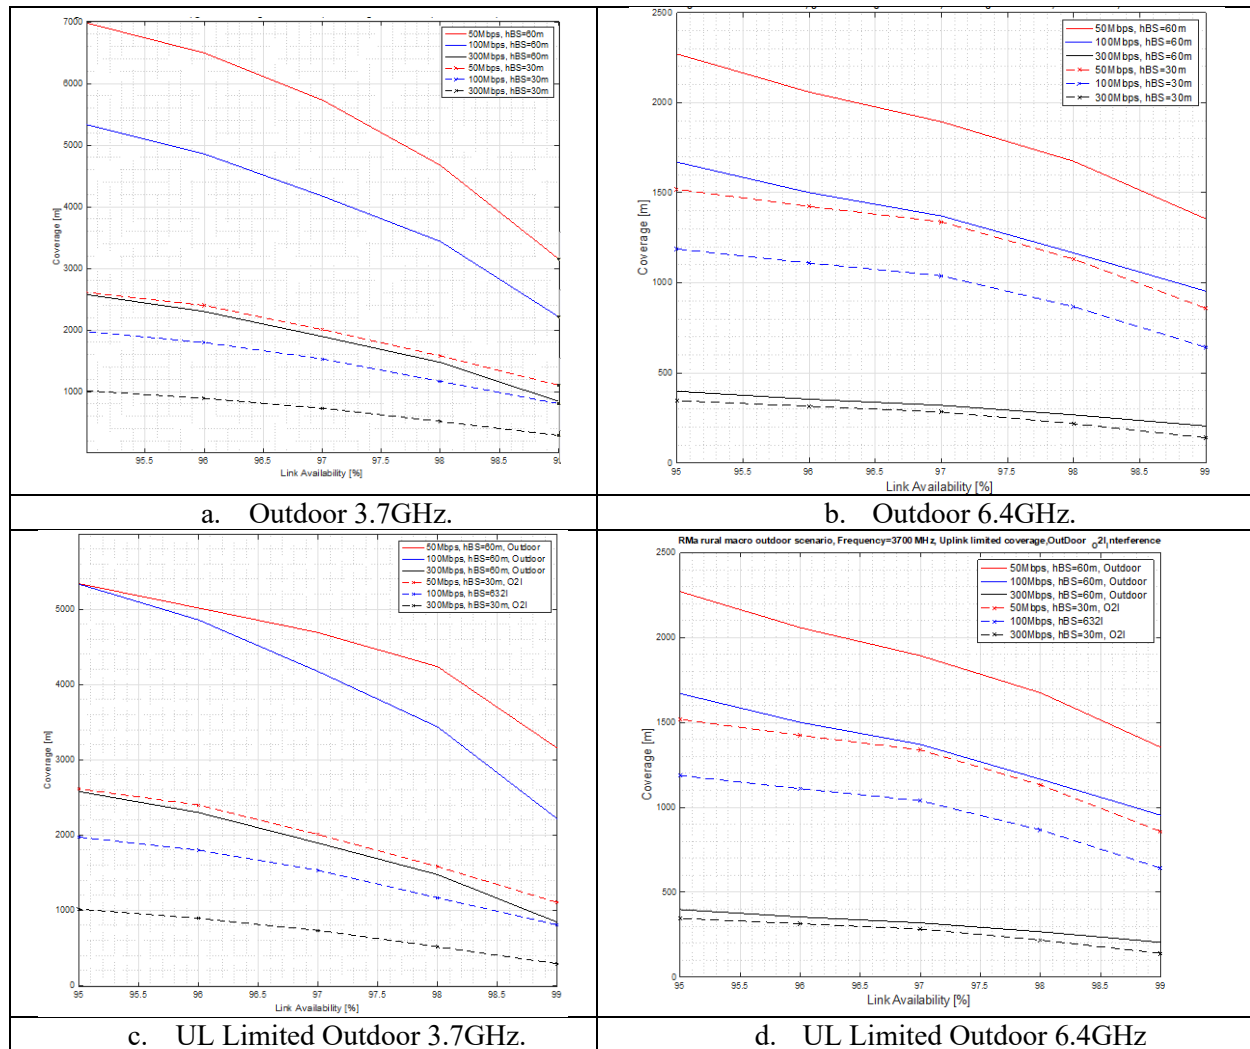

Figure 12. Outdoor (30 and 60m), 3.7GHz, 50, 100 and 300Mbps Coverage

Table 14. Coverage Reduction (50, 100 and 300Mbps), for Outdoor 3.7GHz

	$h_{BS}=60m$			$h_{BS}=30m$		
	50 Mbps	100 Mbps	300 Mbps	50 Mbps	100 Mbps	300 Mbps
95%	6984	5334	2577	2613	1972	1015
99%	3156	2216	806	1104	802	290
Coverage Reduction	80.6%	82.7%	90.2%	68.6%	83.4%	91.8%

Table 15. Coverage Reduction (50, 100 and 300Mbps), for O2I (3.7GHz)

	$h_{BS}=60m$			$h_{BS}=30m$		
	50 Mbps	100 Mbps	300 Mbps	50 Mbps	100 Mbps	300 Mbps
95%	4285	3235	1676	1937	1533	843
99%	2591	1944	1003	1152	880	437
Coverage reduction	63.4%	63.8%	64.1%	64.6%	67%	73.1%

The comparative O2I coverage reduction (3.7 vs. 6.4GHz), subject to UL link budget limitations, follows.

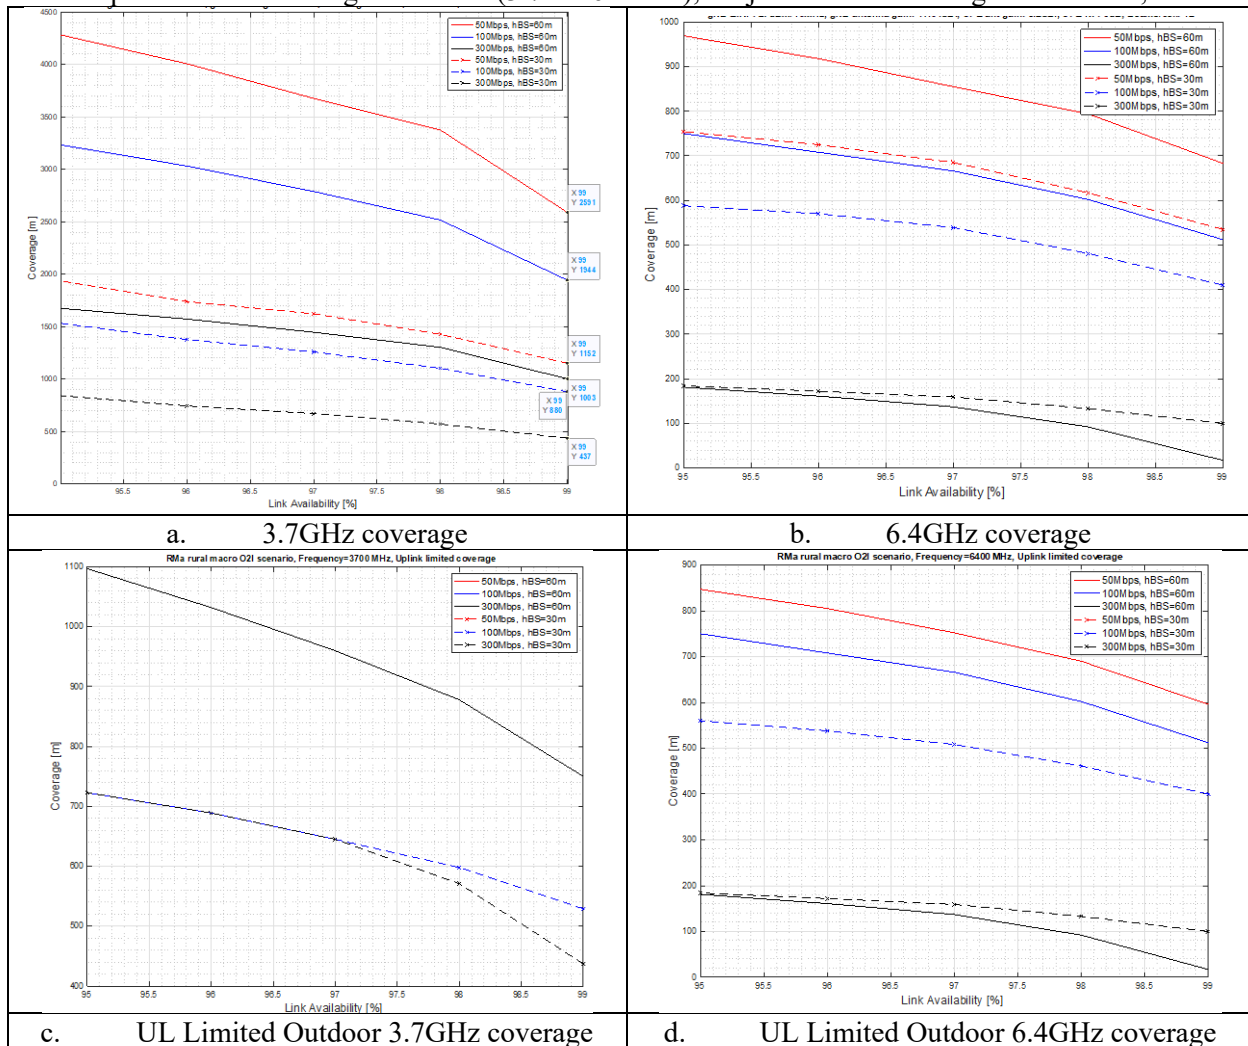

Figure 13. Comparative O2I ($h_{BS}=30$ and 60m) Coverage, for 3.7 and 6.4GHz, When Subject to UL Coverage Limitations

Observations:

- The O2I 3.7GHz coverage is severely UL limited, due the O2I loss.
- The O2I 6.4 GHz ($h_{BS}=60m$ and 30m) 50Mbps related coverage is UL limited, due the UL link budget impairment caused by the O2I fading.
- The UL indoor CPE may require a higher EIRP.

The cell coverage reduction between 95% and 99% service availability is calculated:

$$\text{CoverageReduction [\%]} = (\text{CellRadius}(99\%)/\text{CellRadius}(95\%))^2 \times 100$$

Equation 10

We analyze the comparative coverage reduction KPI, between 99% and 95% service availability.

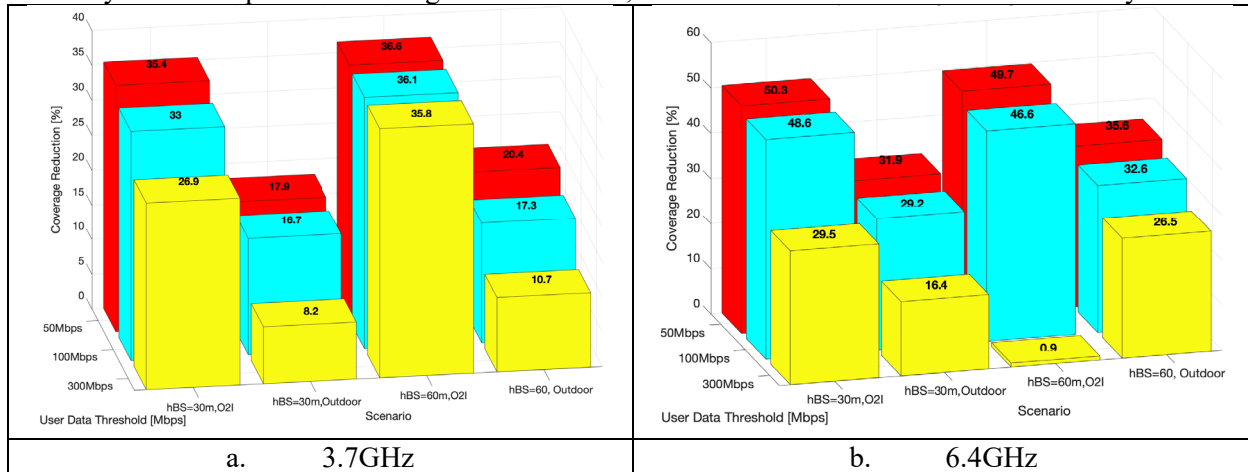

Figure 14. Coverage reduction between target 99% and 95% Service Availability, for 3.7GHz and 6.4GHz.

Observations:

- A severe coverage reduction occurs, when the service availability is increased from 95% up to 99%, for the outdoor, $h_{BS}=60\text{m}$ and 30m scenarios.
 - The outdoor propagation is impacted by large-scale and small-scale fading, resulting into a better coverage for service availability=95% and by a sharper reduction for 99%.
- The O2I propagation is impacted by three fading mechanisms (large-scale, small-scale fading and O2I loss), hence a relatively lower coverage (vs. outdoor coverage) for service availability=95%, and a milder reduction for 99%.
- For the 6.4GHz, O2I, $h_{BS}=60\text{m}$, 300Mbps case, the target service availability is practically non-existent (cell radius=17m), hence a severe coverage reduction degradation.

All of the above considerations highlight the challenges associated with high target service availability (e.g., 99%).

- However, due to the flexible 5G link adaptation algorithm, the user may not perceive the impact, since the user may not run consistently high data applications, close to the data threshold allocated for that user (e.g., most of the households may run applications demanding 30-60Mbps, while being subscribed for a 100Mbps plan).
- A FWA network planning targeting service availability=95% backed by NetLoad=50% may be a realistic target.

4 Conclusions

A variety of FWA scenarios was analyzed based on CableLabs' system simulations engine. The models used a comprehensive set of assumptions, presented in the Appendix. The simulations targeted a comparative technical performance of rural FWA networks, operating in 2.6, 3.7 and 6.4GHz, when operating with tall towers ($h_{BS}=60\text{m}$) and medium size towers ($h_{BS}=30\text{m}$).

4.1 The Impact of Coverage Limiting Factors

- A. The impact analysis of different limiting factors upon coverage indicates:
1. Vertical tilt of the BS antenna array, while supporting a Frequency Reuse 1 topology (3.7GHz)
 - Due to the higher directivity of the outdoor CPE array, A beam's coverage could extend into the adjacent cell, exceeding the target MobEdge (e.g., 4000m for the modeled case).
 - The effective user throughput degradation when the BS array is tilted down to -21deg (-6dB EIPR reduction vs. Horizontal Tilt alignment) from 0deg may not be significant (0.63% per user) but the network interference gets decreased by 3.7dB.
 - Frequency Reuse 1 could be effectively implemented.
 - A sharper vertical beam would reduce even more the Network Interference power radiated towards a victim cell, improving the victim user's SINR and related throughput. As a consequence, a larger subarray vertical size could be used in order to optimize even more FR1 coverage (e.g., 4 subarrays each subarray being 8×4×2 antenna elements).
 - If the BS antenna's tilt is controlled dynamically, as a function of the network load, the system interference, the cell coverage and user throughput could be further optimized.
 2. Comparative Network Load impact upon user throughput and network coverage:
 - The higher is the network load, the lower is the cell coverage and user/cell throughput.
 - The coverage and throughput degradation caused by the increased network load highlights the significance of controlling 5G antenna arrays, dynamically updating Vtilt as a function of network load, across a cluster of cells.
 3. BS Array height impact upon network interference.
 - The DL SINR is degraded, when RH height is reduced from $h_{BS}=60\text{m}$ (MobEdge=-4000m) down to $h_{BS}=30\text{m}$ (MobEdge=2000m):
 - Outdoor scenario: 9dB (2.6GHz), 8.3dB (3.7GHz) and 4.7dB (6.4GHz)
 - O2I scenario: 10.6dB (2.6GHz), 9.9 (3.7GHz) and 0.8dB (6.4GHz)
 - The 2.6GHz system is subject to the highest network interference, among all considered scenarios, due to the lowest propagation losses vs. higher frequencies.
 - The outdoor 6.4 GHz system operates as a quasi-interference free system, due to the lower EIRP density: 27dBm/10MHz vs. 50dBm/10MHz (2.6 and 3.7GHz)
 - The network interference is lower for the O2I case vs. outdoor, due to the O2I propagation.
 4. Small-scale, large-scale and O2I fading mechanisms' impact
 - Large Scale (shadowing component) fading has the strongest impact among the three mechanisms analyzed, due to the NLOS propagation (Rayleigh type fading).
 - The higher is the desired service availability, the higher is the composite fading impact upon the link budget.
 - The O2I Loss could become the driving factor of the composite fading if the CPE is placed deep inside the house (vs. the outer wall facing the BS) and/or other construction materials used for the outer wall.
 -
 - FWA could use a lower target service availability (e.g., 95%):
 - Even for a higher service availability, the user experience impact may not be noticeable (e.g., throughput), as long as the user may not use the highest achievable allocated user speed.

5. DL and UL SNR impact

- DL coverage is larger than the UL one for low and high RH height scenarios (3.7GHz).
- DL and UL coverage are in the same range for $h_{BS}=30m$ (3.7GHz) due the increased DL Interference (MobEdge=2000m)
- The Outdoor 2.6GHz coverage is slightly larger than the 3.7GHz.
- The DL interference limits the cell coverage for 6.4GHz (outdoor case), due to the close DL/UL EIRP difference (6dB/10MHz) and increased UL coverage.
- The O2I coverage is severely limited by the UL coverage (poor UL link budget due to the additional O2I Loss).

B. Cell and User coverage analysis

1. Cell and user throughput

- Outdoor 6.4GHz DL coverage is limited by DL EIRP (36dBm)

DL outdoor coverage is limited by the mobile cell edge (2.6 and 3.7GHz). In return, this supports a larger MobEdge.

- 2.6GHz LOS coverage is smaller than the 3.7GHz one ($h_{BS}=30m$ and 60m), due to the higher network interference impact.
 - NLOS becomes the dominant propagation mechanism; since the network interference is greatly reduced in NLOS conditions, 2.6GHz gets a larger Rma NLOS and Rma composite coverage. Overall, the 2.6GHz overall composite coverage is NLOS driven being higher than the similar 3.7GHz coverage.
- The network interference ($h_{BS}=30m$) is higher for the 2.6GHz, due to MobEdge (2000m).
- The outdoor 6.4GHz RealCellEdge is limited by the lower BS EIRP (36dBm).
- Providing NR-U services in unlicensed 6 GHz spectrum may require a densified network.
- The O2I cell edge is UL limited, due to the additional UL path losses, caused by the O2I loss. Under these assumptions, the indoor CPE is required either:
 - i) have a higher conducted RF power and/or
 - ii) use a directive antenna array with a higher gain vs. an omni antenna.

2. 50, 100 and 300Mbps coverage

- All service availability <99% ($h_{BS}=60m$, Outdoor, 3.7GHz) scenarios are impacted by the UL asymmetric link budget.
- The outdoor 6.4GHz case is subject to no impact by the UL link budget limitation, due to the lower DL EIRP (36dBm/80MHz).
- The higher the service availability target, the shorter is the coverage due to the higher path loss.
- The O2I 3.7GHz coverage is severely UL limited, due the O2I loss.
- The O2I 6.4 GHz ($h_{BS}=60m$ and 30m) 50Mbps related coverage is UL limited, due the UL link budget impairment caused by the O2I fading.

3. Service Availability

- Coverage is severely reduced, when service availability is increased to 99% (outdoor, $h_{BS}=60m$ and 30m).
 - The outdoor propagation is impacted by large scale and small-scale fading, resulting into a better coverage for service availability=95% and by a sharper reduction for 99%.
- The O2I propagation is impacted by O2I loss, hence a relatively lower coverage compared with the outdoor case.
- For the 6.4GHz, O2I, $h_{BS}=60m$, 300Mbps case, the target service availability is practically non-existent (cell radius=17m), hence a severe coverage reduction degradation.

- The user may not perceive the impact of high user data rate reduction, unless the user runs consistently high data applications (e.g., most of the households may run applications demanding 30-60Mbps, while being subscribed for a 100Mbps plan).
- A FWA network planning targeting service availability=95% backed by NetLoad=50% may be a realistic target.

1. Introduction

We propose a novel method for constructing a composite metric for measuring product quality that is predictive/correlated with bottom-line key performance indicators (KPIs) such as customer churn rate or customer engagement. Traditionally, companies would track several individual metrics related to performance of a product. For example, to track customer experience across a hybrid-Mobile Virtual Network Operator (MVNO) network, metrics such as received signal strength, latency, throughput and link speed etc. are fundamental metrics that may be tracked in a dashboard. Subsequently, product owners can get a health check on the product by visualizing these metrics across different applications and across time. However, for deriving actionable insights, product owners would need to know if moving such individual KPIs (quality levers) would move the needle on a bottom-line metric such as customer churn.

AB testing would have to be conducted on a limited sample to derive such causal inferences. However, a bottom-line metric such as churn is a function of non-controlled exogenous variables such as macro-economic factors, competitor product, etc. Hence directly looking for difference in churn rate in test vs control sample would be difficult and hard to influence via a particular change in the product experience. A better approach would be to move the needle on a composite quality metric (CQM) constructed from individual KPIs which are essentially product levers that can be influenced by the product owners. The construction of the individual KPIs and their relative influence (weights) can be chosen such that the composite metric is predictive/correlated with bottom-line metrics. To achieve this, one could build a generalized linear model (e.g., a logistic regression model predicting churn) where the features can be the individual KPIs and the prediction equation will be the composite metric. However, such a metric will often be difficult to interpret for product owners unless they have prior training in statistical modeling.

In this paper, we propose a general framework for creating such an interpretable composite quality metric. The components or individual KPIs are discretized on a Fibonacci scale 8, 5, 3, 2, 1 such that a score of 8 can be interpreted as the best, 3 as bad and 1 as the worst experience. The weights for the components are selected via numerical methods such that the correlation with the bottom-line KPI is measured for each weight combination. The weight combination with the best correlation and non-skewed distribution can be selected as optimal. The result then is a single composite metric constructed from multiple components that is predictive of a bottom-line KPI.

2. Technical Approach

2.1. Methodology Approach Overview

Any customer-impacting initiative to improve product experience is a hypothesis that the product team would prefer to test on limited samples to answer key questions: 1) Did the initiative move the needle on the bottom-line KPI or not? 2) Did the initiative negatively impact customer experience as measured by safety metrics such as increased call volume? Conducting an A/B test on a random sample helps to ascertain the risk vs reward of rolling out a product change to the larger customer base. Since the engineering lift and resources involved in an A/B test are non-trivial, it is critical that the metrics for measuring success of an initiative are clearly defined and influenceable.

However, moving the needle on bottom-line KPIs can be difficult to do. On the other hand, moving the needle on individual KPIs that are quality levers begs the question: 1) What relationships do these individual KPIs have with the bottom-line KPI, if any? and 2) What is the relative importance of each individual KPIs? A composite quality metric gives us exactly this relationship between a bottom-line KPI such as churn, customer engagement, revenue, etc. and individual KPIs which are levers that a product

team can influence: received signal strength, latency, throughput, etc. The following three sub-sections provide a general framework for creating a composite quality metric: 1) Bucketing Metric Components, 2) Optimize Metric Weights, and 3) Model Selection.

We make an important call-out that for relatively mature and complex systems, unmitigated improvements are often impossible. That is, it is often impossible to improve one or more of the base KPIs without some kind of negative impact on others. This puts teams looking to improve the product in an ambiguous situation, which can be addressed by formulating a composite metric that makes explicit the effect of these tradeoffs on customer experience. Making explicit the tradeoffs also helps with institutional information. That is, as the organization's view on what is important to customers change, it is encoded in the CQM and can be tracked over time.

2.2. Bucketing Metric Components

For each individual KPI, we recommend partitioning the distribution of the values based on a large sample. For example, equal partitioning into fifths based on the 20th, 40th, 60th and 80th percentile can be used as thresholds to get roughly equal proportion of distribution in five buckets. This allows us to discretize the individual KPIs on a Fibonacci scale 8, 5, 3, 2, 1 such that:

1. Bucket 8: greater than 80th percentile (interpreted as the best experience)
2. Bucket 5: 80th – 60th percentile
3. Bucket 3: 60th – 40th percentile
4. Bucket 2: 40th – 20th percentile
5. Bucket 1: below 20th percentile (interpreted as the worst experience)

The advantages with the discretized set up are that: 1) product owners can get a sense of the gradation of the customer experience in a simple and consistent fashion across metrics on different scales, and 2) robustness to outliers. Even though we are proposing the Fibonacci scale 8, 5, 3, 2, 1, one could opt for a different scale such as 10, 8, 6, 4, 2, with the same strategy for thresholds. The primary goal is to pick thresholds based on a large sample data such that we avoid concentration of a point mass around one bucket.

In some cases, the discretization has to be specific to a product feature. For example, say we want to build a CQM to measure the effectiveness of the search feature in a particular streaming service. If one of the individual components is average number of characters typed in a search bar then it is important to consider differences in platforms that affect speed of input by the customer. On “1-foot” platforms such as mobile phones, tablets, and laptops it is relatively easy for most customers to enter more search characters compared to “10-foot” platforms such as Roku, Apple TV, Samsung TV, etc. In such a case, instead of creating different iterations of the same composite metric by platform type, it is efficient to simply customize the discretization by product feature. The goal of the product team would be to implement product enhancement that improve one or more components, preferably with high relative weight. As a result, certain components of the composite metric might change in distribution over time, shifting from lower to higher buckets. Therefore, it is worth checking the shift in distribution of the components for re-calibration of the thresholds, especially after a significant product change.

2.3. Metric Construction

Once the thresholds are computed to discretize the individual components, we can combine the components in one composite metric similar to a weighted average framework. We propose the following general formulation:

$$CQM = \left(\frac{\sum_{i=1}^n w_i C_i}{8 * \sum_{i=1}^n w_i} \right) * \prod_{j=1}^k A_j \quad (1)$$

where:

CQM stands for composite quality metric

C_i is the ith component of the composite metric with possible values (8,5,3,2,1)

w_i is the weight assigned to the ith component

$\sum_{i=1}^n w_i C_i$ *is the weighted average of the n components*

$8 * \sum_{i=1}^n w_i$ *is the normalization factor so that the range of CQM is between 0 and 1*

A_j is the jth binary filter with possible values (0,1)

$\prod_{j=1}^k A_j$ *is the product of all k binary filters*

The intuition behind incorporating binary filter terms is to allow a pass/no pass gate for the CQM depending on success of critical events for acceptable customer experience. For example, in a search quality metric, if the page fails to load or search API itself fails then we would want the score to be zero. Alternatively, if there is no page load failure and no search API failure then the metric is allowed to “pass” and would receive a score as per the first term in equation 1.

The normalization factor, which allows for the range of the CQM between 0 and 1 or alternatively between 0% and 100%, is intuitive for product owners to track overtime in a dashboard.

One caveat to note is that the CQM isn't going to be an absolute measure but rather a relative measure aimed at exposing areas for improvement. For a relative measure a low score doesn't necessarily mean the users had a bad experience, and a good score doesn't mean they had a good experience either. Since it is relative to the population base, it will necessitate updating the CQM as the experience of the population of users evolves.

2.4. Optimize Metric Weights and Model Selection

We introduced the construction of the CQM in the previous section. Given typical time constraints on feature engineering and productionizing such a metric, one could assume equal weights, for example 0.5,

for the components and start tracking a version 1 of the CQM. Alternatively, one could increase or decrease the weights based on prior product knowledge. However, the most optimal way to estimate weights would be benchmarking the CQM against a bottom-line KPI for several combinations of the component weights.

We recommend the following choices of weights for each of the n components: (0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0). If the metric has n component, that gives us a grid of 10^n combinations of weights to test for determining the optimal combination. The optimization steps are:

1. For each combination, calculate the CQM as shown in equation 1;
2. Determine correlation with the bottom-line KPI;
 - a. An interpretable way of determining correlation, which can also make it transparent to stakeholders, is bucketing the CQM score in 5 or 10 equal buckets.
3. Subsequently, calculate the average of the bottom-line KPI in each bucket;
4. A simple linear fit can give an idea about the strength of the linear relationship. We can also quantify the strength of the relationship by calculating the R^2 . In addition, the p-value of the slope can help weed out combinations that are not significant;
5. The combination with best R^2 and resembling a bell-shaped distribution of scores can be selected as optimal. The shape of the distribution of scores may not be bell shaped but as long as it is not skewed, we can select the combination as optimal.

As an example, if the optimal combination is found for the CQM, then as we move from a lower bucket of scores to a higher bucket, we should see higher customer engagement as measured by a bottom-line KPI such as customer churn. The advantage of keeping the selection process visual is giving ample transparency to stakeholders about the methodology. An output from all combinations tested can simply be visualized in a spreadsheet. The combination that has the best relationship with the bottom-line KPI while avoiding a skewed distribution of scores can be selected.

One caveat to this numerical approach is that the computational time is highly sensitive to the number of components. Since the number of combinations in the grid is 10^n beyond three components the compute time is unrealistic and unnecessary. In such a case, we advise reducing the combinations to be computed by taking the following approximate approach as shown for a metric with five components:

$$w_1 = (0.2, 0.4, 0.6, 0.8)$$

$$w_2 = (0.1, 0.3, 0.5, 0.7)$$

$$w_3 = (0.2, 0.4, 0.6, 0.8)$$

$$w_4 = (0.1, 0.3, 0.5, 0.7)$$

$$w_5 = (0.2, 0.4, 0.6, 0.8)$$

Even though we alternated through the even and odd sequence of weights, we cover most of the range of possible weights. By using this approximation, we reduced the number of combinations from 100K to 1,024. Also note that the relative combinations of weights are more influential than the absolute combination itself. In addition, we have observed that having a finer grid does not tend to lead to a drastically better metric.

We also recommend performing a basic regression analysis where we regress the individual components post-bucketing as regressors against the bottom-line KPI. This will help us understand which components are significant prior to running the optimization. In addition, we can possibly eliminate non-significant components or substitute for different components. One could argue using the prediction equation from the regression itself as the CQM. However, it is often difficult to explain the interpretation of such a metric to stakeholders who may be unfamiliar with statistical modeling. The advantage of the metric structure as laid out in equation 1 is that it is additive in nature and can be easily broken into components for further investigation by product owners.

3. Conclusion

In this paper, we have introduced a general framework for constructing a composite quality metric which is easy to interpret for stakeholders, effectively combines individual component metrics, and allows for benchmarking against a bottom-line KPI. The composite metric can be further used for testing product improvement initiatives via AB testing. A series of successful experiments that move the needle on the CQM helps make a case for improving the bottom-line KPI over time. The process of product improvements is iterative and the CQM is therefore appropriate as a relative metric. Depending on the industry, product maturity and changing consumption behavior, the threshold for what constitutes “good” quality will change. Hence, a relative measure is more useful than an absolute measure. The framework proposed in this paper is flexible so that the thresholds for the 8, 5, 3, 2, 1 buckets and subsequent re-weighting of the components to align with the bottom-line KPI can be conducted on a regular cadence. We also recommend including (or excluding) components as the range of quality levers at disposal changes to drive product improvement.

1. Introduction

For Augmented Reality (AR) and Virtual Reality (VR) devices to become truly immersive experiences, the industry is investing in R&D focused to address how they can achieve a goal of 20 millisecond (ms) motion to photon (MTP) latency [1] by modelling latency in concert with other systems.

In cloud gaming and other cloud content-streaming scenarios, 100ms “button-to-photon” latency is deemed adequate and is achieved through cloud rendering and bit rate encoding specified at the content source. While some latency variations occur in the transmission path, depending on network conditions, this 100ms “button-to-photon” is usually sufficient for these applications. But for AR/VR, prior art has made the case for 20ms MTP latency to avoid spatial disorientation, motion sickness and other adverse experiences for users.

In Cloud gaming and VR/AR, viewers are not passive—their interactivity (e.g., with objects and avatars) requires active modification of the content within the experience itself. In essence, this means that for non-interactive video experiences, content delivery is a “one-way” transfer of bits over the network (after transcoding) to the client (viewer), whereas interactive content delivery is two-way, where the viewer input from the client is used to determine subsequent content, which must then be rendered prior to transcoding and transmission. This imposes tighter latency requirements in AR/VR content rendering. Achieving 20ms MTP is practically impossible with current network architectures unless the cable service provider makes compute resources available deeper in its network.

This paper discusses a practical approach to cable delivery architectures where compute intensity and latency become the primary determinants of the end-user experience and are inherent properties of the content served to the subscriber. It describes a method and system for delivering latency-sensitive, compute-intensive experiences over a network that allows communications service providers (CSPs) to deliver latency-dependent compute to a subscriber, in concert with an application service provider (ASP), by employing seamless interactions between system components.

2. The Need for a Different Kind of Compute: Interactive Content

Current IP-based media delivery, for example, live and VOD (video on demand) TV content, has a latency sensitivity of ~500ms to a few seconds, dependent on various considerations, most importantly network conditions and buffer size at the client. While CSPs that offer programming can serve media experiences from within their own network, i.e., from a server in close proximity to their customers, there is little competitive advantage to be derived for the customer experience. This is evidenced by the rise of OTT (over-the-top) media service providers that provide programming via servers outside the CSP network. Other benefits, however, accrue with customer proximity to the CSPs such as reduced transit costs with shorter backhaul traffic, as well as access to consumer profile data.

In the context of current programming, we may logically separate the CSP that provides the packet route to the viewer from the Cloud, which we may view as a logical entity where content resides.

To explain an IP media delivery architecture, we may abstract out the network from the point of view of the media source in the Cloud and the consumer in the home. The original source file is encoded (compressed) at various bit rates, stored as a multi-bitrate asset (or chunks of the asset, each of which is multi-bitrate) and then delivered to a client based on requested parameters and network conditions, where it is then decoded and displayed.

Encoding, in this context called *transcoding*, remains the cornerstone of 2D media delivery on flat screens, big or small. At the server, transcoding may be performed by a combination of software and hardware, including CPUs, GPUs, FPGAs, etc. Depending on whether the programming is a live-stream broadcast or a VoD asset, the selection of transcoding platform and architecture as well as network protocols can vary significantly.

It is important to note that current media delivery architecture is non-interactive when it comes to content modification. While the quality with which the content is delivered may vary based on network conditions, and ads may be inserted through instantaneous decision-making in local zones, the actual programming content typically does not change based on viewer input.

Interactive content, on the other hand, can be altered by a viewer. In this sense, the viewer is not passive, but rather is immersed in the experience. Examples include games, Augmented Reality/Virtual Reality (AR/VR) experiences and holograms rendered on 3D displays. Interactivity may include content modification, for example, shooting and killing a formidable foe in a FPS (first person shooter) game that prolongs a player's ability to remain in the game (the content), but also content rendering in real-time encoded AR/VR based on the user's viewport, which controls what the user decides to focus on in their real (in case of AR) or make-believe (in case of VR) environment, ultimately changing what is rendered and displayed "on-the-fly". Streaming 360° video VR is a notable exception, where the viewport based on the user's pose is picked from within the pre-encoded video frame sent to the Head-mounted Display (HMD). It is non-interactive because the content is neither rendered nor encoded in real-time.

The key differences between non-interactive media like television and interactive media like gaming/AR/VR may be described as follows. Figure 1 and Figure 2 describe the abstracted delivery of media for non-interactive content versus interactive content.

Figure 1- Non-interactive content delivery

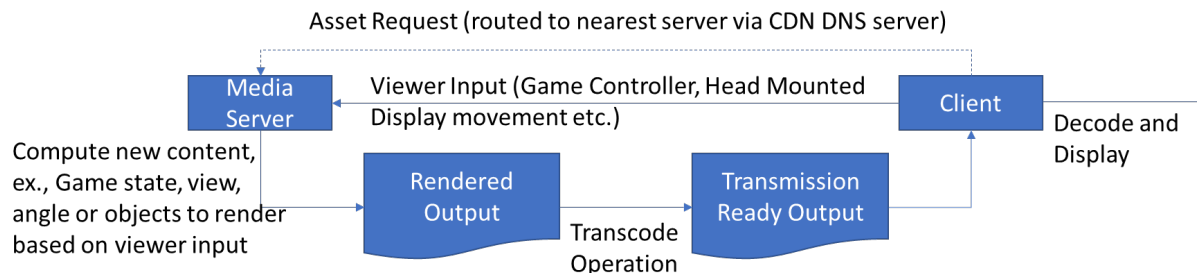

Figure 2 - Interactive content delivery

As mentioned, the key difference between non-interactive and interactive content is that non-interactive content delivery is a "one-way" transfer of bits over a network (after transcoding) to the client (viewer),

whereas interactive content delivery is a two-way street, where the viewer input from the client is used to determine subsequent content, which must be rendered prior to transcoding and transfer over the network.

In the case of non-interactive content, provided there are reasonable network conditions to deliver the bitstream to the client, and the client can buffer for intermittent interruptions in the network or processor use, the viewer gets a good experience. However, for interactive content, the client is typically expecting a higher bitrate (due to higher frames per second and resolution) while at the same time expecting the server to accept and process its current input to determine the subsequent state of the content.

This imposes much tighter latency requirements on interactive content rendering. Using gaming as an example, if the frame displayed at the client is more than three to six frames after the game input was issued, then the user experiences “lag”, i.e., feels that the game is non-responsive. Typical game experiences are served at 60 frames per second (fps) which gives the system 50-100ms to present a frame response back to the user from the time that the user issues their input.

There are many public discourses about optimizing latency for Cloud Gaming [2][3]. Figure 3, from [Nokia](#), is a sample representation of the system latency budget for Cloud gaming [4].

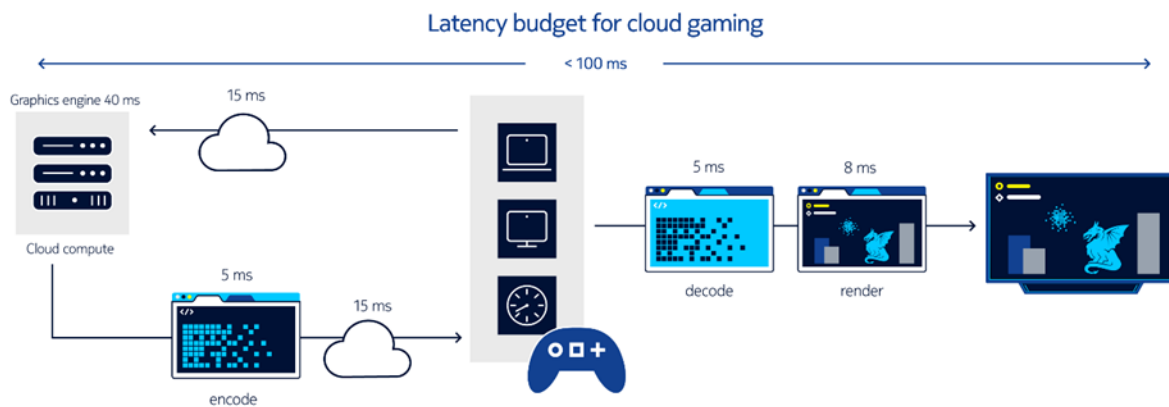

Figure 3- Sample Cloud Gaming System with latency budget

In the above example, the complete response time, i.e., the “button-to-photon” latency, is depicted as 88ms, with the network component of the latency being 15ms one way, or 30ms round-trip-time (RTT).

For a network, meeting 30-40 millisecond RTT latency is a tall order. For example, in a particular home, based on current network conditions, may take 5ms over WiFi and 25ms for DOCSIS, but it could take another 20ms to reach the Cloud due to routing over the backbone network, followed by egress to another carrier network or the Cloud gaming content delivery network (CDN), and ultimately, to the gaming server, i.e., the graphics engine – we assume that the gaming server is not in the same market or Metropolitan Statistical Area (MSA) as the home.

In this example, it becomes challenging to provide such interactive experiences from the Cloud. The unique position of CSPs to affect the quality of experience for services such as Cloud gaming by hosting the service from within their network, coupled with the financial incentives of higher ARPU, is driving some CSPs to bring these services to market.

However, Cloud gaming is only the beginning of immersive media delivery. AR and VR are on the horizon and the rumored launch of Apple Glasses promises to bring these services to mainstream adoption. AR and VR are, however, far less latency-tolerant than Cloud gaming. While public documentation proclaims that 100ms “button-to-photon” (system) latency is acceptable for Cloud gaming, the community of practice has concluded that VR will require 20ms “motion-to-photon” (system) latency. As seen from Figure 3, if a graphics engine takes 40ms to produce the next frame, or if the necessary pipeline steps of encoding and decoding take 10ms, then an exacting standard of 20ms “motion-to-photon” would be nearly impossible even if the network RTT latency is negligible.

In reality, there are several application-level techniques to “relax” the 20ms motion-to-photon latency requirement, such as re-projection, asynchronous time-warp, over-rendering, head movement prediction, etc. This has been validated by our empirical R&D. The type of content, “lean back” vs “lean forward”, also determines whether this “motion-to-photon” latency is a strict or relaxed requirement. For example, an experience such as “theBlu” [5], in which the user moves relatively slowly and interacts with elements in the content infrequently, is “lean back”, and the user will tolerate greater “motion to photon” latency for an acceptable experience. In contrast, VR “lean forward” content such as the popular “Beat Saber” [6], will tolerate less latency.

Overall, VR and AR will be much less tolerant to latency than Cloud gaming. Currently, the network RTT latency and jitter required to serve a particular AR/VR experience may be proprietary knowledge, dependent on the “motion to photon” latency as well as the technology stack of the Application Service Provider that manages rendering, encoding, decoding, etc. We expect that this will become public knowledge as the industry develops and users demand streaming options for delivery (similar to Cloud gaming today). It can be evaluated by ASPs under test conditions and may also be crowd-sourced through session evaluations of users.

In recent years, the Cable industry has embarked on a journey to explore the delivery of new media beyond video, such as gaming, AR/VR and light fields, over the network. For example, in the 2020 SCTE Cable Tec Expo Keynote demonstration, Charter Communications, together with partners, demonstrated a holographic transmission leveraging the “Power of 10G” [7][8][9][10].

Multiple System Operators (MSOs) have also set up the Immersive Digital Experiences Alliance (IDEA) [11] and are working with technology partners to advocate for standards and ecosystem development of immersive media. As MSOs become converged connectivity providers (wired and mobile), it is important that the Cable industry participate in the ecosystem and lead the definition of standards in Fog Computing and Edge Computing [12][13]. The methodology proposed in this paper crystallizes how MSOs can leverage their network to offer Edge Computing as a service to Application Service Providers (traditionally deployed in the Cloud).

3. The Communication Service Provider Network Hierarchy: Architecture and Considerations

When implemented, the methodology described here allows the CSP to provide latency-dependent compute to a subscriber, in concert with an ASP, for current and future interactive content experiences. We elaborate a method where system components interact seamlessly with each other for compute allocation.

We model compute grade and network latency as the most important factors that affect the end-user’s quality of experience (QoE). There may be other factors, such as specifications of an end-user device (ex., head mounted display/HMD); however, due to the nature of interactive immersive experiences (ex., VR

gaming or AR that factors in current context like detection of objects in view, SLAM [simultaneous localization and mapping], spatial anchoring of rendered 3D objects, etc., as opposed to watching a 360-video in VR), the intensity of compute and its latency to the end user become the primary determinants of whether the experience can be served at all. If it can be served, then optimizing delivery, i.e., encoding, streaming, buffering, etc., to match the end user device and pose is a secondary problem that must be solved tactically.

Figure 4- Sample Cable/Telecom Network

Figure 4 depicts the typical network hierarchy of a Cable/Telecom CSP. The access network, i.e., the “last mile” runs between a headend/CMTS (Cable Modem Termination System) to the customer premise for a Cable/broadband network and from a central office/base-station to the customer equipment (ex., mobile phone) for a telecom network. As more latency-sensitive compute is required for immersive media or other applications, it is expected that the central offices and headends may be retrofitted with more compute resources. There is public discourse on CORD (central office rearchitected as a data center) [14] and HERD (headend rearchitected as data center) [15][16] as the logical evolution of these CSP critical facilities.

The local headend/central office, however, is not the lowest level of the network hierarchy. Some of the new cable / fiber deep architectures such as Distributed Access Architecture (DAA) technology [17] [18] create opportunities for putting potential compute “closer” to the consumer along with Hybrid Fiber Coaxial cable (HFC) equipment. When combined with software “virtualization”, the downstream migration of DOCSIS functions may also free significant space and power in the headends, for retrofitting general purpose CPU/GPU compute into critical facilities. Similar cell site architecture proposals are also being considered in the 5G technology umbrella. The equipment on the customer premise (CPE, or customer premise equipment) comprises the lowest level in the network hierarchy. It includes cable modems, wireless routers, set top boxes, fixed wireless small cells, and user equipment such as TVs, holographic displays, AR/VR headsets, mobile devices, etc. As embedded compute becomes cheaper and more available, there is an opportunity to provide more capable devices that leverage built-in compute resources like GPUs.

Above the headends and central offices are the market and regional data centers, which may be considered at the same level or at different levels in the network hierarchy, depending on the specific topology of the network. Since these are already data centers, the CSP may augment these with new and more powerful compute like banks of GPUs.

Finally, the CSP network may have a national data center, or the traffic may be exchanged between a carrier network and the CSP network, to terminate in a Cloud location/CDN. This represents the highest level in the network hierarchy. These facilities are typically medium or large colocation data centers, and

providers of various services and applications such as immersive media may upgrade their equipment with adequate compute to serve new experiences.

It is important to note that today's IP media delivery connections are end-to-end, i.e., only have a source and a destination, meaning that, so far, there has been little need to specify a network hierarchy for media delivery. This also derives from the tolerance that current media applications have for network latency.

It is expected that a CSP will have a hierarchy of compute where, starting from the customer premise, each level of the network would typically have greater compute than the lower level, but less compute than the next level. Therefore, at the lowest level in the customer premise, the least amount of compute may be available. The headend/central office will have more compute than the customer premise, but less than the market or regional data centers, and so on. This is because each level of the network is serving more and more customers, requiring a larger serving radius. For example, while a CPE may serve only one home, a Remote-PHY (R-PHY) node [19] may serve 50 homes, a headend may serve 500 homes and a market data center may serve 10,000 homes. This is generally true for connectivity and packet routing today, however, as service providers augment their networks with compute for future applications, this will likely also be true of compute resources.

The other reason for this hierarchy is that it is easier to augment higher levels with compute as they are already data centers, and often have adequate space, power and cooling. Since the demand for compute at any point in time is statistical, adding servers with a bank of GPUs as a consolidated compute asset in a market or regional data center is logistically feasible. By comparison, a CSP may have to arrange for space, power and cooling to retrofit a central office or headend into a data center at the lower level. In a similar vein, a CSP may have to ship upgraded CPE, such as a router or a device to add compute in the customer premise. Therefore, it is relevant that the latency to the compute increases for each higher level in the network hierarchy.

4. Delivering Latency-Sensitive Compute for AR/VR Experiences

In this section, we describe how a CSP network may determine the intensity (or grade) of compute as well as the class of latency needed to serve an immersive AR/VR experience, as well as provide the specified compute to the customer from within its network.

4.1. A Priori Setup, CSP

- A. A CSP organizes its compute resources into units and compute grade/intensity. Each unit maps to a self-contained compute system capable of running a class of experiences, such as a Virtual Machine (VM) or a container. Each unit also has a compute grade associated with it, which refers to the quality of its resources, such as CPU cores, RAM, OS, GPU flops and vram. The compute grade may be a simple descriptor (say, a scale of one to ten) or a more complex descriptor that may be more descriptive on individual elements of the compute. Each unit is also associated with a hierarchy level in the network.
- B. The CSP sets up a global network compute orchestrator for management of all compute resources, as well as local compute orchestrators in each network compute element from data centers to CPE. A network compute orchestrator negotiates the compute resources on behalf of the subscriber from the network. The negotiation is based on the subscriber's service-level agreement (SLA) with the CSP – higher levels of service authorize higher compute grades for a subscriber, perhaps for longer time periods. Further, a network compute orchestrator may command a local compute orchestrator in a specific data center/headend/central office/CPE to reserve its resources.

- C. The network compute orchestrator has real-time visibility into the use of compute resources by receiving responses to queries, success/failure to commands or periodic messages from local compute orchestrators. It organizes this data using an efficient data structure that may be logically equivalent to an Available Compute Resource table wherein each entry represents Compute Resource Label - Compute Grade – Total Units – Available (Free) Units.
- D. The CSP maintains a data structure of network latencies required to reach its compute resources from each consumer's home (or a group of consumers' homes), at various levels in the network hierarchy. The CSP may deploy a latency measurement system between several probes at different points in the network. Some latencies may be directly measured and averaged. Other latencies may be deduced by addition or subtraction of aggregated, measured latencies based on knowledge of the topology of the network. Each measurement shall update a previously-averaged value using a weighted approach by allotting a higher weight to the most recently received value. A CPE may also periodically measure its latency to the central office/headend as part of this latency measurement system.

4.2. A Priori Setup, Application/Media Service Provider

- A. The ASP maintains a list of compute grade and the (worst case) latency required to serve a particular content/experience to a subscriber.

4.3. Connection Setup

- A. Subscriber requests an experience/content to be delivered to the premise on any of their devices. This request is routed to a network compute orchestrator.
- B. The network compute orchestrator queries the ASP for the compute grade and the latency required to serve the requested experience.
- C. The network compute orchestrator calculates the latencies from the subscriber to each of its compute units in an efficient data structure equivalent to a Network Hierarchy – Latency table.
- D. It then finds the lowest level of the network that has a latency equal to or better than the worst-case latency and a compute grade equal to or better than the compute grade for the requested experience using its Network Hierarchy – Latency (built from the point of view of the subscriber) and the Available Compute Resource (global compute resource information) tables, respectively. If the compute resource is not available, then the network compute orchestrator attempts to find the compute unit at the next higher level in the network hierarchy. This continues until either the compute unit is found, or the worst-case latency threshold is exceeded. If the compute unit is not found, the network compute orchestrator informs the subscriber that their requested experience cannot be served at this time.
- E. If a compute resource is available, the network compute orchestrator reserves it by issuing a command to the specific local compute orchestrator. It receives a token if the request is successful. It passes this token to the ASP and updates its Available Compute Resource table.
- F. If the Application Service Provider receives a token successfully, it proceeds to use the compute unit.

Table 1- Network Orchestrator "Available Compute Resource" Table

Compute Resource Label	Compute Grade	Total Units	Available (free) Units
.....
CPE – Router Subscriber S	3	1	1
CPE – Set Top Box Subscriber S	5	2	1
Headend / CMTS Domain D	9	10	4
Regional Data Center Region R	10	70	33
.....

Table 1 illustrates a network orchestrator Available Compute Resource table. In this example, we show compute grade (intensity) as a simple descriptor on a scale of one to ten. These descriptors can be mapped internally to specific attributes like GPU flops, vram, etc. The table shows entries for one subscriber, S. If the network makes compute available at the CPE level, then there would be entries for each subscriber. A tree data structure may be used for efficient storage and traversal, where the leaf nodes represent CPE at the subscriber level.

Table 2 - Application Service Provider Content Table

Content	Compute Grade / Intensity (descriptor 1-10)	RTT Latency, Customer to Compute (milliseconds)
.....
Content-X	8	30
Content-Y	6	10
.....

Table 2 illustrates an ASP content table. In this example, Content-X may be a “lean-back” experience where the user is immersed in a VR session but does not require fast-paced interaction with their environment. On the other hand, Content-Y may be a first-person shooter game in VR, where the targets are moving with high velocity. Thus, the RTT latency requirement for these experiences is significantly different.

Table 3- Network Orchestrator “Network Hierarchy – Latency” Table

Hierarchy	Compute Resource Label	RTT Latency, Customer to Level/Compute (milliseconds)
1	CPE – Router Subscriber S	3
2	CPE – Set Top Box Subscriber S	3
3	Headend / CMTS Domain D	9
4	Regional Data Center Region R	23
5	National “Cloud” Data Center NOC	55

Table 3 illustrates a “Network Hierarchy – Latency” table built by the network orchestrator for serving Subscriber S.

Consider that subscriber S wishes to experience Content-Y, which is both latency and compute sensitive, as observed from Table 2. From Table 3, it is evident that the content must be served from a headend/CMTS or a lower network hierarchy, due to latency constraints. Now, from Table 1, we observe that the CPE in Subscriber S's home does not have the compute intensity to drive this experience. In this case, the compute unit must be allocated at the headend/CMTS. In our example, four units of compute resources with grade nine are available, as seen in Table 1 (that is greater than the requirement of six for Content-Y, Table 2). Therefore, one of these units may be allocated to delivering Content-Y in Subscriber S's premise.

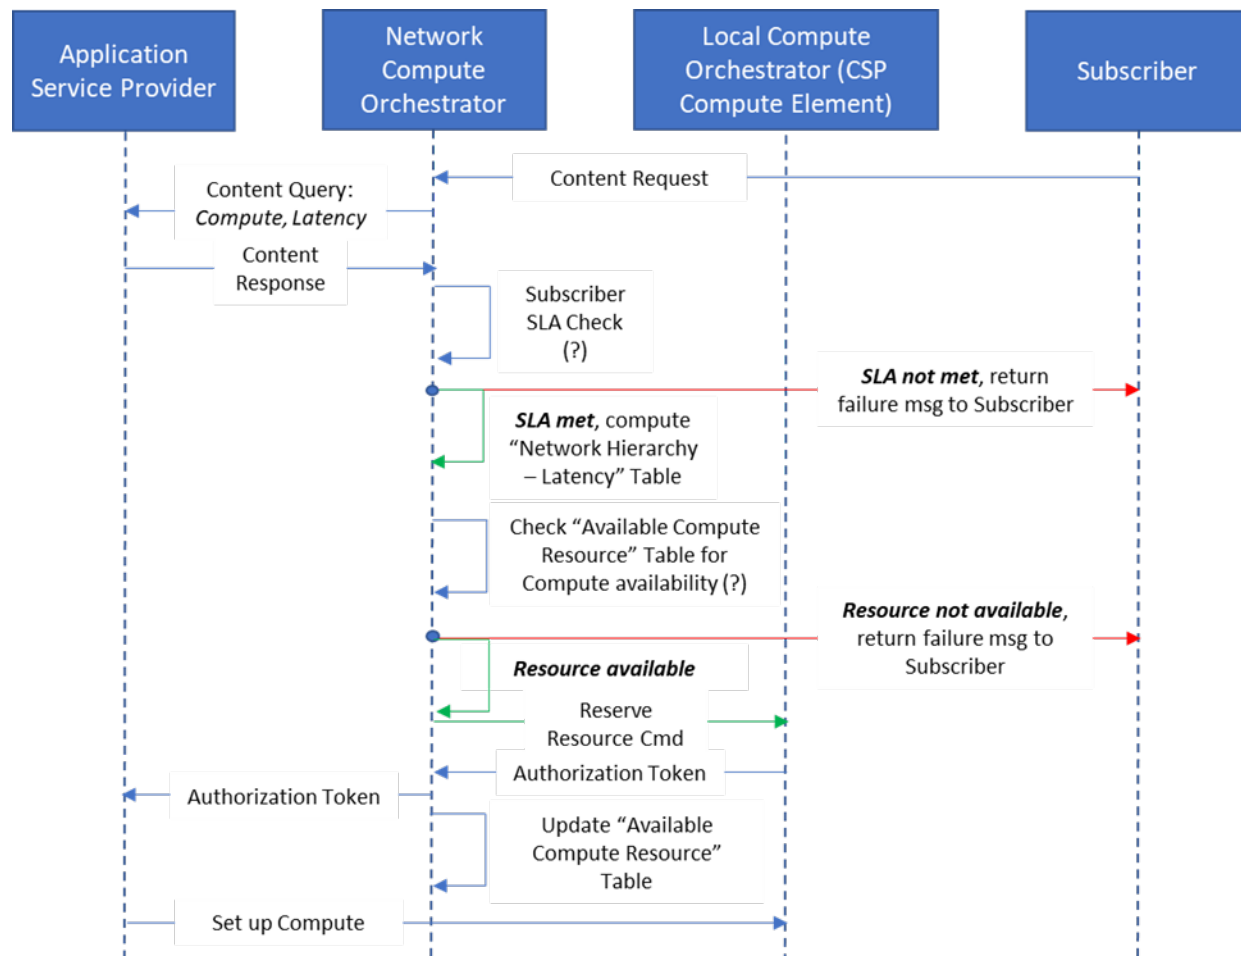

Figure 5 - Sample Session Setup

Figure 5 shows a sample session setup where a subscriber requests an AR/VR experience and the CSP allocates the compute resource for that content from within its network. The subscriber may request the experience either from the ASP that then contacts the CSP for low-latency compute, or directly from the CSP that may forward the request to the ASP. This may depend on the business relationship between the subscriber, the ASP and the CSP. The initial query to the ASP is used to determine the latency and compute intensity requirements. The CSP, after receiving these requirements and checking the subscriber SLA, proceeds to find the compute unit within its network. From the subscriber-centric "Network Hierarchy - Latency" table, the CSP determines the (one or more) levels in the network hierarchy from which the request may be served based on latency. Thereafter, a determination of the critical facility from which the request shall be served is made by the CSP's Network Orchestrator based on latency and

compute intensity. The Network Orchestrator updates its “Available Compute Resource” table accordingly. Once the compute is allocated, the ASP loads the application. It is worth noting that while the subscriber initiates the request, the delivery of content occurs when the ASP and the CSP work together.

5. Discussion of Compute Grade and Latency

In this paper, we used a simple descriptor on a scale of one to ten to denote Compute Grade or Compute Intensity. In reality, gaming/VR storefronts use detailed Minimum and Recommended Compute configurations to specify the grade. Figure 6 illustrates three examples from Steam [20], one of the largest distribution storefronts for gaming and VR:

Figure 6 - Example System Specifications for Delivering Experiences

ASPs that provide Cloud compute, on the other hand, may use a single system configuration or a tiered system where a higher monthly rate entitles the subscriber to better system (compute) specifications.

Currently, content stores and ASPs may be separate or “all-in-one”. In this example, Steam is the content store that offers downloadable games, while an ASP would be a Cloud gaming/VR provider that runs game executables in its own data centers or in the public Cloud. In this paper, we treat ASPs as an “all-in-one”, wherein they have agreements with content publishers and storefronts to present content and, in concert with the CSP, compute for delivering the experience.

The immersive community has been exploring “split rendering”, wherein the compute required to serve immersive experiences is shared between a client device and a Cloud compute unit. Qualcomm’s “Boundless XR” [21] concept provides details on their implementation of split rendering.

The “split rendering” paradigm, an active area of R&D, divides compute between a client and the Cloud such that highly latency-sensitive rendering is delivered from the client (if the Compute Grade is available) while less latency-sensitive rendering is delivered from the Cloud Compute unit, and these renders are then composited to deliver a seamless experience to the user. Our methodology is easily modified to specify compute for split rendering. To enable this, the client device must send its available compute specifications, and the ASP, once aware of the locally-available compute, may provide a modified Compute Grade entry from its Content Table.

Finally, it is important to note that many latency measurement systems measure latency and jitter by sending a train of packets to a network device/Point of Presence (PoP), and monitoring RTT for each individual packet as well as the inter-packet delay when they are returned to sender. If a jitter value is available, the service provider may also make that a part of the Network Hierarchy – Latency table. If the jitter value from the subscriber to an element in the table exceeds a threshold, the network compute orchestrator shall reject that element as a potential render/compute candidate even if the latency is below the threshold required by the content/experience.

6. Conclusion

In this paper, we explored how a CSP such as a Cable and broadband service provider may work in conjunction with an ASP to commission on-demand compute for delivering immersive experiences to customers. We explained how it will be possible to serve AR/VR content from within the CSP network even if the “motion to photon” latency is published to be as low as 20ms. This has been validated through empirical observation.

1. Introduction

Traditionally, networks serving different purposes operate in siloes with little-to-negligible overlap in their infrastructures or management processes. For example, DOCSIS networks, optical networks, and mobile networks, each employs specialized hardware functions managed by proprietary element management systems. Operators who offer both wireline and wireless services have dedicated teams to provision and manage each of their different services. This disjointed model of network management is challenged by operational economics. Consequently, designing, deploying, and operating end-to-end services are long and manual processes with long lead times (weeks to months) for effective service delivery.

On the contrary, the networks of tomorrow are envisioned to operate multiple different physical and cloud-native functions over a single flexible, programmable convergence platform whose hardware, software, and data storage resources are shared across multiple access technologies. Convergence is the process of unifying heterogeneous technologies to deliver seamless and ubiquitous connectivity. For operators, convergence creates opportunities for delivering novel, differentiated services, as well as allows for enhanced operational agility.

The umbrella term convergence consists of multiple building blocks such as access convergence, transport convergence, core convergence, platform convergence, operations convergence, and security convergence. Operations convergence entails creating a common operations framework for deploying, configuring, and managing network functions constituting a service. To make business models associated with converged networks and services increasingly attractive, in both wired and wireless domains, strategic research is required to devise the best integration architectures and appropriate accompanying integrated operations and management solutions.

When it comes to solving these challenges, technologies like software-defined networking (SDN) and network functions virtualization (NFV) have already addressed certain pieces of the puzzle. SDN enables decoupling the control plane (signaling/routing traffic) from the user plane (data/application traffic) to provide a global view of the network for efficient centralized control and allows for simpler forwarding devices. NFV allows for the separation of network functions from the underlying hardware and enables running them as virtual machines (VMs) or containers on commercial off-the-shelf (COTS) hardware. Additionally, the cloud computing paradigm provides efficient means to offer flexible resources and economies of scale. A converged service operator would need the capability to integrate all these disparate technologies into a single comprehensive framework to model end-to-end services and to abstract and automate the control and management of physical and virtual resources.

The Converged Service Management Layer (CSML) project — a key piece of the operations convergence puzzle — began in response to the rising need for a common automation platform for different network lifecycle processes. The goal for the project is to leverage and integrate existing next-generation network technologies to highlight the importance and novelty of converged service operations. We envision CSML acting like a master element management system (EMS) which communicates southbound to various domain-specific infrastructure layers, EMS, network functions (physical and virtual) in order to develop converged services. Typically, domain-specific management systems, such as for hybrid fiber-coaxial (HFC) or mobile networks, do not have the visibility or control over other domains for FCAPS tasks, and a central management entity such as CSML can enable that inter-domain communication to achieve multi-access convergence. By supporting management mechanisms of various domains, CSML can act like a single point of control that allows operators to employ virtual functions alongside physical functions and utilize their different network domains more coherently.

The term service orchestration is oftentimes used to describe distinct concepts in the industry. In addition, terms like workload orchestration or network orchestration are also employed in similar but different contexts. Workload orchestration typically refers to installing an application and its associated components over a single target virtual infrastructure, such as using OpenStack for virtual network functions (VNFs) or Kubernetes for cloud-native network functions (CNFs). It is predominantly limited to the management of a single cluster running its own control and user planes. Network orchestration refers to managing network configurations and policies for physical or virtual functions through a single pane of glass, typically employing a SDN controller for centralizing the control planes to manage multiple user planes. Service orchestration operates at a higher layer than workload and network orchestration and leverages them to deploy and manage services comprising of multiple applications to be installed on different target infrastructures, while integrating all control functionalities into a single framework. It uses workload orchestration to instantiate network functions as VNFs or CNFs over various target infrastructures and uses network orchestration to configure physical and virtual networks spanning multiple domains. Figure 1 highlights the difference between different layers of orchestration. Each domain, such as cable access and core, or mobile RAN and core, generally employ domain-specific orchestrators and controllers. For a converged service encompassing multiple domains and utilizing separate workload and network orchestrators, a service orchestrator such as CSML can help integrate all the different components to provide true operations convergence.

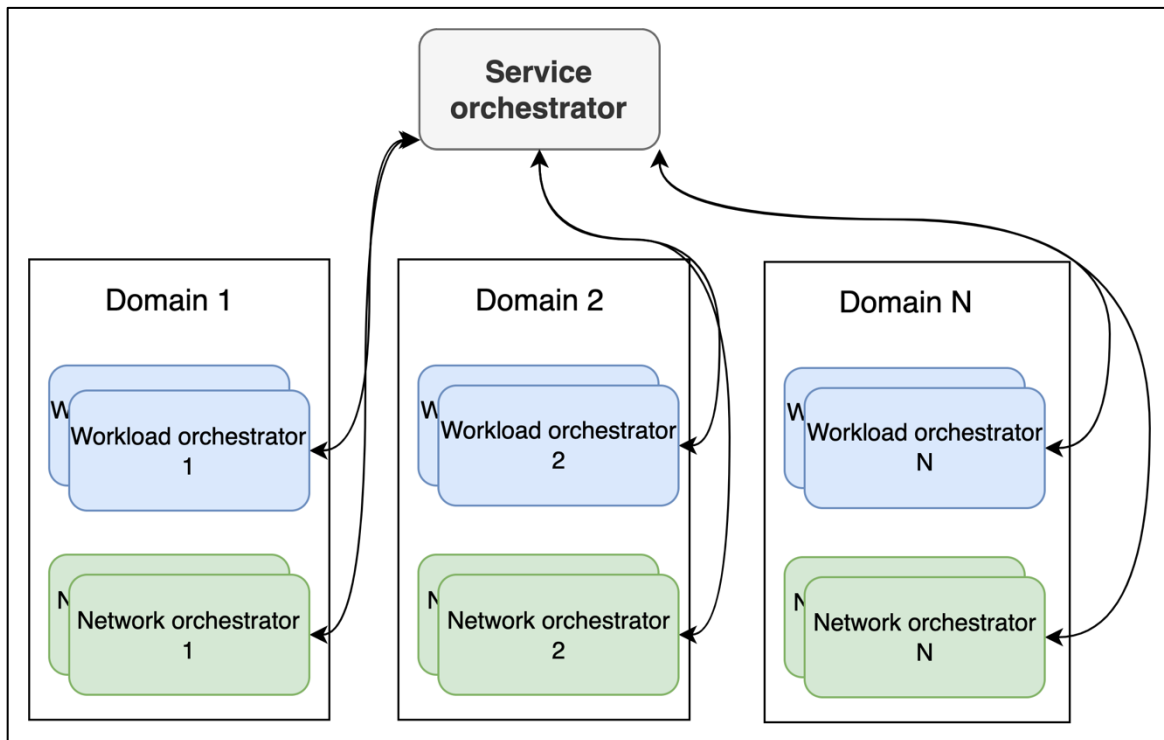

Figure 1 - Service orchestration as compared to workload or network orchestration

During the runtime of the project, several different use cases were developed and implemented targeting different network domains and lifecycles. The first use case targeted virtualized functions in the mobile and Wi-Fi domains, while the second use case focused on incorporating HFC-domain physical functions into the framework to demonstrate hybrid orchestration. This paper presents details on the second use case developed on HFC networks – dynamic speed boost - to demonstrate the value of operations convergence.

Typically, in cable networks, the process of requesting for and implementing a change in subscriber bandwidth or QoE is manual and requires a reboot of the cable modem (CM) for the change to take effect. The PacketCable Multimedia (PCMM) technology provides a mechanism to create dynamic quality of service QoS policies by leveraging functionalities defined in the DOCSIS and PacketCable DQOS specifications [1]. We onboard PCMM into CSML to enable dynamic, closed-loop, application-specific QoS control over the legacy CMTS to support existing and future QoS-enhanced services.

This paper presents details on the overall PoC architecture involving CSML, physical network functions (CMTS and CM) and a virtual PCMM domain controller, and discusses the end-to-end technicalities of the PoC. The rest of the paper is organized as: section II presents details on CSML, its different building blocks, and describes the first use case briefly, section III provides details of the dynamic cable speed boost PoC developed, and section IV presents the conclusion and directions for future work.

2. Converged Service Management Layer

The European Telecommunications Standards Institute (ETSI) Industry Specification Group for NFV (ETSI ISG NFV) developed a framework for NFV management and orchestration (MANO) of all resources in a virtualized data center [2]. Figure 2 shows the NFV MANO framework and the different components managing different network layers. The virtualized infrastructure manager (VIM) communicates with the NFV infrastructure (NFVI) layer to manage the underlying virtualized resources – virtual compute, virtual networking, and virtual storage (such as OpenStack or Kubernetes). The VNFM (VNF manager) interacts with both element managers (EM) and VNFs directly to manage the fault, configuration, accounting, performance, security (FCAPS) of individual VNFs. The NFV orchestrator (NFVO) interacts with OSS/BSS and the underlying management entities (VNFM and VIM) to manage the lifecycle of complex services comprising of multiple VNFs.

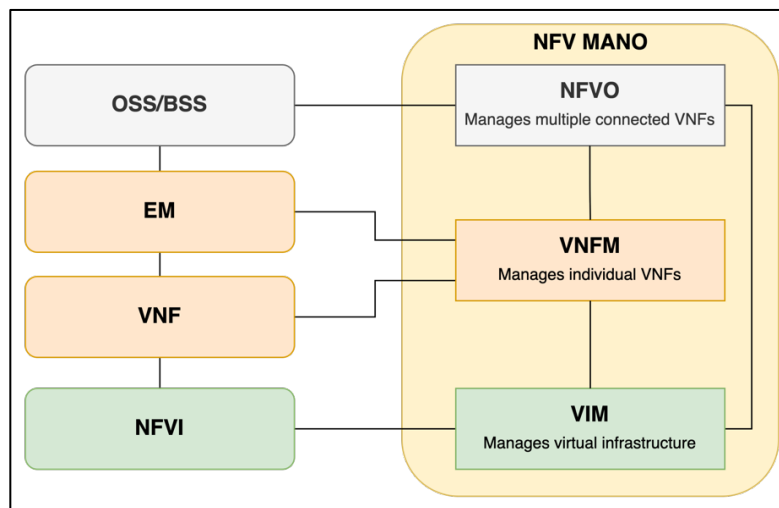

Figure 2 - NFV MANO framework [2]

In the context of different orchestration layers, the NFVO is a subset of the service orchestrator for NFV infrastructure, the VNFM maps to the workload orchestrator managing the lifecycle of individual functions, while the VIM compares with the network orchestrator providing underlying network connectivity. Since DOCSIS, optical, and mobile networks all include some functions implemented in specialized hardware, CSML extends the NFV MANO framework to include the management of physical network functions (PNFs) as well. Figure 3 illustrates the enhanced MANO framework employing CSML to manage PNFs as well. CSML acts as the NFVO and VNFM components from the NFV MANO framework. It includes the

capability to manage VNFs using either its in-built generic-VNFM (gVNFM) or by interacting with specific-VNFMs (sVNFM), including an interface to the VIM layer for virtual resource management over the NFVI. Similarly, CSML can manage PNFs either through specific EMs or by directly interacting with PNFs using its PNF manager (PNFM) over well-known management protocols.

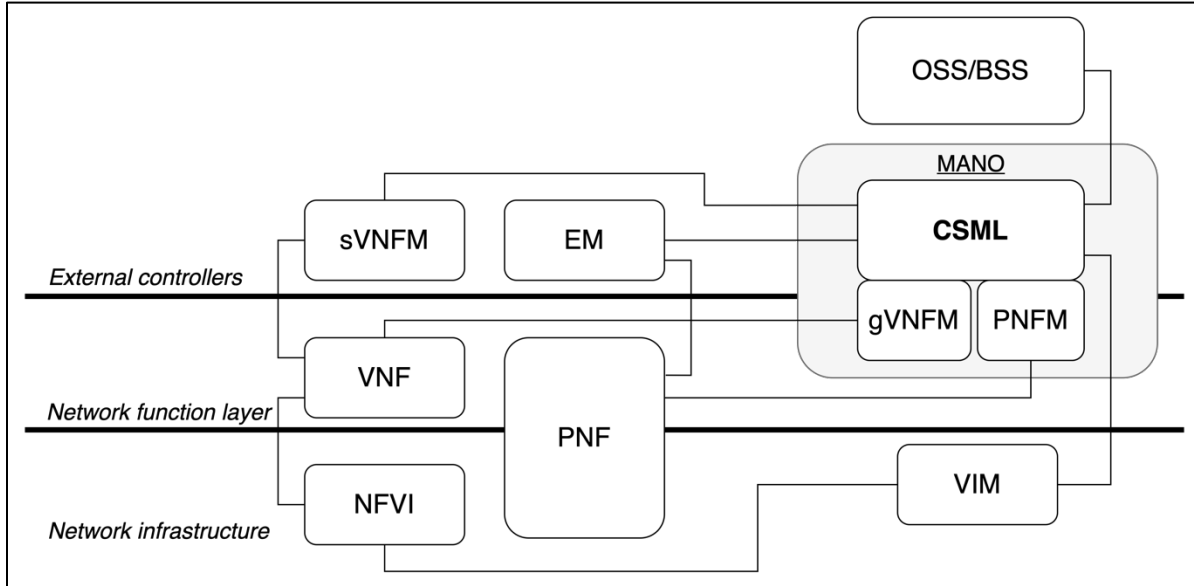

Figure 3 - Enhanced MANO framework using CSML for VNF and PNF management

On a high-level, as illustrated in Figure 4, CSML enables three types of lifecycle management (LCM) activities as a part of its two primary frameworks, namely the design-time framework and the run-time framework:

1. Service design: Involves composing services comprising of multiple xNFs, along with their Day-0 and Day-N configuration parameters and policy rules to enable elastic management of the service.
2. Service deployment: Involves instantiating the modeled services on to the target infrastructures (both physical and virtual) and supervising scale-in/out as needed.
3. Service assurance: Involves monitoring the deployed services and taking closed-loop actions using analytic tools to make the framework self-healing and self-optimizing.

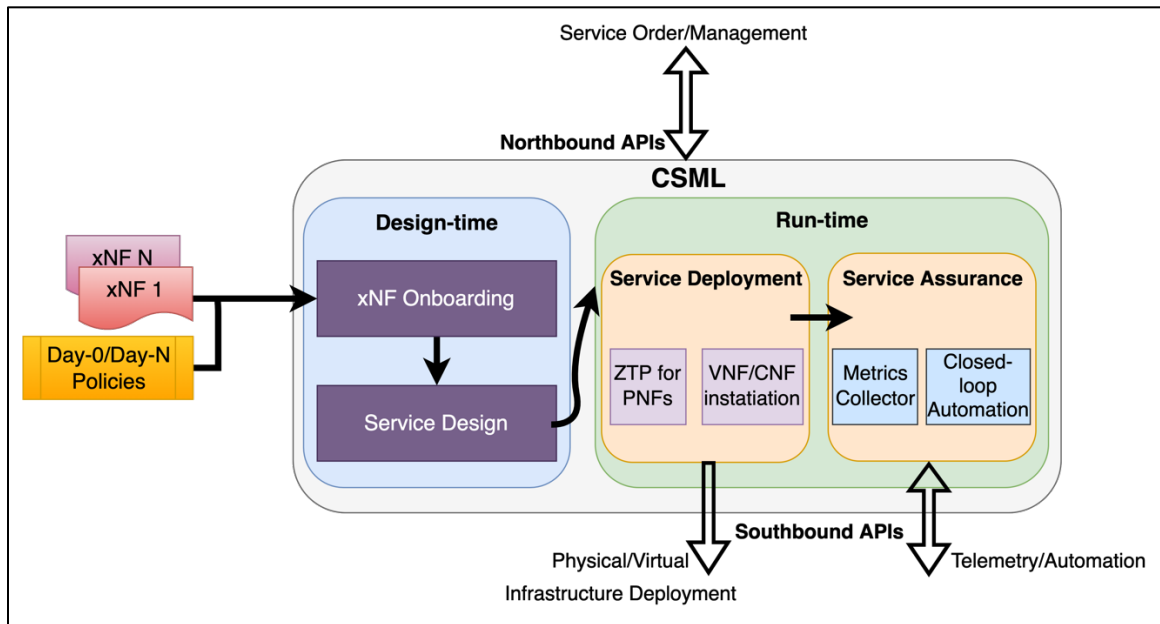

Figure 4 - High-level CSML architecture

The first use-case developed as part of the project activity was to orchestrate and assure a wireless steering application [3]. This application provides an over-the-top solution to steer user traffic over Wi-Fi or mobile network based on current network performance or operator requirements. It is a client-server-based application with the client running on user's mobile device and the server running in the cloud. The server service comprised of eight containerized network functions which needed to be running on different cloud locations simulating an operator's production network setup. This use case highlighted the value of using a service orchestrator such as CSML that can interact with multiple underlying workload orchestrators to deploy a distributed service over different cloud locations comprising of both public and private clouds.

Figure 5 illustrates the network topology developed for this use case. The different server components of the application are deployed on different cloud regions to showcase the capability of CSML to deploy network functions based on their network and compute requirements. For example, the control gateway is an edge component and needed to be geographically closer to the user, therefore it was deployed on Azure Central region, while the data gateway is the data path component through which all user traffic traverses, and therefore it is deployed on a private cloud. The VIM layer consisted of Kubernetes-based providers – Azure Kubernetes Service (AKS) for the public cloud locations and RedHat's OpenShift for the private cloud location. CSML itself was implemented to run in AKS, acting as the service orchestrator and was able to demonstrate multi-cloud service orchestration involving instantiating components over different locations, interconnecting them over virtual networks, and ensuring the end-to-end service operated as expected.

CSML was also responsible for assuring and healing the service by continuous monitoring and taking a specific closed-loop action when an issue was detected. The scenarios tested included - (i) Application-level healing – The control gateway component was responsible for leasing out IP addresses from a pre-defined IP pool to UEs connecting to the steering application, and as the IP pool would start to get exhausted, no new UEs would be able to connect to the application. CSML was able to identify this issue by continuously monitoring the control gateway's runtime via one of its REST endpoints and as 90% of the pool became exhausted, a new IP pool was allocated to by invoking another REST endpoint and modifying its Day-N configuration to ensure service continuity; (ii) Infrastructure-level healing – Since the control

gateway component is running on a shared cluster along with other services, there could be instances when the underlying compute resources become deficient. CSML was able to identify this issue by monitoring cluster resources via Kubernetes APIs, and resolving it by migrating the control gateway to another cluster and interconnecting all other components to the new cluster to ensure no service disruption.

Furthermore, additional utilities were developed in order to enable federated collection of telemetry data of both the infrastructure-level metrics as well as application-level metrics in order to enable centralized decision-making. This use case proved the value of service orchestration for virtualized environments spanning multiple locations and provided a common, abstracted framework for deploying and managing novel services.

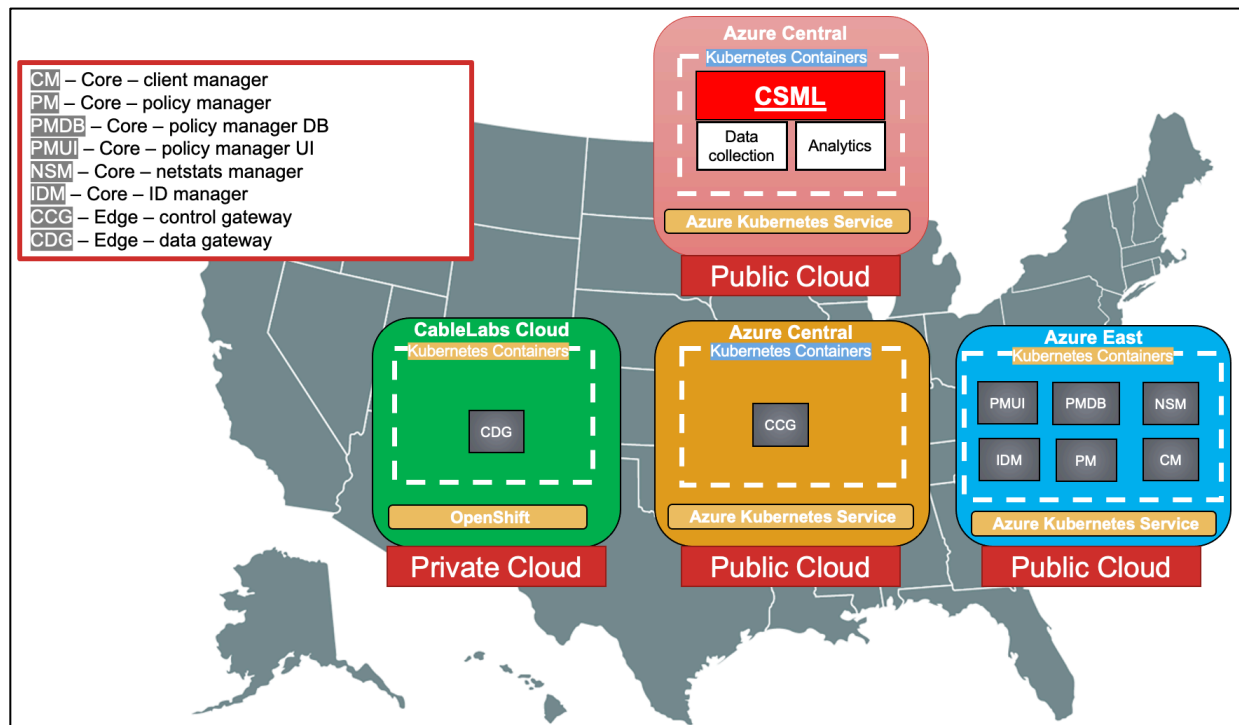

Figure 5 - Multi-cloud service orchestration using CSML

3. Dynamic Cable Speed Boost

The second use-case developed, to demonstrate hybrid physical-virtual orchestration, was to use CSML to enable dynamic speed boost in the cable network. DOCSIS provides two mechanisms to configure service flows (QoS policies) – (i) Static, which are established during the CM registration process, and (ii) Dynamic, which can be configured on an as-needed basis. Typically, operators employ the first mechanism which entails pushing a new configuration file to the CM manually and requires a reboot of the CM for it to take effect. This process is relatively lengthy and leads to disruption in traffic for the time it takes the CM to boot back up. The dynamic service flow mechanism requires an entity to interact with multiple controllers and network devices in order to translate the required QoS request into configurable DOCSIS service flows. CSML can act as the central orchestrator in this scenario to realize this use case by leveraging its capability to control both virtual and physical functions.

Figure 6 illustrates the high-level network topology of the use case implemented. The dynamic speed boost app is a web-based GUI developed using the Python-Flask framework, running in a VM in public cloud, which provides the user with the choice to boost or un-boost a specific application for a definite or indefinite time [4]. The application options included as part of this use case include YouTube (classified based on TCP port 443), Zoom audio (classified based on DSCP value 56), and Zoom video (classified based on DSCP value 40). Additional application options could be included based on requirements and differentiating parameters. CSML exposes northbound REST APIs which the dynamic speed boost app invokes to pass the user requested QoS parameters. In the southbound direction, interfaces were developed for CSML to connect to a PCMM controller and a CMTS in order to create, modify or delete service flows and verify if they have been pushed to the CM, respectively. OpenDaylight (ODL) was used as the PCMM controller in this use case as it is open-source and includes an implementation of the PCMM service as an additional module [5]. ODL was also running as a VM in public cloud. ODL exposes northbound REST APIs to provision a CMTS and service flows, and uses the Common Open Policy Service (COPS) protocol as transport to communicate with the CMTS. CMTS uses MAC-layer DOCSIS Dynamic Service Add/Change/Delete (DSA/DSC/DSD) messaging for service flow management for a specific CM. A Cisco cBR-8 was used as the CMTS and an Arris SURFboard model was used as the CM. A laptop was connected behind the CM for speed-testing purposes.

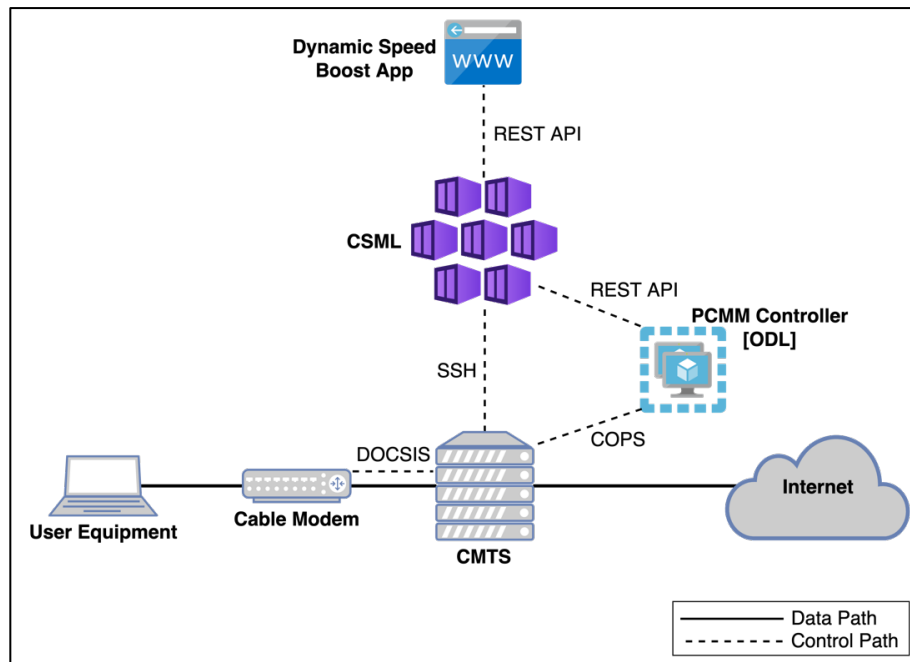

Figure 6 - Network topology of dynamic cable speed boost

The design-time work within CSML involved creating blueprint models for ODL and CMTS in order to enable their Day-N configuration. The network function (NF) model is essentially an archive consisting of TOSCA-based definitions represented in JSON, and specifications for run-time actions. The blueprint definitions include reusable data dictionaries, and component and node workflows to allow for intent-based configuration of the NFs. The run-time model defines the southbound interface and the associated actions that can be invoked to automate NF configuration. The southbound interface used to configure ODL was a REST-based environment that enables pipelining multiple API request-responses defined in a workflow, while the southbound interface used for the CMTS was a Python-based environment that allowed reusing existing scripts to SSH into the CMTS and change configuration. The Python-SSH script employed the

Netmiko library to set up connections with the CMTS, and send and receive commands related to service-flow configurations [6].

The run-time work within CSML involved developing northbound APIs and defining their associated payloads that could be used by an external application, the dynamic speed boost app in this scenario, in order to request for a boost for a particular application. CSML translated this request and invokes a defined workflow to transfer the requests to the correct run-time environments and take corresponding actions based on responses received from the NFs. This process enables an abstracted service framework which can be used by external northbound systems to interact with CSML, and in turn the underlying NFs, without knowing specific details about individual NFs.

Figure 7 depicts the multiple interactions of CSML with different NFs. The end-to-end flow works as:

1. User requests for a speed boost by logging into the dynamic speed boost app and providing details of the application requiring boost and an optional end time.
2. The request gets communicated to CSML over its northbound REST API including the CM IP of the requesting user.
3. CSML invokes a workflow defined for this purpose that includes the steps to fulfil this request.
4. CSML first checks if the COPS connection between the CMTS associated with the requesting CM and ODL is up. If it is not, CSML initiates the connection by sending an API request to ODL.
5. Next, CSML communicates the service flow request to ODL consisting of the CM IP, classifier to match specific application traffic, and either a pre-configured service class name on the CMTS or DOCSIS QoS parameters to define the speed boost requested.
6. ODL uses COPS protocol to communicate with CMTS the new service flow required.
7. CMTS uses DOCSIS to push the service flow to the specific CM.
8. Once ODL returns the confirmation to CSML that the flow has been pushed, CSML initiates a SSH connection directly to the CMTS and requests all service flows active for that CM IP.
9. CMTS returns the list of active service flows to CSML.
10. CSML verifies that the new service flow pushed matches the original request from the user.
11. After verification, CSML returns the boost confirmation message to the dynamic speed boost app over its northbound REST API.

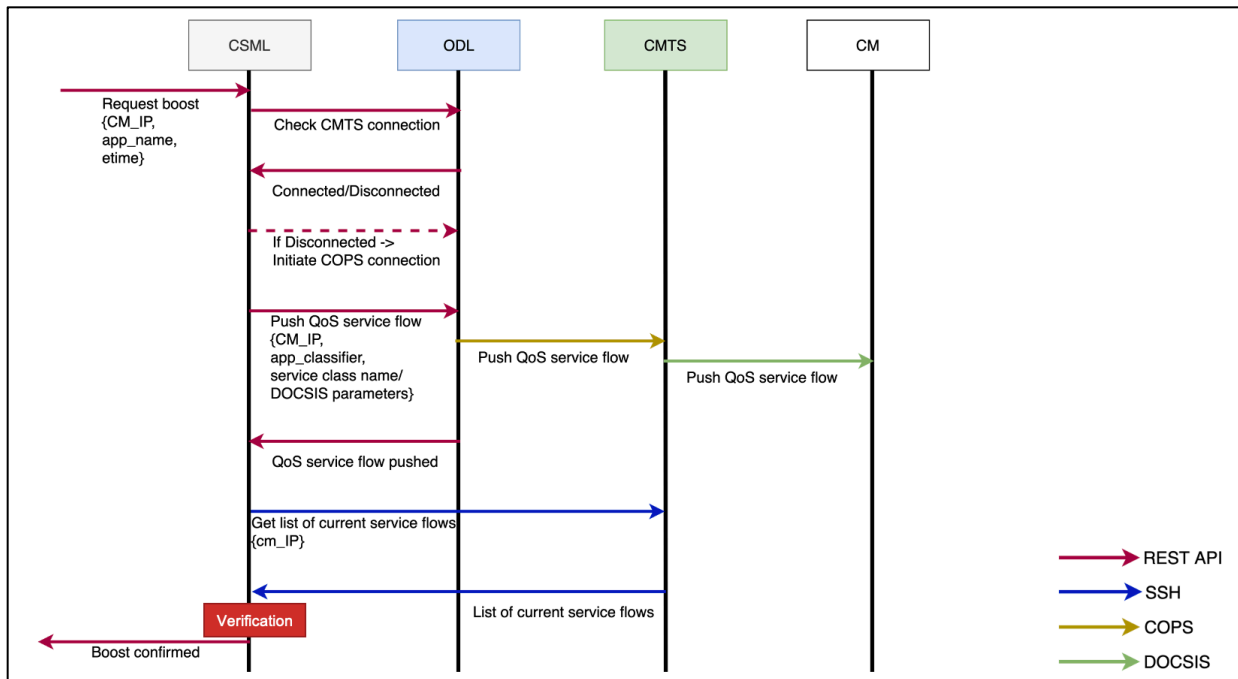

Figure 7 - End-to-end interactions of CSML with different NFs

The end-to-end flow described above illustrates the level of abstraction offered by using a converged service orchestrator. The OSS/BSS or external applications are only required to send a single request to CSML, and all the non-trivial interactions with different NFs, both physical and virtual, are implemented on the backend within CSML to fulfil the request. This enables integrations with multiple different NFs and controllers, and allows for the development of novel use cases with the orchestrator handling much of the operational complexities associated with them.

To test the overall functioning of this use case, the user laptop was used to test different application speeds before and after requesting for the boost. The user laptop was running a speed test application, YouTube application, and an iPerf client which was connected a public iPerf server on TCP port 5002. The default subscriber bandwidth was set to 10 Mbps for both upstream and downstream in the CM configuration file. Next, a 4K video was opened on the laptop and real-time video statistics were enabled to check connection speeds for the running stream. Initial speeds were capped at 10 Mbps, which resulted in excessive video buffering, and the iPerf speeds were also capped at 10 Mbps for both upload and download. To improve video performance, the user then requested for a speed boost of the YouTube application by logging into the dynamic speed boost app. Almost in real-time, CSML was able to fulfil this request and pushed a new downstream service flow (since YouTube video streaming is primarily downstream data-driven), and the video statistics indicated connection speeds going up to ~85-90 Mbps now, with the video no longer buffering anymore, as shown in Figure 8. At the same time, iPerf download speeds were still capped at 10 Mbps since it was running on a different port as that of the requesting application. This demonstrated the capability of CSML to achieve a dynamic cable speed boost for a specific application based on user requirements.

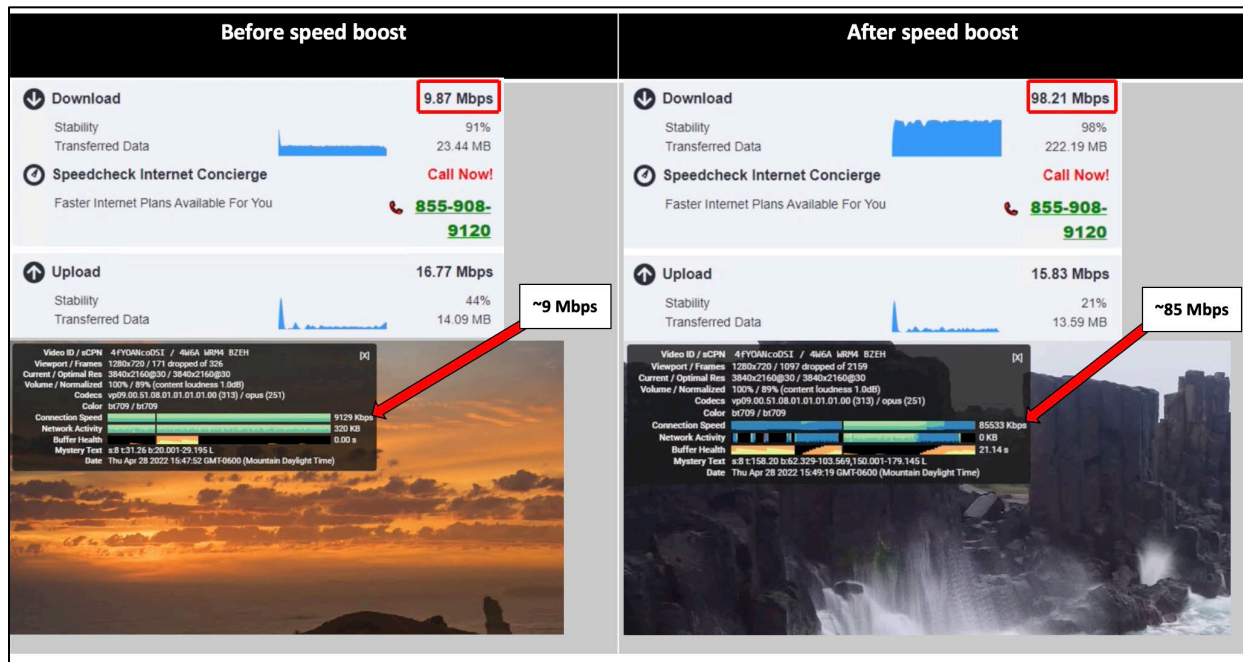

Figure 8 - Speed test results and 4K video connection speeds before and after speed boost

Although, individual scripts could also be used to achieve the same use case, however, orchestration provides additional value to the process. Firstly, developing scripts to communicate with different NFs is not trivial, CSML includes a run-time framework that removes much of the complexity to communicate with NFs and controllers, and simplifies creating complex workflows with multiple interactions. Secondly, once a NF or controller has been modeled within CSML, the same run-time environment can be extended to similar devices running the same management protocols. For example, while in this scenario a Python-SSH and a REST-API environments were developed to communicate with the CMTS and ODL controller respectively, the same could be leveraged to manage switches/routers over SSH and other controllers exposing REST APIs. Thirdly, once a NF or controller has been onboarded within the orchestrator, it can be reused for other use cases to create complex service chains employing different xNFs.

4. Conclusion

With the proliferation of virtualized network functions and the need to converge the management and operations of different network domains, a centralized service orchestrator is required for integrating different systems, thereby enabling novel use cases while reducing operational complexities. This paper introduced the CSML framework along with specific use cases developed to demonstrate the value of service orchestration and automation. The dynamic cable speed boost use case is described in detail which allows for changing the cable subscriber bandwidth on the fly. Both physical and virtual NFs and controllers were onboarded within CSML, and specific southbound run-time environments were leveraged in order to create a complex service chain including a PCMM controller and CMTS. Speed testing was performed to compare different application speeds before and after the user requests for a speed boost, and the results indicated that granular, real-time changes to subscribed bandwidth are achievable in DOCSIS networks using an intelligent, converged orchestrator framework such as CSML. The broader goals of the CSML project are to drive the adoption of network automation, virtualization, and operations convergence at scale. Also, as the transition to NFV is progressing, the project aims to demonstrate how physical network elements can be harmonized with virtual elements to preserve existing network investments.

While the use cases described in this paper demonstrated both physical and virtual orchestration, they were limited to domain-specific architectures. The next phase of the project is to develop a true converged use case that involves incorporating 5G core into the framework in order to provide additional value to operators that provide both cable and mobile services. For example, the cable speed boost use case could be extended by – (i) Identifying customer devices that are subscribed to both cable and mobile services from the same operator and, (ii) Boosting their Wi-Fi bandwidth to offer more value and help differentiating from other operators.

1. Introduction

As Data Over Cable Service Interface Specifications (DOCSIS[®]) access networks evolve through multiple versions technology Borders have been created. Evolving Hybrid Fiber Coax (HFC) plant upgrades, utilizing different Cable Modem Termination Systems (CMTS), and cable modems also create Borders as well. The evolution of technology within a coax access network has maintained backwards compatibility. However, we do not have forward compatibility through these evolutions. An optimized access networks must find the best balance between maintaining legacy services and building for future offerings.

This paper will define technology borders, and key data elements used in optimization. In addition, it will discuss the CMTS feature impacts, optimization drivers, and calculation methods to optimize an access network. Using case studies are also included which go through examples of utilizing this optimization method. Finally, it will discuss the impacts DOCSIS 4.0 will have in the future to this methodology.

2. Identifying Technology Borders

Technology borders can be summarized into two categories HFC and DOCSIS. These two categories are related but evolve independently from each other. Typically, the HFC plant is ready for technology evolution ahead of the needs of new DOCSIS version readiness.

2.1. HFC Borders

The HFC plant, utilized for data, is a bi-directional setup. There are two major data points for technology borders: total spectrum capability and diplex filter spectrum location. Total spectrum consists of the highest downstream frequency available, such as 750 MHz, 860 MHz, and 1 GHz. 1.2 GHz and 1.8 GHz. Builds of 1.8 GHz capable HFC plants are just beginning in preparation of DOCSIS 4.0 Frequency Division Duplexing (FDD).

The second data point of technology borders is the diplex filter which in North America is typically at 42, 85 or 204 MHz. With DOCSIS 4.0, operators will have options to either move the diplex filter higher, with FDD, or use software define spectrum division in Full-Duplex DOCSIS (FDX).

2.2. DOCSIS Version Borders

DOCSIS versions have modified spectrum range and offer multiple channel types. Every one of these changes creates a new border. The spectrum boundaries have changed each version on both the downstream and upstream, and the range of options have grown with each version. The range of support may differ between CMTS and cable modem devices. DOCSIS specifications state the following ranges as supported for each version:

Table 1 – DOCSIS Version Borders

DOCSIS Version	Downstream Plant (MHz)	Return Plant (MHz)	Full Duplex Plant (MHz)
2.0	54-864	5-42	-
3.0	54-1002 108-1002	5-42 5-85	-
3.1	54-1218 108-1218 258-1218	5-42 5-85 5-204	-
4.0 (FDD)	108-1794 258-1794 372-1794 492-1794 606-1794 834-1794	5-85 5-204 5-300 5-396 5-492 5-684	-
4.0 (FDX)	684-1218	5-85	108-684

2.3. Cable Modem Borders

Cable modems since DOCSIS 3.0 also have multiple variations of support within the same DOCSIS version. This variation usually revolves around bonding groups sizing and diplex filters. The diplex filters match the spectrum boundaries in the above table (Table 1). The below table (Table 2) shows common bonding group sizing for each DOCSIS version:

Table 2 – Cable Modem Bonding Capability

DOCSIS Version	Downstream Bonding Group Size	Upstream Bonding Group Size
2.0	1	1
3.0	4 8 16 24 32	4 8
3.1	32 (includes support of up to two OFDM channels)	12 (includes support of up to two OFDMA channels)

Table 3 shows the different diplex filter configurations that have typically been used in DOCSIS access networks:

Table 3 – Cable Modem Diplex Filter Capability

DOCSIS Version	Low-Split (42 MHz)	Mid-Split (85 MHz)	High-Split (204 MHz)
2.0	✓	x	x
3.0	✓	✓	x
3.1	✓	✓	✓

These tables do not include DOCSIS 4.0 cable modems yet, but we expect greater number of orthogonal frequency division multiplexing (OFDM) and orthogonal frequency division multiple access (OFDMA)

channel supported per cable modem, in addition to the many options of duplex settings available within the DOCSIS 4.0 specification.

3. Key Data Elements

As choices are made to modify the capability of the HFC plant or CMTS, data driven optimization decision making becomes necessary. The below data elements provide key information required to make these types of decisions. These data elements focus on each cable modem or DOCSIS channel. Note that service group data elements do not work for boundary optimizations.

3.1. Cable Modem Distribution

Looking at a service group's cable modem distribution can provide insight into traffic patterns seen at the service group level. If a certain border is operating below expectations, looking to see if the service group has enough cable modems that can access that capacity can provide a strong reason for this behavior. This can provide further insight into the potential for future capacity additions and can help predict the offloading of current capacity to the new capacity.

Table 4 – Cable Modem Distribution Example

Capacity Type	Count	% Of Distribution
DOCSIS 2.0	5	5%
DOCSIS 3.0	45	45%
DOCSIS 3.1	50	50%

3.2. Cable Modem Consumption

Consumption data from each cable modem within a service group can be very useful. This provides information on how much data was used during a given period. Adding the cable modem capabilities to this data allows for an enriched view to the service group's usage in that period, and by cable modem capability. Modifying the period can enable even more insights. For example, obtaining consumption data for certain peak hours and reviewing over a 30 to 90 day period can enable a better understanding of average consumption and overall usage for a particular service group. Using this type of consumption data ultimately enriches the cable modem distribution data set.

Table 5 – Cable Modem Consumption Example

Capacity Type	Count	% of Distribution	Total Consumption (Peak Hour) Gb
DOCSIS 2.0	5	5%	10
DOCSIS 3.0	45	45%	20
DOCSIS 3.1	50	50%	70

Table 5 illustrates the information gained from consumption data. In this example, the majority of traffic comes from DOCSIS 3.1 cable modems. Without this detailed view traffic would appear to be even between DOCSIS 2.0/3.0 versus DOCSIS 3.1 cable modems.

3.3. Capacity by Service Group

Understanding the capacity of a service group has long term been a key data element. Understanding the capacity you have made available on the downstream and upstream is very important. This is a very common data point historical for capacity planning an access network.

Table 6 – Capacity By Service Group Example

Capacity Items	Achievable Bit-rate (Mbps)
Downstream 32 SC-QAM (@256-QAM)	1216
192 MHz of OFDM (@1024-QAM)	1647
Total Downstream Capacity	2863
Upstream 4 SC-QAM (@64-QAM, 6.4 MHz)	104
42 MHz of OFDMA (@256-QAM)	285
Total Upstream Capacity	389

3.4. Capacity by Capacity Type

Understanding the capacity of the service group is very common data element. For this data element, it is important that the focus is on a *per* DOCSIS *channel* capacity level. Single carrier quadrature amplitude modulation (SC-QAM) channels are simple examples to understand; however, OFDM and OFDMA add complexity.

The spectrum location of DOCSIS channels is another important metric that can be used to enrich our data. The ability of the capacity type to be utilized becomes important when it is located within new boundary areas. For example, SC-QAM channel location within mid-split spectrum can only be utilized by mid-split capable cable modems.

Table 7 – Cable Modem Consumption Example

Capacity Type	Capacity (Mbps)
48 Downstream SC-QAM	1824
OFDM (192 MHz @1024-QAM)	1647
4 Upstream Low-split SC-QAM (@64-QAM)	104
2 Upstream Mid-split SC-QAM (@64-QAM)	52
OFDMA Mid-split (25.4 MHz @512-QAM)	195

3.5. Peak Traffic

Traffic usage at peak times provides insight into a congestion level of a service group. Breaking down this data into the channel level or channel type can provide insight on the performance of each capacity type.

Table 8 – Peak Traffic by Capacity Type Example

Capacity Type	Capacity (Mbps)	Peak Traffic (Mbps)
48 Downstream SC-QAM	1824	590
OFDM (192 MHz @1024-QAM)	1647	940
6 Upstream SC-QAM (@64-QAM)	156	46
OFDMA (25.4 MHz @512-QAM)	195	87

3.6. Burst Capacity

For service groups that do not have congestion, peak traffic is a powerful data element to understand burst capacity. Burst capacity becomes an output of capacity minus peak traffic. This data can also be organized to boundary focused elements as well. For example, DOCSIS 3.0 downstream burst capacity — which is based on only the SC-QAM capacity can be countered with DOCSIS 3.1 downstream burst capacity that includes both SC-QAM and OFDM capacity.

$$\text{Capacity} - \text{Peak Traffic} = \text{Burst Capacity}$$

The below table provides an example of utilizing this formula:

Table 9 – Burst Capacity by Capacity Type Example

Capacity Type	Capacity (Mbps)	Peak Traffic (Mbps)	Burst Capacity (Mbps)
48 Downstream SC-QAM	1824	590	1234
OFDM (192 MHz @1024-QAM)	1647	940	707
6 Upstream SC-QAM (@64-QAM)	156	46	110
OFDMA (25.4 MHz @512-QAM)	195	87	108

3.7. Spectrum Efficiency

This data point is a powerful indicator of operational issues. For SC-QAM capacity this indicator will show channel impairments and codeword error rates (CER), while for OFDM/OFDMA, this indicator will show low capacity profile use. This data is obtained by collecting information on each cable modems performance on each DOCSIS channel it utilizes and provides data on channel impairment, CER, and active profile/interval usage code (IUC) usage for each of these channels.

This data element is primarily an operational key performance indicator (KPI) but can be used to validate that an operational issue is not causing odd traffic patterns during optimization, avoiding a service group capacity change that impacts customers' services.

3.8. Cable Modem Upgrade Churn Rate

For long term planning (or forecasting), it is important to understand the churn rate of cable modems from older version (that have less capabilities) to newer versions that are more capable. Insights from churn rates can allow a more assertive decision making in transitions to new capacity methods. A good example of this is the rate of DOCSIS 3.0 modems upgrading to DOCSIS 3.1 modems. This can provide a better understanding of when OFDM capacity can be added (with a reduction to SC-QAM capacity) when spectrum is limited.

3.9. Current Product Offerings/Distribution

Understanding the products that are currently offered to customers can help determine the burst capacity needed per service group. In addition to the max speed, the limitations of the cable modems offered with each product is required. For example, a 1 Gbps product requires a OFDM capable cable modems, whereas a 100 Mbps does not require a OFDM capable cable modem, and DOCSIS 3.0 cable modems can still be used.

4. CMTS Capabilities

As each CMTS has differing capabilities, it is important to understand the possible options that can be utilized for managing technology borders, and if any capabilities can impact capacity and traffic patterns.

4.1. MAC Scheduler

The MAC scheduler is the controller of the DOCSIS access network and determines what channel a data packet is transmitted over. This functionality can assist or hinder the behavior the technology borders. There are two common schedulers: balanced scheduler and prioritized scheduler.

4.1.1. *Balanced Scheduler*

A balanced scheduler provides equally load-balanced traffic across all DOCSIS channels regardless of channel type and is usually based on percentage of utilization. This type of scheduler is effective where a large majority of cable modems have access to all DOCSIS channels. This is especially effective for DOCSIS 3.0 with low-split designed capacity.

As DOCSIS 3.1 was released and operators enabled several new technology borders with OFDM, OFDMA, and different upstream splits issues with type of scheduler started to become evident. Traffic offloading to new technology capacity was held back or legacy capacity was over utilized by more capable cable modems. This limitation forces an increased cable modem churn rate, or a different scheduler type is needed. However, if the new capacity is only dedicated to new product offerings, traffic offloading becomes manageable with this type of scheduler.

4.1.2. *Prioritized Scheduler*

While a balanced scheduler can be the most effective solution in certain situations, a prioritized scheduler—which is based on priority of certain channel types or user settings—is the preferred type of scheduler. By allowing priority to lower utilized capacity, the greatest amount of traffic offloaded from older capacity can be achieved. A simple example that most CMTS vendors have adopted is to prioritize OFDM channel traffic. OFDM capable cable modems need to utilize the full capacity of the OFDM channel before their bonded SC-QAM channels. This process offloads the OFDM capable cable modems' traffic from SC-QAM allowing more capacity for legacy services.

Though uncommon in the access network user controlled priority, would be the most powerful example of this type of scheduler. With DOCSIS 4.0 FDD, the expansion of OFDM to new spectrum would make the simple example above less effective. Ideally, a user would set the scheduler to prioritize the new spectrum OFDM channels over current OFDM channels.

Another example of the power of user controlled priority would be in low-split. With upstream channels that tend to have high forward error correction (FEC) error rates due to their location within the spectrum, these channels should be set to a low priority, which would mean that the channel is avoided until the capacity is required.

4.2. Dynamic Configuration Features

Dynamic configuration features like upstream agility and profile management application (PMA) can dramatically modify the capacity of a channel. Utilizing spectrum efficiency prevents these features from causing issues during planning.

5. Optimization Drivers

An understanding of the technology borders and data elements provides the background to start identifying optimization opportunities that can be applied to the access network. With numerous drivers for optimization, this paper will focus on service group capacity, customer experience, and cost reduction. The weighting of each of these drivers will be different for each network operator based on business goals.

5.1. Service Group Capacity

Historically the primary driver for access networks was congestion mitigation, achieved by adding additional service group capacity. This was typically done in tandem with segmentation to maintain enough capacity for IP services. However, as operators reach low levels of congestion more weight should be put behind offering higher burst capabilities for customers.

5.2. Customer Experience

Customer experience focuses on ensuring each customer in a service group achieves quality services. From the capacity management perspective, customer experience established through the burst capacity for that customer. Note the capacity planning is not focused on plant conditions or in-home issues.

5.3. Cost Reduction

When performing capacity management, cost reduction can be achieved through two methods. These methods include license reduction and service group combining.

5.3.1. License Reduction

Depending on the CMTS product, a license is likely utilized for each type of capacity. If the deployment of capacity is in excess, there is an opportunity to reduce the capacity. Each operator will have different agreements with their CMTS vendors, and as a result cost savings will differ from operator to operator.

5.3.2. Service Group Combining

Another option for cost reductions is the combining of two service groups that have low utilization. This reduces the license use by half between those two service groups. Furthermore, it may free up a service group resource for use for another HFC node, though this benefit would not reduce costs.

6. Identifying Optimization Opportunities

For long term forecasting our industry commonly utilizes the 2014 traffic engineering formula[1]. This formula is wonderful to forecast capacity needs for a service group going into the long term future.

$$C \geq (N_{sub} * T_{avg}) + (K * T_{max_max})$$

For access network optimization this formula is still interesting for forecasting but utilizing additional formulas to find opportunities. These opportunities are to maximize each serving group for products offered, and to continue to support legacy products. The starting point for optimization identification is burst capacity. The rest of the data elements discussed within this paper are supporting the decision making process around burst capacity.

6.1. Legacy Capacity Need Identification

As the access network moves towards new capacity methods, identification of legacy capacity need is beneficial in order to support legacy cable modems. Each access network will have service groups that behave outside of the norm and this process will identify them.

Utilizing burst capacity of legacy capacity, helps create a better understanding of the remaining capacity that is available during peak hours. By taking the highest offered service on a legacy cable modem and subtracting its value from burst capacity, you are left with remaining legacy capacity.

$$\text{Legacy Burst Capacity} - \text{Highest Legacy Service Tier} = \text{Remaining Legacy Capacity}$$

Table 10 – Example Data for Legacy Capacity

Data Element	Value (Mbps)
Legacy Burst Capacity (32 SC-QAM Channels)	342
Highest Legacy Service Tier	250

As an example, we can use the figures in Table 10 above to calculate the remaining legacy capacity:

$$342 \text{ Mbps} - 250 \text{ Mbps} = 92 \text{ Mbps}$$

There is 92 Mbps of remaining legacy capacity at peak burst capacity. We understand that the highest service on legacy services can achieve their burst speeds during peak hours. So, if the remaining legacy capacity was equal to or less than zero, this would reflect a greater need for legacy capacity.

6.2. New Capacity Need Identification

Typically, new technology capable cable modems have access to the new technology and legacy capacities. A simple example of this is a DOCSIS 3.1 cable modem would have access to both the SC-QAM and OFDM capacity. Using a similar formula as in the legacy example, you can calculate remaining capacity for new capacity.

$$\text{Burst Capacity} - \text{Highest Service Tier} = \text{Remaining Capacity}$$

Table 11 – Example Data for New Capacity

Data Element	Value (Mbps)
Burst Capacity (32 SC-QAM + 1 192 MHz of OFDM Channels)	848
Highest Legacy Service Tier	1000

We can apply the figures in Table 11 above to calculate the remaining capacity for new capacity:

$$848 \text{ Mbps} - 1000 \text{ Mbps} = -152 \text{ Mbps}$$

From this example we lack 152 Mbps of burst capacity for new capacity modems. A second OFDM channel could be utilized to gain further capacity for the DOCSIS 3.1 cable modems.

7. Optimization Cases Studies

In order to bring together the preceding information together thus far, this section will address several case studies. The scenarios presented below are commonly experienced by operators and can provide direction on how to optimize access networks. The cases studies are as follows:

1. Service group congestion
2. Spectrum efficiency congestion
3. Billboard service with low burst capacity
4. Low utilization service group
5. High utilization of legacy capacity
6. Spectrum boundary

7.1. Case Study 1 - Service Group Congestion

Congestion of a service group is typically handled by adding more capacity, and this additional capacity can be created by adding DOCSIS spectrum or a segmenting the HFC plant. Due to the state of congestion, using per DOCSIS channel utilization and burst data becomes challenging, but understanding each cable modem's usage and capability can provide insight into the type of capacity that will be required into the future.

This case study is based Node 14A, which is capable of 1 GHz with an 85 MHz return. The current DOCSIS configuration and utilization is:

Table 12 – Capacity – Case Study 1

Capacity Type	Capacity (Mbps)	Peak Utilization (Mbps)	Peak Burst Capacity (Mbps)
32 Downstream SC-QAM	1216	1,140	76
OFDM (114 MHz @256-QAM)	774	644	130
6 Upstream SC-QAM (@64-QAM)	156	61	95
OFDMA (25.4 MHz @512-QAM)	195	77	118

The CMTS' MAC scheduler prioritizes OFDM traffic on the downstream and tries to balance traffic on the upstream.

Figure 1 – Hourly Downstream Traffic Graph – Case Study 1

Because the upstream is not congested, the current configuration looks strong. However, on the downstream there is heavy usage on both channel types. At its current configuration, the downstream channel configuration only reaches 750 MHz, so spectrum expansion is recommended.

The Internet/IPTV cable modem distribution is:

Table 13 – Cable Modem Distribution – Case Study 1

Capacity Type	Count	% Of Distribution
DOCSIS 2.0	0	0%
DOCSIS 3.0	160	36.5%
DOCSIS 3.1	278	63.5%

This cable modem distribution and the OFDM channel flatline illustrates that adding OFDM capacity will also lower SC-QAM usage.

After expanding OFDM spectrum to 192 MHz and adding 1024-QAM flat profile, 873 Mbps of capacity was added to OFDM. The new DOCSIS configuration and utilization is as follows:

Table 14 – Updated Capacity – Case Study 1

Capacity Type	Capacity (Mbps)	Peak Utilization (Mbps)	Peak Burst Capacity (Mbps)
32 Downstream SC-QAM	1216	694	522
OFDM (192 MHz @1024-QAM)	1647	1136	511
6 Upstream SC-QAM (@64-QAM)	156	53	103
OFDMA (25.4 MHz @512-QAM)	195	58	137

The CMTS' MAC scheduler prioritizes OFDM traffic on the downstream and tries to balance traffic on the upstream.

Figure 2 – Updated Hourly Downstream Traffic Graph – Case Study 1

These updates have eliminated congestion; in addition, we can support the current product offerings. As seen in figure 2 a significant behavior change on the SC-QAM capacity can be observed.

7.2. Case Study 2 – Spectrum Efficiency Congestion

When dealing with multiple boundaries it is possible for legacy capacity to reach congestion without impact to the entire service group. This example shows how spectrum efficiency can cause congestion that appears like scenarios such as poor cable modem distribution. The root cause can be hidden and difficult to identify if the data elements being used are too few. In the example below, the problem presents as a legacy capacity issue but is an OFDMA channel performance issue.

This case study is based Node 3435B, which is capable of 1 GHz with an 85 MHz return. The current DOCSIS configuration and utilization is:

Table 15 – Capacity – Case Study 2

Capacity Type	Capacity (Mbps)	Peak Utilization (Mbps)	Peak Burst Capacity (Mbps)
48 Downstream SC-QAM	1824	127	1697
OFDM (168 MHz @1024-QAM)	1438	134	1304
6 Upstream SC-QAM (@64-QAM)	156	153	3
OFDMA (25.4 MHz @512-QAM)	195	72	123

The CMTS' MAC scheduler prioritizes OFDM traffic on the downstream and tries to balance traffic on the upstream.

Figure 3 – Hourly Downstream Traffic Graph – Case Study 2

The downstream capacity is strong for this service group, but upstream SC-QAM burst capacity is very close to zero. This appears to be a cable modem distribution issue. The Internet/IPTV cable modem distribution is:

Table 16 – Cable Modem Distribution – Case Study 2

Capacity Type	Count	% of Distribution
DOCSIS 2.0	0	0%
DOCSIS 3.0	68	54.4%
DOCSIS 3.1	57	45.6%

Upon closer examination, the majority of the codewords on OFDMA are passing at 16-QAM, a much lower modulation order than 512-QAM. This service group also has several cable modems that are currently impaired on OFDMA. At 16-QAM the OFDMA channel can only achieve 86 Mbps. Correcting this upstream performance issue could restore 109 Mbps of upstream capacity back to this service group. As seen in the information below, correction of this issue also initiated the correction of the traffic pattern.

Table 17 – Updated Capacity – Case Study 2

Capacity Type	Capacity (Mbps)	Peak Utilization (Mbps)	Peak Burst Capacity (Mbps)
48 Downstream SC-QAM	1824	395	1495
OFDM (168 MHz @1024-QAM)	1438	991	447
6 Upstream SC-QAM (@64-QAM)	156	72	84
OFDMA (25.4 MHz @512-QAM)	195	108	87

Figure 4 – Spectrum Efficiency – Case Study 2

Figure 5 – Updated Hourly Downstream Traffic Graph – Case Study 2

7.3. Case Study 3 - Billboard Service with Low Burst Capacity

If service group congestion is not an issue, the focus moves to the next highest priority - supporting the highest service levels. Users of the highest services are generally heavier users, though in the majority of cases, the maximum service rate is rarely used. Ensuring efficient burst capacity for these services will enable the customer to achieve their max speeds during all hours. This will drive higher customer happiness as their service is capable during all hours.

This case study is based Node 402A, which is capable of 1 GHz with an 85 MHz return. The current DOCSIS configuration and utilization is:

Table 18 – Capacity – Case Study 3

Capacity Type	Capacity (Mbps)	Peak Utilization (Mbps)	Peak Burst Capacity (Mbps)
32 Downstream SC-QAM	1216	899	317
OFDM (112 MHz @256-QAM)	774	624	150
6 Upstream SC-QAM (@64-QAM)	156	46	110
OFDMA (25.4 MHz @512-QAM)	195	87	108

The CMTS' MAC scheduler prioritizes OFDM traffic on the downstream and tries to balance traffic on the upstream.

Figure 6 – Hourly Downstream Traffic Graph – Case Study 3

The upstream is not congested so the current configuration looks strong. On the downstream, despite heavy usage on OFDM, there is room on SC-QAM channels. The Internet/IPTV cable modem distribution is:

Table 19 – Cable Modem Distribution – Case Study 3

Capacity Type	Count	% Of Distribution
DOCSIS 2.0	3	1%
DOCSIS 3.0	92	32.1%
DOCSIS 3.1	278	66.9%

This service group has a high DOCSIS 3.1 distribution which explains the high OFDM usage and low SC-QAM usage. The top service tier for this service group today is 1 Gbps/100 Mbps, and the current burst capacity on the downstream is 803 Mbps, and most of it is on SC-QAM channels. Because the 1 Gbps service tier is only offered on DOCSIS 3.1 cable modems, increases to OFDM capacity would be the best path forward. In this example, reclaiming SC-QAM capacity for OFDM is not required since additional spectrum for OFDM is available.

After expanding OFDM to 192 MHz and adding 1024-QAM flat profile, 873 Mbps of capacity was added to OFDM. The new DOCSIS configuration and utilization is:

Table 20 – Updated Capacity – Case Study 3

Capacity Type	Capacity (Mbps)	Peak Utilization (Mbps)	Peak Burst Capacity (Mbps)
48 Downstream SC-QAM	1824	590	1234
OFDM (192 MHz @1024-QAM)	1647	940	707
6 Upstream SC-QAM (@64-QAM)	156	46	110
OFDMA (25.4 MHz @512-QAM)	195	87	108

The CMTS' MAC scheduler prioritizes OFDM traffic on the downstream and tries to balance traffic on the upstream.

Figure 7 – Updated Hourly Downstream Traffic Graph – Case Study 3

This configuration change has provided considerably more burst capacity, but due to the OFDM priority of the MAC scheduler the greatest usage change occurred to OFDM not SC-QAM capacity. Now, not only does this service group now have the burst capacity to support the 1 Gbps product, it can also support a higher service offering if offered.

7.4. Case Study 4 - Low Utilization Service Group

This case study applies to situations in which operators must reclaim capacity in order to reduce licensing costs. Licensing agreements with each multiple system operators (MSO) can vary from vendor to vendor. If reduction of DOCSIS spectrum can yield a license cost savings this case study provides a good example.

This case study is based Node 236A, which capable of 1 GHz with an 85 MHz return. The highest service tier offered is 1.5 Gbps/100 Mbps. The current DOCSIS configuration and utilization is:

Table 21 – Capacity – Case Study 4

Capacity Type	Capacity (Mbps)	Peak Utilization (Mbps)	Peak Burst Capacity (Mbps)
48 Downstream SC-QAM	1824	100	1724
OFDM (192 MHz @256-QAM)	1647	154	1493
6 Upstream SC-QAM (@64-QAM)	156	72	84
OFDMA (25.4 MHz @512-QAM)	195	87	108

The CMTS' MAC scheduler prioritizes OFDM traffic on the downstream and tries to balance traffic on the upstream.

This service group is efficient in its upstream capacities. However, the downstream is very much over built. Because this is an economic choice there is some difficulty in determining the “right” direction. Assuming cost savings were the same between SC-QAM and OFDM reductions, the most sensible option would be to reduce SC-QAM capacity by 50%. Pushing more capacity towards the ideal conditions for capacity per hertz.

7.5. Case Study 5 - High Utilization of Legacy Capacity

After the deployment of new capacity legacy capacity customers maybe impacted *if* their capacity was reduced during the process. Even with extensive planning, abnormal service groups can appear to have congestion or high utilization of legacy capacity.

This case study is based Node 1, which is capable of 1 GHz with an 85 MHz return. The highest service tier offered is 1.5 Gbps/100 Mbps. The current DOCSIS configuration and utilization is:

Table 22 – Capacity – Case Study 5

Capacity Type	Capacity (Mbps)	Peak Utilization (Mbps)	Peak Burst Capacity (Mbps)
48 Downstream SC-QAM	1824	366	1458
OFDM (192 MHz @256-QAM)	1318	604	714
6 Upstream SC-QAM (@64-QAM)	156	116	40
OFDMA (25.4 MHz @512-QAM)	195	63	132

The CMTS' MAC scheduler prioritizes OFDM traffic on the downstream and tries to balance traffic on the upstream.

Figure 8 – Hourly Downstream Traffic Graph – Case Study 5

The Internet/IPTV cable modem distribution is:

Table 23 – Cable Modem Distribution – Case Study 5

Capacity Type	Count	% of Distribution
DOCSIS 2.0	5	1.8%
DOCSIS 3.0	124	43.5%
DOCSIS 3.1	156	54.7%

The downstream is distributed very well and can support top tier packages, and the downstream SC-QAM has a significant amount of capacity to support legacy capacity customers. The problem shows up on the upstream, where there is low burst capacity on SC-QAM channels. While the highest upload package sold for this service group for legacy capacity is 30 Mbps, and there is sufficient burst capacity to support that package, this is playing very closely to the edge.

The legacy capacity could be increased by adding an SC-QAM channel and reducing OFDMA by 6.4 MHz. This would increase the legacy capacity by 26 Mbps to 66 Mbps, but reduce the OFDMA capacity by 36-37 Mbps.

7.6. Case Study 6 – Spectrum Boundary

As the industry moves towards DOCSIS 4.0 the possible net increase of new capacity becomes significant. Recently, high-split upgrades were completed that can provide insight into a scenario with a marked increase in poor cable modem distribution of capable modems. This is an interesting case study that showcases what can occur with an activation of a new spectrum boundary.

This case study is based Node 7518, which is capable of 1 GHz with an 85 MHz return. The current DOCSIS configuration and utilization is:

Table 24 – Capacity – Case Study 6

Capacity Type	Capacity (Mbps)	Peak Utilization (Mbps)	Peak Burst Capacity (Mbps)
32 Downstream SC-QAM	1824	68	1756
OFDM (192 MHz @256-QAM)	1318	140	1178
6 Upstream SC-QAM (@64-QAM)	156	23	133
OFDMA (25.4 MHz @512-QAM)	195	39	122
OFDMA (64 MHz @512-QAM) – High-split	476	52	458

The CMTS' MAC scheduler prioritizes OFDM traffic on the downstream and tries to balance traffic on the upstream.

Figure 9 – Hourly Downstream Traffic Graph – Case Study 6

The Internet/IPTV cable modem distribution is:

Table 25 – Cable Modem Distribution – Case Study 6

Capacity Type	Count	% Of Distribution
DOCSIS 2.0	0	0%
DOCSIS 3.0	7	24.1%
DOCSIS 3.1 (Mid-split)	21	72.4%
DOCSIS 3.1 (High-split)	1	3.5%

Even with this service group having very low utilization it still shows inefficient use of the high-split OFDMA channel. Given there is no congestion, immediate actions to rectify spectrum inefficacy from occurring is not required. Traffic distribution could normalize if more high-split capable modems were added. Another option to increase efficiency would be to prioritizing the high-split OFDMA channel over the remaining capacity, which would drive all high-split modem traffic to the high-split OFDMA channel until full. This would require fewer cable modems to be switched out to maintain capacity below the high-split spectrum addition.

8. Looking Forward to DOCSIS 4.0

As we move towards DOCSIS 4.0, what changes in the ways we manage technology borders to optimize access networks? The methods above can be applied, like an example reduction of legacy capacity in place of new capacity. DOCSIS 4.0 increases the importance of understanding the necessary planning in the reduction of legacy capacities, which has the potential to impact legacy services. DOCSIS 4.0 comes in two major designs: FDD and FDX. These designs will have different impacts on their technology borders from each other.

8.1. FDD Changes

For FDD DOCSIS 4.0 access network will largely have the same types of boundaries discussed in this paper. However, there is greater risk to legacy services due to the conversion of forward spectrum to return spectrum. Strong pre-planning is required to avoid poor legacy services post upgrade. After the upgrade is completed, the operator is able to return to modem upgrades and spectrum management as before. Given that is the largest spectrum upgrade that has occurred so far, operators will need to be aware of a number of important considerations - from spectrum efficiency for each customer to identified plant condition issues - to maintain capacity for each customer. Each OFDM channel representing a large chunk of capacity, cable modems that are unable to utilize most OFDM channels could have poor experiences, but a single OFDM impairment can be non-impacting. DOCSIS 4.0 FDD will require the management of the reduction of SC-QAM capacity. The continual forward progression towards OFDM/OFDMA only networks will require the application of the above optimization approaches in optimization to know when to take the next step forward.

8.2. FDX Changes

With FDX, the change for DOCSIS 4.0 access network is greater than that of FDD. Despite FDX having the advantage of software upgraded spectrum (up to 684 MHz), this capacity is *not* available to the whole service group, but is shared between interference groups (IG). This creates an additional technology boundary to manage. Due to the capacity gains achieved by this upgrade interference groups will not be an issue at the inception of this technology, as time goes forward it has the potential to restrict product offerings and capacity management options.

Figure 10 – DOCSIS 4.0 FDX N+1 Interference Groups[2]

In the diagram above, an N+1 FDX setup and corresponding interference groups are displayed. For capacity issues with IG 4, segmenting Amp 1 to its own Fiber Node is a logical solution. However, congestion on IG 1-3 how is this managed? Do you segment between these IG to management congestion? As is evident, the new technology boundary of interference groups will be challenging to overcome, but challenges can be overcome.

9. Conclusion

Operators will be required to build processes to manage capacity by channel or capacity type, in addition to the service group level moving forward. This is a key steppingstone as we move forwards towards mature DOCSIS 3.1 access networks, and to the path forward to DOCSIS 4.0. Other key steppingstones are distributed access architecture (DAA), PMA, and multiple OFDM/OFDMA channel configurations. The next few years will bring a lot of change to access networks, but the industry is ready to manage this. Enjoy the road towards 10G.

Abbreviations

CER	Codeword error rate
CM	Cable modem
CMTS	Cable management termination systems
DAA	Distributed access architecture
DOCSIS	Data over cable service interface specifications
FDD	Frequency division duplexing

FDX	Full-duplex DOCSIS
FEC	Forward error correction
Gbps	Gigabits per second
GHz	Gigahertz
HFC	Hybrid fiber coax
IG	Interference group
IPTV	Internet protocol television
KPI	Key performance indicator
Mbps	Megabits per second
MHz	Megahertz
MSO	Multiple System Operators
OFDM	Orthogonal frequency-division multiplexing
OFDMA	Orthogonal frequency-division multiple access
PMA	Profile management application
SC-QAM	Single carrier quadrature amplitude modulation

1. Introduction

The term “DevOps” is derived from the combination of the terms “development” and “operations”. While there is no universal meaning of DevOps, it is generally accepted that it is a combination of specific practices, culture change, and tools [1] intended to reduce the time between committing a change to a system and the change being placed into normal production, while ensuring high quality [2]. Most commonly today DevOps is used in the operation of compute and storage resources, but increasingly these same concepts are being applied to connectivity (overlay and underlay network) resources.

The term “GitOps” describes additional practices, culture change, and tools that can be applied to DevOps to enable the state of a system to be version controlled through a persistent repository, such as the Git repository system [3]. As the state is updated in the versioned repository, automated processing pipelines are leveraged to verify, validate, and deploy the changes into normal production, while ensuring high quality. Like DevOps, GitOps is commonly applied to compute and storage resources today, but it is increasingly being applied to connectivity (overlay and underlay network) resources.

This paper describes how we integrated full network capabilities into a GitOps paradigm by first establishing a network model and integrating that model into Kubernetes to produce a capability that reconciles desired network state (intent) to a physical or virtual network. This paper then describes how the defined base network model can be leveraged to compose higher level or abstract intents changing the infrastructure from a “how” configuration model to a “what” configuration model. Finally, the network operator culture changes required to transition an organization to a controlled and stable GitOps infrastructure are discussed along with lessons learned and future work.

2. Kubernetes as an Intent Engine

Kubernetes is commonly used as an intent engine to orchestrate and reconcile the state of workloads onto a cluster of compute nodes. The implementation of Kubernetes provides many capabilities that intent systems require, including best practices for model definition, model control mechanisms, reconciliation capability, and model decomposition. Kubernetes also provides core context capabilities around the intent functions for security, scale, and tooling. This combination of capabilities makes Kubernetes a good platform on which to build a system that provides intent-based network operations. As Kubernetes already provides intent capabilities for non-network domains, building NetOps on Kubernetes means that a single intent can express a desired state across network, compute, and storage. Thus, Kubernetes can provide the backbone for a unified reconciling control plane.

2.1. Device Model

The most specific level of an intent system correlates to a specific target’s configuration, in that when a specific configuration parameter is set on a target the operator is essentially specifying their intent for the parameters value. When designing our intent system, we decided to start at this most specific level and considered the models that should be used for and directly map to the targets.

Evaluating the targets of which our network consisted as well as industry standards it was found that a common management paradigm of NETCONF and YANG models was applicable. We considered attempting to create a unique device model and then create adapters to various vendor targets, but instead opted to support the existing YANG models both to simplify the overall system and because historically, in our experience, least common denominator (LCD) or common models tend not to be complete or successful long term. Simply put, models already existed, and we saw no justification to not use them.

2.2. YANG to Kubernetes

Kubernetes operates on a set of resource definitions, or models, defined using open schema, known as the Kubernetes resource model (KRM). The first step in supporting the existing YANG models in Kubernetes was translating the YANG models into the KRM. Extending the KRM in this way is referred to as extending Kubernetes with custom resource definitions (CRD) and involves not only creating the schema model, but also developing a controller to provide the behavior or implementation behind the model.

KRM schema is defined using Open API Schema [5] specification and so we built a tool that produced Kubernetes compatible CRDs from YANG source models. These models could then be imported into Kubernetes and instances of these models could be created.

2.3. Model to Target Association

Leveraging the existing YANG models exposed a situation which was not originally considered, and is not common in existing Kubernetes models. Under a NETCONF/YANG configuration model, multiple, independent models are applied to a single target under control (TUC), where each associated model represents a unique configuration intent. In Kubernetes it is typical that a TUC and its configuration model are a single manifest or model definition. To account for this new associative model, we separated the definition of the TUC and the intent models into separate resource definitions with a reference from the models to the TUC to which they are applied, as depicted in Figure 1. By defining the association from the model to the TUC, the solution provides support for multiple models and allows associated models to be added or removed without having to update the TUC directly. Using Kubernetes's label selector pattern to associated models to TUCs was briefly considered, but discarded as this pattern tends to implement a 1:N relationship, while in a network environment a specific model instance is typically not applied to multiple TUCs, and thus only a 1:1 relationship was required.

It was determined that the model instance that represented a TUC would include the information required to provide connectivity to the target and the models to be applied to the TUC would reference the target via an "annotation" as described by the Kubernetes models [4].

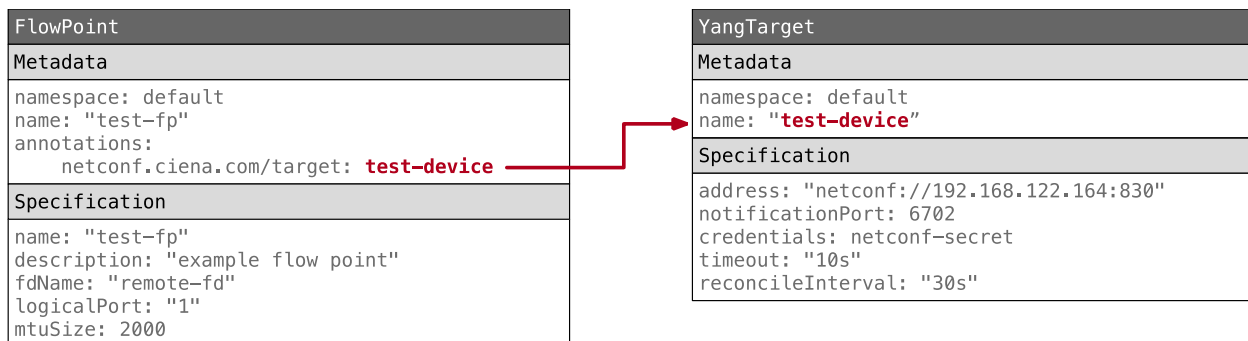

Figure 1 - Example Model to Target Relationship

2.4. Single Operator / Controller

In Kubernetes it is common that a single CRD is controlled by a unique controller that interprets the model changes and realizes them in the TUC, such as creating a Pod based on the Pod resource definition. When leveraging YANG as a CRD, if a unique controller was associated with each YANG model it would mean each model would require a controller and each of these controllers would have near 100% code overlap.

<working>

An additional goal was to allow YANG models to be added into the system without requiring the addition of more code, i.e., a new controller or the modification of an existing controller. This would allow individuals that were not “programmers” to more easily augment the system to support new models. This goal, coupled with the realization that most YANG controllers would have near complete code overlap, drove our decision to build a single controller that could provide the behavior for all YANG models. It was felt that this approach would be more sustainable as well as allow for dynamic model additions. Using this approach meant an individual could execute a tool that would generate a CRD schema from the YANG model and then add the new model into the Kubernetes environment with a simple command line action, as depicted in Figure 2. This capability also could be used in conjunction with the ability to query YANG schema from the TUCs to directly pull and add the models supported by a TUC into the system at runtime.

```
$ yang-to-crd -I /path/to/models ./new-model.yang | kubectl apply -f -  
customresourcedefinition.apiextensions.k8s.io/new-model.company.com created
```

Figure 2 - Sample command to add YANG model into system

During implementation, it was discovered that some YANG models had attributes that duplicate names already common to the KRM, such as name. We originally planned to eliminate this repetition to simplify usage of the model, but this led to the need to have custom mappings from existing KRM attributes, such as name, to YANG specific attributes, such as name or fdName. This quickly led to model specific behavior in the operator / controller or external metadata that represented that mapping that could not be automatically generated. Both these scenarios meant a more complex procedure to enable dynamic additions of YANG models at runtime. This path was abandoned, and it was determined that there should be a separation of the KRM object information, represented as Kubernetes metadata, i.e., Name, Namespace, and Labels, from the models which represented the TUC configuration, i.e., the YANG model.

Following this pattern of separation meant that we could provide a generic translation from the specification portion of the CRD to a NETCONF/YANG request, but also meant that there is some repetition between the Kubernetes metadata and the specification. It was determined that this tradeoff was worth being able to provide a generic translation capability, which additionally allows the system to dynamically add new YANG models without recompiling existing controller code, creating a customized controller per YANG model, or accommodating a manually generated mapping via metadata.

During the implementation of the portion of the controller that generates NETCONF/YANG requests from the CRD model, it was discovered that some level of YANG model specifics needed to be included and could not be avoided. To avoid embedding specifics into the operator / controller, patterns were determined and an additional CRD was developed to specify how these patterns applied to the CRD representation of a YANG model. This CRD, named YangMetadata, allows for the specifics such as key fields, YANG module information, and model XML namespace information to be specified externally and used to drive the translation of a CRD specified model to a NETCONF/YANG request. An example of a YangMetadata instance is depicted in Figure 3. It is important to note that the information contained in the YangMetadata resource relates only to the mechanics of translating one model to the other and does not involve mapping KRM attributes to YANG model attributes.

YangMetadata	YangMetadata
Metadata	Metadata
namespace: default name: "fp-metadata"	namespace: default name: "interface-metadata"
Specification	Specification
reference: kind: Fp group: netconf.ciena.com apiVersion: netconf.ciena.com/v1alpha1 wrapper: xmlRequestName: "fps" xmlName: "fp" keyField: "name" module: "ciena-mef-fp.yang" moduleSearchPath: "yang"	reference: kind: Interface group: netconf.ciena.com apiVersion: netconf.ciena.com/v1alpha1 wrapper: xmlRequestName: "interfaces" xmlName: "interface" keyField: "name" module: "openconfig-interfaces-ciena.yang" moduleSearchPath: "yang" augmentor: config.type: "xmlns=http://ciena.com/ns/yang/ciena-openconfig-interfaces" config.underlayBinding: "xmlns=http://ciena.com/ns/yang/ciena-underlay-binding" ipv4: "xmlns=http://ciena.com/ns/yang/ciena-openconfig-if-ip"

Figure 3 - YangMetadata Instance Examples

By externalizing the patterns required for special handling of the translations, the reconciling model controller maintains its independence from any specific model and allows models to be dynamically added to the system.

It is possible that there is overlap between the YANG models supported by a single TUC, i.e., two different YANG models can be used to manage a single TUC attribute. While this is acknowledged as a possible issue, in the system being described, the user controls which models are applied to which TUCs and, as such, this overlap can manually be avoided at present. As the implementation progresses some level of precedence may need to be introduced into the model structure to deterministically process model overlap.

3. Reconciling Model Controller

Kubernetes functions as a set of models that are reconciled by a set of controllers that perform operations when model instances or observed states change. The controllers can act on both virtual and physical resources. For example, when an instance of a standard Kubernetes [virtual] resource named Deployment is created, it creates another standard Kubernetes [virtual] resource named ReplicaSet. The ReplicaSet in turn creates Pod [virtual] resources, which are then physically realized on a compute capability as set of container instances. If an operator modifies the intent, as specified by the Deployment resource, the changes are propagated by the controllers through the ReplicaSet, Pods, and containers. If the status of the container changes, the status is propagated from the container, through the Pods, ReplicaSet, and Deployment.

As state and status are propagated the controllers can modify the resources that exist. For example, if the operator changes the value of the replicas property on the Deployment, this changes value replicas on the ReplicaSet, which in turn determines how many Pod instances are created. If a container fails, then this status is propagated to the Pod resource where the Pod's status is updated. This status is then propagated to the ReplicaSet controller, which in turn may delete the failed Pod and create a new Pod instance.

This behavioral model has been implemented as part of our solution. When the resource instances that represent a YANG model are applied to a TUC, the solution's controller converts the model from the CRD representation to a NETCONF/XML edit request to the TUC. The controller is also watching for asynchronous change notifications from the TUC so that if the TUC's configuration is changed the controller will receive a notification and reconcile the desired state, as represented as the Kubernetes resources, back down to the TUC. This reconciling control loop, depicted in Figure 4, ensures that the system continually maintains the operator's desired state.

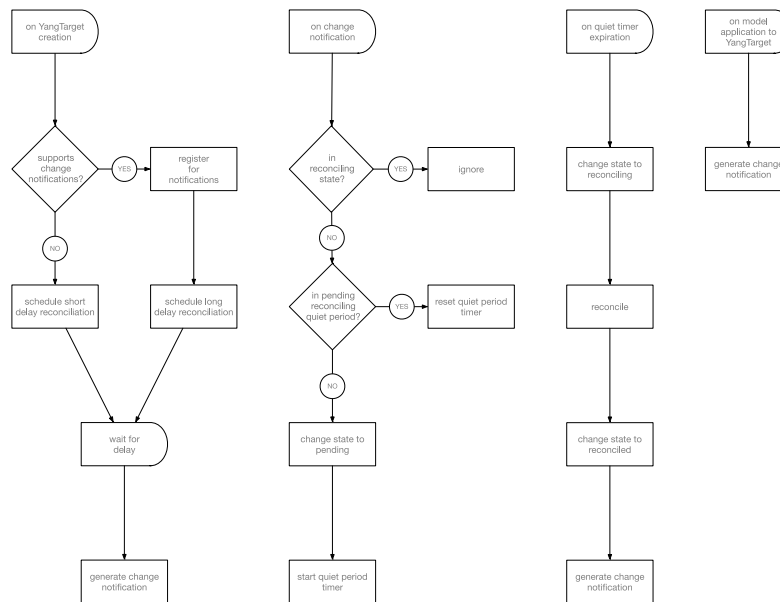

Figure 4 - Reconciliation Behavior

The difference of a TUC's observed or actual state from the desired state is known as drift. When a TUC supports asynchronous change notification the system utilizes that capability to optimize drift detection, using the change notification as an indication of drift. For TUCs that don't support asynchronous change notification, a periodic poll and drift determination is used.

A further optimization is the implementation of a quiet period. Experience demonstrated that changes to a device typically come in rapid succession and thus attempting a reconcile on every change is compute intensive and not efficient. To optimize for this situation, a quiet period is used so that reconciliation will not proceed until no change for a given TUC is detected within this quiet period. This mechanism has the effect of squelching changes to minimize reconciliation without compromising the time it takes to complete the reconciliation.

3.1. Order of Operation and Eventual Consistency

When configuring a TUC using traditional mechanisms or manual manipulation (CLI), order of operations can be important. This is due to dependencies between objects. If object A references B and then A cannot be created until B is created. Management systems, including orchestrators, often are designed, and implemented with knowledge of these order dependencies to ensure the higher-level goals are achieved.

In a model-based reconciliation system, order of operation does not have to be considered by the operator or the implementation. Using the previous example, if an instance representing A is created before an instance representing B, the reconciling of A to the TUC will fail, but will be continually retried. Eventually the reconciling of A to the TUC will succeed because the controller will also be working to reconcile B to the TUC. At some future time, B will exist on the TUC at the time A is reconciliation is retried, thus allowing A to be created.

4. Intent

An intent is the declarative specification of a desired state at some level of abstraction, the “what”, with limited or no direction to the implementation on “how” to achieve the desired state. There is a cultural change that an organization must make as they transition to intent-based specifications. This is because today, in general, the “how” is tightly bound to the “what” in many organizations, or at least the relationship between them is commonly known and utilized for daily operations including troubleshooting. The urge to include “guidance” as part of the “what” should be resisted so that the system that realizes the intent can fully optimize across multiple requests and the available resources.

4.1. Abstract to Specific Decomposition

Because an intent is specified at a level of abstraction, it can be decomposed to a set of more specific abstractions recursively until the level of abstraction is roughly the same as the specific configuration values of a TUC.

As an example, walking into a restaurant, asking the server to provide you food, and leaving the selection of the actual meal to the server can be viewed as an intent. The server might translate that level of abstraction to something more specific as the “daily special” when they submit the order to the kitchen. The kitchen staff decomposes the “daily special” into specific dishes and sides, and so on down to specific food elements and their preparation. At each level of intent specification, a set of declarative states can be defined that represents the translation of the more abstract request to one or more increasing specific intents. This same decomposition, in the context of network resources is depicted in Figure 5.

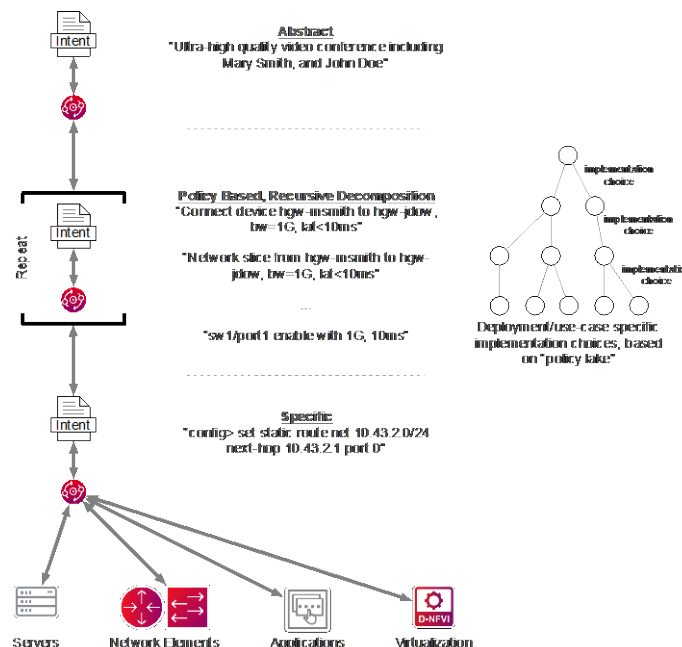

Figure 5 - Intent Decomposition Example

In the system being described, the most specific intent is represented by the YANG models that are applied to a TUC. On top of these intents increasing abstract sets of intents can be established, such as Fabric, Bridge, and Link. For each of these abstract intents there exists a controller that analyzes the intent and generates more specific intents that will realize the desired state.

As abstract intents are decomposed into a set of more specific intents decisions are made by the controller of the abstract intent with respect to how to implement the abstraction, as depicted in Figure 5. Decisions such as which more specific intents should be leveraged, i.e., VLAN or segment routing, as well as which TUCs should be considered.

How a more abstract intent is decomposed includes implementation logic that is outside the bounds of a single, “generic” controller. While a single controller manages all YANG models and their application to YangTargets, the larger system consists of multiple controllers to manage the abstract intents. This abstraction model, is common in Kubernetes for managing resources, as described in the Deployment example above and allows additional intents to be added to system at runtime as well as allows implementation up/down grades to existing abstract intents.

While we have experimented with more abstract intents, the bulk of the existing work has focused on the most specific intents, the YANG models. The abstractions we have experimented with, as a proof of concept (POC), express network fabric semantics to which end user hosts as well as intermediate network elements may be included as part of the fabric. While these POC abstractions successfully proved the point of intent decomposition, we have not formally defined a set of more abstract intents for our system

4.2. Intent Relationships

When considering decomposition, it is important to understand the relationship between the more abstract and the less abstract. In its simplest form this relationship could be considered a 1:N, creator to created relationship and is important during several lifecycle stages. For example, if resource A creates resource B, then when resource A is deleted, it is likely that resource B should be deleted. Additionally, if an attempt is made by an operator to directly delete a resource created by another resource (i.e., B), then this operation should fail because the resource that created B (i.e., A) should control the lifecycle of B. In short, when one resource creates another as part of a decomposition it has a responsibility towards the created resource’s lifecycle.

Complicating this relationship model is the fact that when dealing with network resources it is possible that more than one higher level abstraction may decompose and influence the configuration of more specific abstraction. So the relationship between an abstraction and its decomposition is not necessarily 1:N, nor a tree dependency relationship, as depicted in Figure 6(A), but could be N:N and a graph, as depicted in Figure 6(B). Thus, the relationship between intents (abstract to specific) might better be described as “interest” rather than ownership or creator to created.

Figure 6 - Abstraction / Intent Decomposition Models

With an interest relationship, the more specific intent cannot be removed until all more abstract intents are removed. At the same time, when a more abstract intent is removed, the more specific intent may be modified. Additionally, a more specific intent can be influenced by changes in more than a single more abstract intent, as such when an abstract intent changes, all “peer” abstract intents must be evaluated to determine the values of the shared, more specific intent.

While the Kubernetes framework does not prohibit the modeling of an acyclic dependency graph, it is not a common usage of the capabilities and may require special considerations when implementing such relationships. This pattern of reconciliation is not currently, to our knowledge, implemented as part of the Kubernetes framework. As this work continues, introducing this relationship will be avoided, if possible, as it significantly increases the complexity of the overall system.

One alternative to allowing an acyclic dependency graph may be to allow each more abstract intent to decompose into its own more specific intent and then predictably and consistently merge those intents when they are being applied to a single TUC.

4.3. Intent Specification and Alternative Tooling

The system being described utilizes YANG models to define the most specific intents as Kubernetes CRDs. Within this system, higher level intents can also be specified as CRDs, but can also be expressed using alternative tools including Helm [6] or Kustomize [7]. The result of these alternative methods is the generation of a set of KRM/CRD instances that represent some abstract intent. When using these alternative tools, there is no Kubernetes intrinsic relationship between the KRM/CRD resources deployed to Kubernetes and originating intent specification, i.e., Helm chart or Kustomize overlay.

As the Kubernetes operating model represents the state of the KRM, it is recommended that CRDs are used to define mature abstractions. We have found that tools such as Helm and Kustomize are valuable when prototyping abstractions, but as the abstraction matures being able to take full advantage of the KRM for implementation is advantageous and allows users to interact with the abstraction using the full ecosystem of Kubernetes based tooling.

It is important to note that while we do not recommend tools such as Helm or Kustomize for the modeling of abstract intents, other organizations may differ in opinion and nothing in the system being described prohibits from taking advantage of the full toolsets available through the Kubernetes communities.

Additionally, these tools can often be integrated into the GitOps processing pipelines, as described in section 7.

4.4. Unified Intents

Because the network intent model is built as CRD extensions to the KRM and it is instrumented via the Kubernetes controller framework, it is possible to create and deploy intents that include compute, network, and storage via a single model and toolchain. This allows infrastructure operators to define intents that are composed of these, and potentially other, resource types to ensure reconciliation across the resource domains, as depicted in Figure 7.

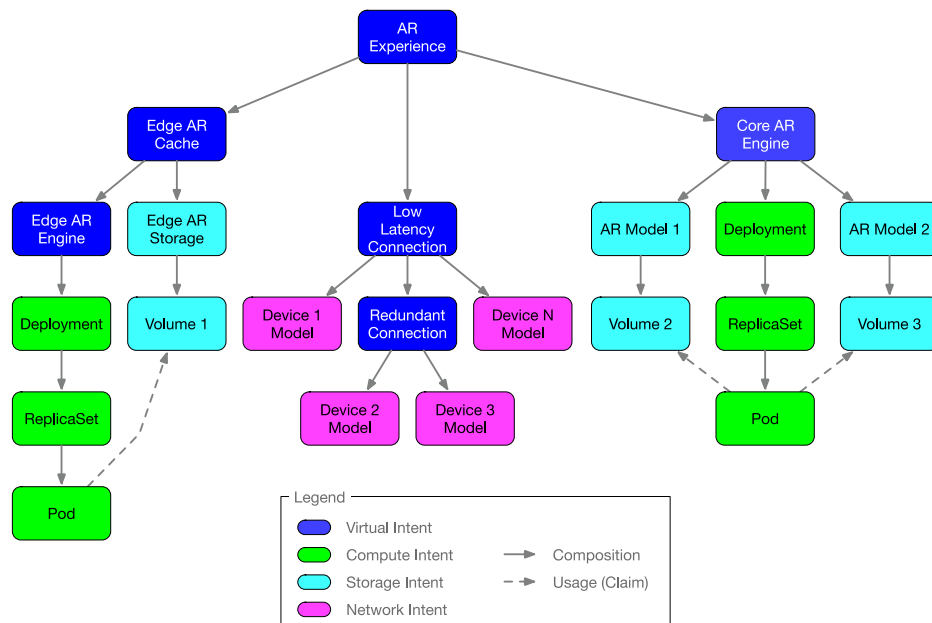

Figure 7 - Multi-Resource Domain Intent Decomposition

Again, while it is recommended that abstract intents be defined as extensions to the KRM as CRDs, this is not required, and they can be defined using many Kubernetes ecosystem tools including Helm and Kustomize. While GitOps was originally designed around the concept of directly deploying KRM resources into a cluster, many GitOps tools chains support tools like Helm and Kustomize directly so that, from the GitOps tool chain perspective, they are first class citizens. Integration of these tools into the GitOps tool chain extends the unification of the resource domains into the GitOps paradigm.

5. Reconciliation

An intent, as previously stated, declares the desired outcome, including capability and performance characteristics. To realize this outcome an intent is decomposed into more and more specific intents until the point where the intent is equivalent to a TUC configuration, including any configuration or modification to telemetry collection that is required to maintain performance characteristics of the intent. However, a TUC does not always maintain the state to which it was set. The difference between and intent's intended states and its actual or observed state is referred to as drift and can be caused by many factors, including errors, failures, or configuration change originating outside standard management practice, either intentional or malicious.

Drift in the system indicates that an intent or desired outcome is likely no longer being met, and thus, the drift must be addressed. When drift is encountered in a reconciling system, the system attempts to correct the drift in several ways, from the least disruptive to the most disruptive and from the most specific intent to the most abstract intent.

5.1. Drift

Within the system there are two types of drift which must be considered: static and constraint. Static drift (SD) is the difference between a desired configuration and the actual configuration. At the most specific intent level this can be the difference between the configuration set on a device and the device's actual configuration. In a "perfect" world SD is not encountered because all system change is driven through the control systems, but, as the world is not perfect, the control system must account for SD and when it is detected reconcile the desired state back to the actual. Reconciliation, in this context, consists of the control system resetting the TUC's configuration to the desired state.

Constraint drift (CD) is when the performance constraints specified by an intent are no longer being met even though there is no SD. CD is detected by telemetry collection and evaluation. When CD is detected the controller for the intent in which drift is detected re-evaluates how the intent can be realized and may create new more specific intents or modify/delete existing intents while attempting to eliminate CD. If a controller cannot eliminate CD, it will update the status of the intent. This status update serves as a trigger/indicator to more abstract intents that they need to be reevaluated to attempt to reconcile the CD. This process is recursive until a more abstract intent can eliminate the CD. If the CD cannot be eliminated then the status of the intents indicates the CD drift and it is up to the operator, or other controlling system to determine how to proceed.

It is important to recognize that CD may be a temporary situation, and that immediately attempting to correct for CD as soon as it is detected may not be the best action, as the effort and time to correct the CD may be more "painful" and take more time than the temporary CD might otherwise exist. For example, if the bandwidth for a connection is desired to be at 500 Mbps and CD is detected at 300 Mbps, the time it takes to reconfigure to a different path to maintain 500 Mbps may be longer than simply waiting for the CD or return to its normal operating state. This is not true in all situations, as in the case of a true failure, but can be true when the cause of the CD is a temporary "blip". Because of this, a waiting period should be observed before any correction of CD is attempted.

5.2. Drift Prediction

Drift prediction (DP) is the process of analyzing desired state, telemetry, and other sources of operation state and status to predict a future time where CD may occur. While our current implementation does not provide DP, it is believed that analysis, including AI/ML analysis, could be leveraged to calculate DP and use these predictions to re-evaluate intents before actual CD occurs, minimizing or eliminating potential issues.

6. Multiple Sites

Even in an organization where the desired state of the infrastructure, compute, network, and storage, is relatively static, the level of communication between the infrastructure TUCs and the reconciling controllers can be significant, particularly when you consider telemetry collection and CD detection. As such, it is prudent to separate an organization into domains each with their own control system. This practice can be seen in the evolution of Kubernetes with respect to workload control. In practice the

controller and the TUC should be “network close”, indicating sufficient bandwidth, connection stability, and reasonable latency.

When architecting multi-site control system, various patterns can be leveraged, such as hierarchical and peering. As our system is leveraging the Kubernetes platform, hierarchical control was a natural fit, where each site is a Kubernetes cluster and the clusters are aggregated via a multi-cluster console, such as provided by various open source and commercial products. A simple aggregation console does not address the issue of cross site intents but does allow administration of each site/cluster directly while providing a global view of a deployment.

Supporting cross site intents implies that an intent can be specified to a system such that the realization of the intent deploys and connects resources from multiple sites, while control of those resources are individually controlled by the site or Kubernetes cluster that “owns” them. To date, in our implementation we have not addressed the issue of cross site intents, but it is envisioned that a centralized Kubernetes cluster could house models and controllers that represent cross-site intents. These models, along with information about the remote clusters, could then be leveraged to implement intent-based configuration of our organization’s global infrastructure resources. As we believe our requirements and goals closely align to those of the larger Kubernetes ecosystem, we continue to monitor projects under organizations like the Cloud Native Computing Foundation (CNCF) and the Linux Foundation (LF) that consider cross-site or multi-site control architectures.

7. Source of Truth and the Pipeline

The operational source or truth (SOT) for the system being described is the model states as maintained by the Kubernetes reconciliation engine. These states can be made redundant, highly available, and persistently stored via standard Kubernetes deployment practices. These states represent the desired state toward which the system is working.

When extending the system beyond the operational state to utilize a GitOps environment, the SOT for the organization is maintained and versioned, in the git repository as a set of files that represent the desired states. In practice these states are represented as model instances formatted as YAML documents. These YAML documents, in Kubernetes parlance, are referred to as manifests. Events within the git SOT, such as the modification and commit of a manifest or the releasing (tagging) of a git repository that may contain many manifests, causes the state from the git repository to be applied to the operational system(s). At steady state, the state maintained in git and the operational state are equivalent. Figure 8 depicts a typical GitOps pipeline, including manual merge approval, automated unit testing, and multiple pre-production deployment environments.

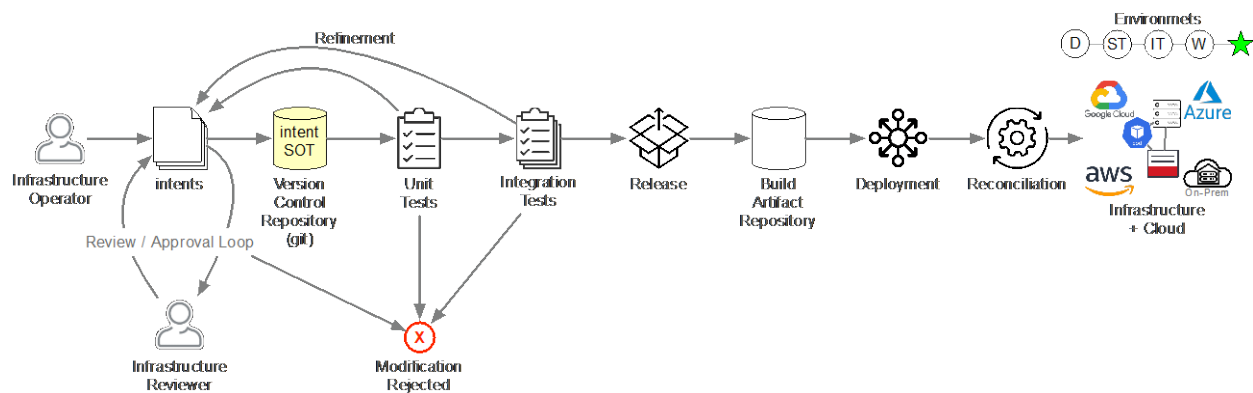

Figure 8 - Representation of GitOps Pipeline

7.1. Test and Digital Twin Environments

As part of GitOps, organizations can establish automated pipelines that verify a change in compute, storage, and network state before it is pushed into production. Minimally, this can include some basic static analysis and regression testing; but it can also include the deployment into a digital twin environment may include full system and failure tests.

The level of testing is up to the organization with the goal of not only protecting the production system from accidental configurations, but also improve the confidence that a new change will not adversely affect the capability or performance of the production system.

7.2. Rollback

Because the state of the environment (compute, storage, and networking) is maintained in a versioned repository and because the environment is controlled by a reconciling controller, it is possible to set the state of the environment back to any previous states by running the GitOps automated pipeline on a previous version of the desired state.

The pipeline will deploy the desired (previous) state to the Kubernetes reconciling control plane and the controllers within the Kubernetes control environment will reconcile the desired (previous) state to the actual state on the TUCs. Thus, rollback becomes the process of identifying the version of the desired state and executing the automated process pipeline, changing rollback from an anomaly in the environment to a normal process that is not to be feared.

7.3. Kubernetes Drift from Git

GitOps solutions do not typically monitor Kubernetes deployments for change or attempt to determine drift between the Git SOT and the operational SOT in Kubernetes. This is because it can be expensive and it is not required because of the Kubernetes reconciliation model.

When a state is applied to a Kubernetes control plane it compares values in the new state to values in the current operational state. If the values are equivalent, then no action is taken, and the application of the state is essentially a no-op. If the values are different, then the associated controllers are invoked, and the updated state is reconciled and propagated throughout the system.

This operational state allows GitOps solutions to simply reapply existing state multiple times with little computational consequence, rendering drift detection between git and Kubernetes unnecessary. Instead,

the GitOps systems re-apply the desired states at a [configurable] interval. Thus, git and Kubernetes are kept synchronized within the time error of this period.

7.4. Lockdown

A key aspect to any controlled environment is to minimize the ability of individuals to introduce unauthorized SD into the system. All changes to the TUCs **must** be handled through the GitOps pipeline, for normal operations as well as in times to failures.

This operational change is another instance of culture change an organization should be willing to accept before moving to GitOps management of their environment. While it may seem counter intuitive to force operators to drive changes through the GitOps pipeline in the presence of a customer affecting failure it is also, precisely at these times when extra care should be taken to remediate the problem to prevent a proposed remediation from exasperating the original issue and consequences.

While exceptions to this rule may be natural to consider, such as when the GitOps pipeline can no longer communicate to the Kubernetes control plane, it is recommended that this communication error between GitOps and Kubernetes be resolved first and then proceed through the GitOps process. One risk of not following this pattern and directly manipulating the configuration of the Kubernetes control plane or the TUCs is that when connectivity is restored, the GitOps pipeline will reconcile its version of the SOT, through the Kubernetes control plane, down to the TUCs, overwriting any direct manual change made and potentially reproduce the original problem.

7.5. Two Sets of Eyes

GitOps evolved from the software development practices related to continuous integration and continuous deployment (CI/CD). One of these practices is related to how code becomes accepted as part of the production code for a project. In this model, a developer develops some code and submits that code to be merged into the production code. Before the code is accepted, or merged, into production product, automated tests are run with the code and an individual with authority must review and approve of the code change. Within some projects, multiple people must review the code and the code is not accepted until a given number those individuals agree and approve of the code change.

With GitOps as part of infrastructure management, this process should be adopted. The equivalent of code when using GitOps for infrastructure management is an intent specification. When an operator makes a change to the desired intent state, this is submitted to the Git repository for automated testing, review, and approval. Only when the change is approved is it merged as part of the production SOT in Git and propagated to the Kubernetes control plane to be deployed in the production environment.

7.6. Cultural Change

GitOps, as previously defined is meant to provide a continuous, controlled, predictable, and stable change process while maintaining the highest level of correctness in the system. Before GitOps can successfully be deployed in an organization the wild west must be sacrificed as must the lone hero. Change process is controlled. Changes are automatically verified and reviewed regardless of the source. Even in the face of customer outages the process is followed. This can be a difficult pattern to follow and enforce when dealing with software development projects as many developers will attest. This can be even more challenging when attempting to apply this to infrastructure management.

8. Conclusions

A reconciling control plane is an effective control model for network elements and the service across those network elements. When the control plane used for network connectivity can be shared, as is the case with a Kubernetes control plane, the paradigm becomes even more powerful for infrastructure and infrastructure service control.

Adopting the culture and best practices from GitOps adds benefit on top of the core reconciling control plane and can lead to a more predictable and stable infrastructure change model. With the additions of manual review and automated checks in the GitOps pipeline, as well as system wide pre-deployment test in alternate environments, including digital twins, the incidence of misconfiguration can be minimized.

By introducing abstract intents into the system, the operators are allowed to specify the goals of the system while automated control loops optimize the implementation. It is important with the introduction of intents that the ability to troubleshoot in the context of explicit configuration be supported, including the ability to map from the explicit device configuration back to the intent or intents from which it was derived and why it was derived.

Kubernetes was a good choice for a system as described. It provided much of the “context” required for such a system, the ability to unify control across resource domains (compute, storage, and network), and provided opinionated processes for the definition of models and controllers. This opinionated process allowed most questions about the implementation of the system to be answered based on existing precedent and allowed the development to focus on those aspects that were unique to the solution.

When introducing a system as described into an enterprise it is important that the organization should feel empowered to extend the service intent model in ways that best meet their needs. This includes the development of new or organization specific CRDs that model required services. This is not an “out of the box solution” and an organization should expect and train their employees to be infrastructure model and control developers or rely on 3rd party product and support.

8.1. Future Work

8.1.1. *Abstract Intents*

As previous stated, the existing implementation has focused on the most specific intents. Work has started on developing more abstract intents. This work needs to continue in cooperation with the organization’s IT services groups so that the set of intents instrumented match the infrastructure services offered.

It is expected that as more abstract intents are developed issues may arise with decisions previously made and those decisions may have to be revisited. It is a guiding principle of this work to avoid complexity where possible, even at the cost of operational usability. It is believed that by keeping the underlying technology as simply as possible that the result will be a more stable system. It is also believed that operational usability can be managed through user interaction methods that implemented best practices or common usage patterns.

8.1.2. *Troubleshooting*

As this system evolves, the team will be investigating how to integrate better troubleshooting, performance monitoring, and predictive techniques. Being able to provide human consumable explanations as to why a system took a specific action or reevaluated an intent can be valuable when

understanding failures as well as it could provide a bases for an automated feedback system to the consumers of the services.

8.1.3. Multi-site Intents

Another area of exploration will be cross-site or multi-site intents and the comparison of a hierarchical solution vs. a peer-based solution. While we will heavily leverage the direction and learnings of the CNCF, there may be something unique with respect to network connectivity and decentralized environments that points us in a different direction. When controlling connectivity, the inter-site connections are as, if not more, important than the intra-site connections. Understanding that, for connectivity, the problem being addressed is not simply distribution of workloads across a decentralized environment. Site inter-connects are imported and must influence how workloads and storage are placed or replicated to optimize the connectivity to meet the desired performance and failure characteristics.

9. Acknowledgements

The author of this paper would like to acknowledge the efforts of Karthick Ramanarayanan and Himani Chawla for their contributions to both the design and implementation of the model-based reconciliation controller. Without their continued hard work this project might not have come to fruition.

The team would also like to show his appreciation to their manager, Marco Naveda, and their peers in the organization for their support, input, and suggestions. While they are not listed as authors on this paper, without their support it would not have been written.

1. Introduction

Comcast has deployed DOCSIS[®] 3.1 (D3.1) orthogonal frequency division multiple access (OFDMA) in the mid-split (MS) and high-split (HS) bands of the upstream (US) spectrum on our virtual cable modem termination system (vCMTS) platform. D3.1 OFDMA allows higher modulation levels with up to 2x efficiency increases, with 2048-QAM today and anticipating 4096-QAM in the near future, compared to single carrier-quadrature amplitude modulation (SC-QAM) of 64-QAM. More importantly, D3.1 US technology allows configuring the modulation per 400 KHz mini-slot, enabling adaptation to the ingress and distortions discovered in the network. Several ingress and impairment sources that have the potential to degrade capacity and customer experience have been identified; examples include off-air very high frequency (VHF) broadcast, linear distortions, in-home analog TV modulators, frequency modulation (FM) radio, NOAA weather radios, and pre-equalization stability. As we deployed OFDMA initially on the network we quickly realized that in order to take full advantage of the capabilities OFDMA has to offer, most notably delivery of hundreds of Mbps US product speeds, a profile management application (PMA) system is required similar in concept to the one deployed downstream for managing orthogonal frequency division multiplexing (OFDM) profiles, which we reported on in previous SCTE contributions [1-4]. This paper presents the initial results from adapting the OFDM PMA system for OFDMA and testing in both lab systems and production field deployments. We share some examples of spectrum impairments, characterization methods, our thinking around how profiles are constructed based on device-level MER measurements, and the validation of the profiles against the vCMTS internal PMA function. We also comment on some of the intricacies of expanding upstream spectrum that warrant revisiting the core algorithm in the future.

2. The Upstream Split Change Evolution

DOCSIS-based broadband access has historically been operated with lower upstream capacity capabilities due to the amount of spectrum available in traditional splits of the 42 MHz low-split (also known as sub-split), 85 MHz MS, 204 MHz HS, as well as the upcoming full-duplex (FDX) with adjustable upstream and downstream spectrum usage, including simultaneous spectrum overlap. Today many hybrid-fiber-coax (HFC) networks still operate with a low-split configuration as shown in Figure 1 and are limited to upstream speeds under 100 Mbps.

As operators migrate to an 85 MHz upstream MS spectrum band as shown in Figure 2, they can offer increased product speeds, for example 300 Mbps, and with a 204 MHz HS spectrum band, 1 Gbps upstream products are possible. While updating the network to one of these upstream split scenarios, downstream spectrum may also be expanded to include up to 1 or 1.2 GHz of spectrum. This spectrum update allows additional downstream data capacity. Managing this spectrum is the topic of another Comcast 2022 Technical Forum Paper focused on delivery of multi-Gbps DS services [5]. Ensuring the quality and speeds of this new US spectrum requires using D3.1 OFDMA technology, which is designed to adapt to network conditions to maximize capacity and robustness based on the same platform described in prior SCTE papers on the Comcast PMA solution [1-4].

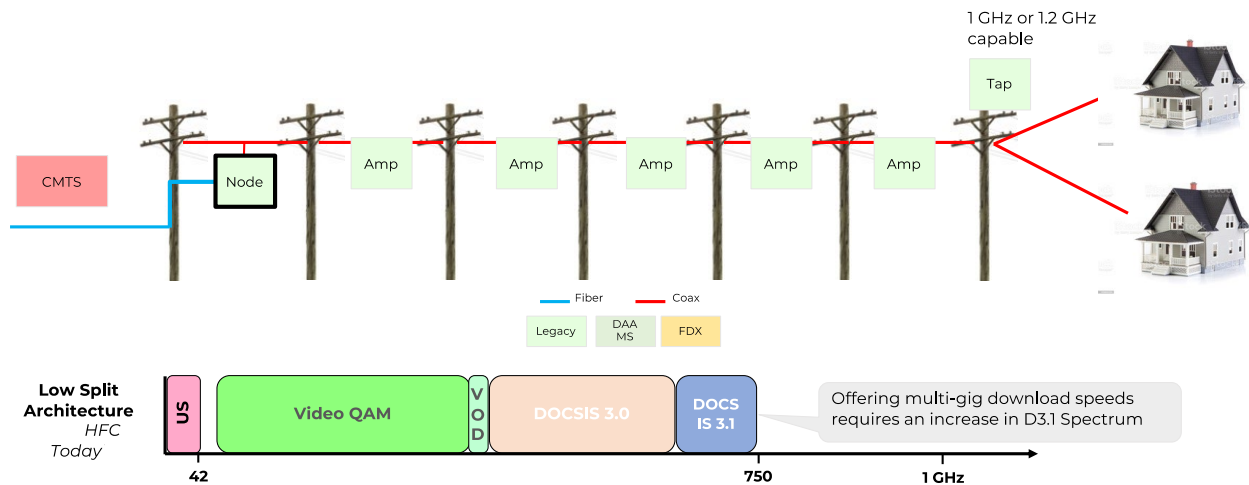

Figure 1. Yesterday's low-split (sub-split) network utilizes mostly 750 MHz analog fiber coax network, with typically Node +6 Amps or less.

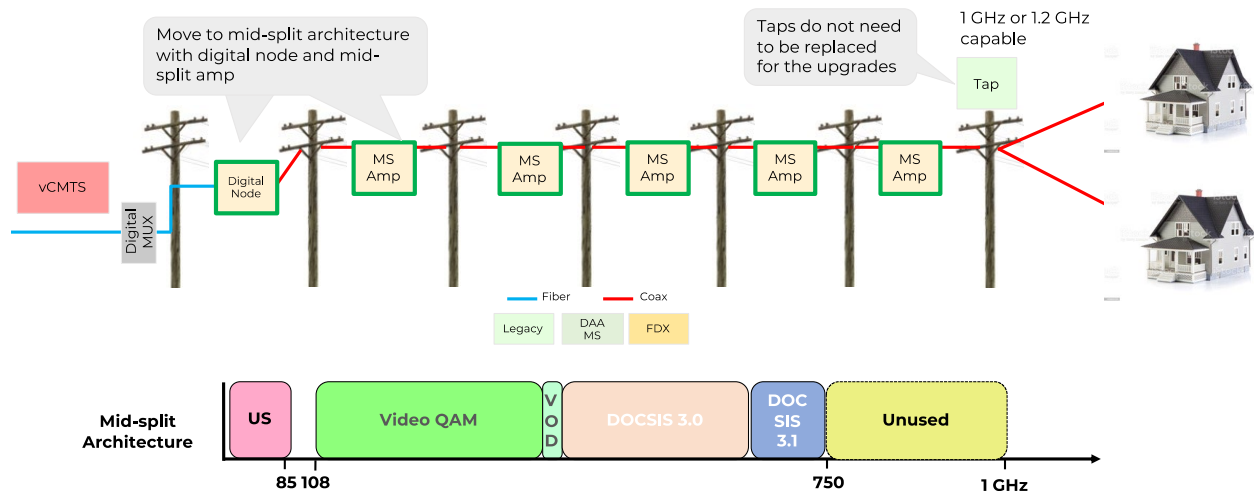

Figure 2. Mid-Split expanded upstream using D3.1, increasing capacity by >4x and enabling speeds up to 300 Mbps; overall network spectrum is extended to 1 GHz enabling multi-Gbps downstream speeds.

3. OFDMA Capacity Analytics

Deploying OFDMA in the mid-split spectrum increases capacity >4x compared to low-split pre-OFDMA US channel plans. During the COVID outbreak and the increase in bandwidth growth, particularly in the upstream direction, Comcast deployed six upstream channels and a PMA solution for D3.0 upstream channels to manage performance and rapidly add new capacity [2-3]. When deploying OFDMA spectrum on the nodes with high utilization and reducing the number of D3.0 channels, the resulting capacity needed to be equal to or greater bonded capacity than the six D3.0 channels in addition to enabling higher upstream product speeds. As a result, Comcast developed capacity analytics to understand in detail how the evolution to OFDMA would impact network performance from a capacity perspective.

It is instructive first to understand how this new capacity is provisioned to enable hundreds of Mbps product speeds. As shown in Figure 3 the channel plan was migrated from 6 US D3.0 channels to 4 D3.0 channels plus a single OFDMA channel. The blue line in the example node shows that the capacity of the 4 D3.0 channels is about 85 Mbps. This is less D3.0 capacity than the black line in the chart, which represents 100 to 120 Mbps of capacity available with the 6 US D3.0 channel lineup. As a result, Comcast needed to ensure that when we added the OFDMA capacity, enough traffic could be shifted into the OFDMA channel such that the net result would be equal or greater capacity available to the cable modem (CM) population on average. When the vCMTS bonds the D3.0 and D3.1 capacity for the D3.1 CMs in the service group (SG), it was possible – as depicted by the green line – to exceed 500 Mbps with the right PMA solution and network quality.

Depending on how the traffic is allocated across the channels, we are introducing a new metric known as “effective capacity” or “aggregate_speed” (yellow line in Fig. 3), which is the traffic-weighted capacity of the service group. This is a function of the amount of traffic enabled on the D3.1 OFDMA spectrum vs. the D3.0 spectrum along with the total capacity in the D3.0 and D3.1 channels based on the profile management solution optimization of the channels. Both the traffic allocation and the capacity of the channels change over time, based respectively on bandwidth demand and network quality. If the yellow line drops below the black line the goal of exceeding the D3.0 capacity when adding OFDMA is not met for that node and unit of time. This chart is one example node with 24% of the D3.1 modems able to access the OFDMA channel.

Figure 3. DOCSIS upstream capacities for the mid-split scenario. Total effective capacity is a function of PMA for OFDMA based on signal and noise quality, D3.1 penetration, and traffic, and consumption statistics.

The data of Figure 3 can be aggregated to the network level across a set of remote PHY device (RPD) Distributed Access Architecture (DAA) nodes. This aggregation for hundreds of nodes is illustrated in Figure 4 with the following key points:

- >1000 RPDs are mid-split activated (panel 1).
- ~20% of devices are OFDMA active with the potential to increase by > 10% as our in-home test solution [6-7] migrates each home to use of the OFDMA channel (panel 2).
- ~17% of traffic goes through the OFDMA channel on average; this is sufficient to increase the net effective capacity above the capacity of the full spectrum D3.0 (panel 3).

- Current traffic-weighted effective capacity (yellow) is higher than projected throughput if D3.0 spectrum was configured with 5th and 6th channels (i.e., the legacy six channel configuration shown as black line in panel 6).
- The consumption of individual customers on smaller nodes can influence the results such as a heavy consumer with a D3.1 vs. D3.0 CM.
- The abrupt increase in OFDM capacity (red line) represents the switch from 32-QAM to 256-QAM. As PMA is added and higher order modulations are included, as detailed in this paper, the net effective capacity will further increase (panel 6).
- 200 Mbps speed test passes > 98% of time with only 256 QAM.

Figure 4. Critical mid-split set of performance and capacity statistics.

While aggregating across all RPD nodes, the net effective capacity is positive at only 256-QAM flat modulation configured in the OFDMA channel. There may be specific nodes that fall below the break-even line due to challenges in CM's connection to the OFDMA channel, or due to the low penetration of

D3.1 modems along with the utilization of the D3.0 vs. the D3.1 spectrum.

Figure 5 illustrates how at the above OFDMA configuration, and without migrating the traffic reliably to OFDMA, the effective capacity could fall below the break-even line for D3.0 spectrum. Fortunately, for ~20k nodes in this analysis, only 1 is projected to have D3.0 utilization go above alert level without gaining benefit from OFDMA due to low D3.1 penetration as shown in Figure 6. Increasing the OFDMA capacity with the use of PMA, as illustrated in Figure 5 moves the modems all above the break-even line, as will the organic increase of the D3.1 relative CM population.

Figure 5. Effective capacity correlated to OFDMA-to-D3.0 SC-QAM traffic ratio. Enabling PMA is expected to lift most nodes above the break-even line.

Figure 6. Utilization and D3.1 cable modem penetration for ~20,000 to-be-converted analog nodes. The intersection of the 2 tails of the distributions reveals that only 1 node will be driven into alert level due to loss of the 5th and 6th SC-QAM channels to accommodate OFDMA in the mid-split.

4. Mid-Split Deployment Data

OFDMA deployment in mid-split spectrum results in increased capacity and higher upstream speeds for D3.1 customers. It is critical to track and manage consumption and traffic from a capacity analytics standpoint to ensure that there are no capacity constraints driven by change in customer behavior and that spectrum utilization is within the normal operational range. There are additional factors like operator-initiated speed tests to check OFDMA connectivity and available speeds that could be adding additional consumption that need to be accounted for in this analysis.

In our tests, speed increase analysis was based on capturing the 98th percentile traffic and utilization for OFDMA and SC-QAM interfaces at a digital node and PPOD level for the test group (OFDMA-enabled and speed tier increases) and the control group (OFDMA-enabled and no speed tier increases) over a period of 3 months. For calculating traffic (consumption), the speed test-driven traffic was subtracted from the total per subscriber traffic. Pre and post-speed tier upgrade traffic was compared to assess the impact of the speed tier increase between test and control group.

As noted in

Figure 7. SC-QAM and OFDMA 98th utilization and traffic (Mbps). The vertical line in all panels marks the timestamp of the speed increases. The top row tracks the traffic on OFDMA (left) and SC-QAM channels (right) for test group (blue lines) and control groups (green and red lines). The bottom row tracks the utilization on OFDMA (left) and SC-QAM channels (right) for test group (blue lines) and control groups (green and red lines).

analysis of OFDMA utilization and traffic post-speed increase in one deployment area, there were no notable increases in both utilization and traffic for the test group as noted by the blue trend line.

Additionally, SC-QAM traffic and utilization dropped for the test group (as noted by blue line) due to customers utilizing available OFDMA capacity.

Analysis of test and control groups showed that consumption per device post-speed increase saw a marginal increase of up to ~20%, as noted in

Figure 8. Per device (CM) total consumption for the 3 groups pre and post speed increase.

. Additional speed increases within the mid-split spectrum can absorb customers' increased consumption; overall traffic (SC-QAM and OFDMA) utilizations are within the current utilization trend.

With additional capacity gains due to OFDMA enablement, speed increases are not resulting in increased utilization.

Figure 7. SC-QAM and OFDMA 98th utilization and traffic (Mbps). The vertical line in all panels marks the timestamp of the speed increases. The top row tracks the traffic on OFDMA (left) and SC-QAM channels (right) for test group (blue lines) and control groups (green and red lines). The bottom row tracks the utilization on OFDMA (left) and SC-QAM channels (right) for test group (blue lines) and control groups (green and red lines).

Figure 8. Per device (CM) total consumption for the 3 groups pre and post speed increase.

5. PMA for OFDMA

5.1. Why PMA for OFDMA

In addition to needing the capacity for bandwidth growth, and for higher product speeds, OFDMA managed through a PMA solution can significantly improve customer experiences, as we have discovered with OFDM in the downstream and D3.0 US profile management. During initial OFDMA deployments several challenging network impairments and distortions limited the capacity of the OFDMA channel without a PMA solution. In some cases, the ingress sources coupling into the network were so severe that modems were challenged even to connect to OFDMA and a more robust modulation was required for interval usage code (IUC) 13, which CMs use to try and perform initial ranging on the OFDMA channel. Several examples are shown here along with some analytics of different impairments discussed later in section 6 (mid-split ingress).

Figure 9 illustrates ingress from a very high-powered VHF transmitter that was impacting a variety of nodes. As can be seen, the lower VHF channels 2 and 6 are both coupled into the upstream at very high levels through loose connectors or damaged cables. During this initial deployment, a 256-QAM flat modulation profile was tested on the OFDMA channel. At the receiver, the spectrum analyzer showed noise at a level that would have required a flat 32-QAM, or even more robust configuration, to allow the modems to range on the OFDMA channel. As a result of this impressive ingress, Comcast did some of the network analytics detailed in section 6.1 (VHF TV Ingress) to identify the probabilities of this type of ingress impacting the wider network. Delivering the higher speed services cannot be done in the presence of this type of ingress without an OFDMA PMA solution.

Figure 9: Lower VHF ingress into mid-split channel would have required 32-QAM or lower modulation without PMA solution.

Figure 10 illustrates a second example of why PMA is required to achieve Gbps symmetrical speeds. This node had loose connections or cracks in the cable near three ingress sources:

- 1) An upper VHF spectrum transmitter with channels 9 & 10;
- 2) A NOAA weather radio transmitter, that although narrow, needed to be properly managed by PMA; and
- 3) FM radio ingress between 88 & 108 MHz.

The lower channel in the high-split node is stopped at 85 MHz primarily to enable mid-split capable CMs on this node to achieve the hundreds of Mbps speeds as these CMs cannot bond to a channel above their capabilities while the HS capable modems can bond to all of the spectrum. While not intended or preferred for capacity reasons, this does avoid the FM radio band which can impact HS node performance. Technology development is happening currently to allow a mid-split modem to use an OFDMA channel that extends above 85 MHz while only being scheduled in minislots below 85 MHz with appropriate upstream channel descriptors.

If a channel is deployed across the FM spectrum, it is clear that a PMA solution would be required while remediating the network. The right chart in Figure 11 shows the PMA response to this ingress. The modulation levels of the OFDMA profile are tailored around the spectrum and shown as yellow segments. The modulation in the minislot containing the NOAA radio needed to be modulated at QPSK to avoid using error correction capabilities to resolve it. Note that most of the spectrum is modulated at 2048-QAM with the future option of 4096-QAM (when the feature is available on the vCMTS platform). Without a PMA solution to manage the capacity, this node would not have been capable of delivering 1 Gbps upstream speeds.

Figure 10: (right panel) Example high-split spectrum capture showing upper VHF and NOAA radio ingress. Mid-split channel has excellent signal quality. (left panel) PMA constructed profile for the high-split channel.

5.2. PMA Virtual Network Functions Development Starts and Ends in the Ingress Lab

In addition to the analytics of field data, a critical component of developing a PMA solution for OFDMA is the ability to recreate ingress from the field within the lab as a test vector for the PMA algorithm. In the example shown in Figure 12 the VHF ingress in Denver is measured at a Comcast lab, injected into a software defined radio (SDR) platform, and played back into the lab node. The OFDMA IUC or modulation profile design of the algorithm is then evaluated to verify that it resolved the packet loss and automatically configured on the lab vCMTS. This SDR platform is also capable of converting MER per subcarrier or per minislot into a signal that simulates the ingress in the field that would have caused that MER profile. The OFDMA is run periodically in the continuous integration and continuous deployment (CICD) environment to ensure that all the test vectors are well managed as vCMTS, CM, or PMA software is evolved.

Figure 11. Lab testing flow. VHF Ingress is captured (left panel) and injected into the node using SDR platform (top right panel). PMA adjusts to the ingress by constructing the proper modulation profile (bottom right panel).

5.3. OFDMA PMA Comes Together

The PMA base platform has been described in several previous papers [2-5]. Figure 13 describes the base platform including 3 primary components: the configuration manager which automates the instantiation of

new IUC/profile configurations; the analytics engine which recommends changes to configuration; and the data engine that collects the real time streaming OFMDA telemetry and makes it available for the PMA solution along with other proactive network maintenance (PNM) tools used to direct fix agents that remediate the network. Building on this same existing platform for OFDM has dramatically accelerated the time-to-market for the OFDMA solution.

Figure 12. PMA architecture supports DS and US D3.1 and US D3.0 profile management.

Several examples of OFDMA support the platform descriptions in the previous papers are referenced in this paper. Figure 14 shows an example of a fairly consistent MER signature for a node in which most of the spectrum could support 2048-QAM except for a small region. Each modem MER per minislot is aggregated over several days of 5-min samples with statistics such as the 10th percentile calculated as representative of the minislot-aggregated MER value. In this example, a cable modem, labeled as “Device 9” was having some attenuation issues and could not operate with this IUC configuration, so a second configuration (row 2, column 1) was configured by PMA, along with a third to cover “Device 4” that was experiencing another drop in MER (row 1, column 4).

The PMA analytics engine compiles this data for each cable modem, clusters them into similar performance groups, and then sends a set of recommended configurations to the configuration manager. The configuration manager then schedules and automatically implements the new configuration along with pre- and post-checks and change management tickets (auto-open & close) with transactional integrity.

Figure 13. Example PMA IUC/profile design across mid-split spectrum that improves the channel capacity compared to adopting a “flat modulation” IUC design.

Figure 15 shows a HS channel with a single CM from one of the first HS trials. 7 IUC profiles were constructed by PMA, but only 1 was required for the HS modem. This is the same case shown at a different time for the spectrum analysis shown in Figure 10. This is a recommendation that was updated as the level of the ingress varied over time while the channel was being dynamically managed by PMA.

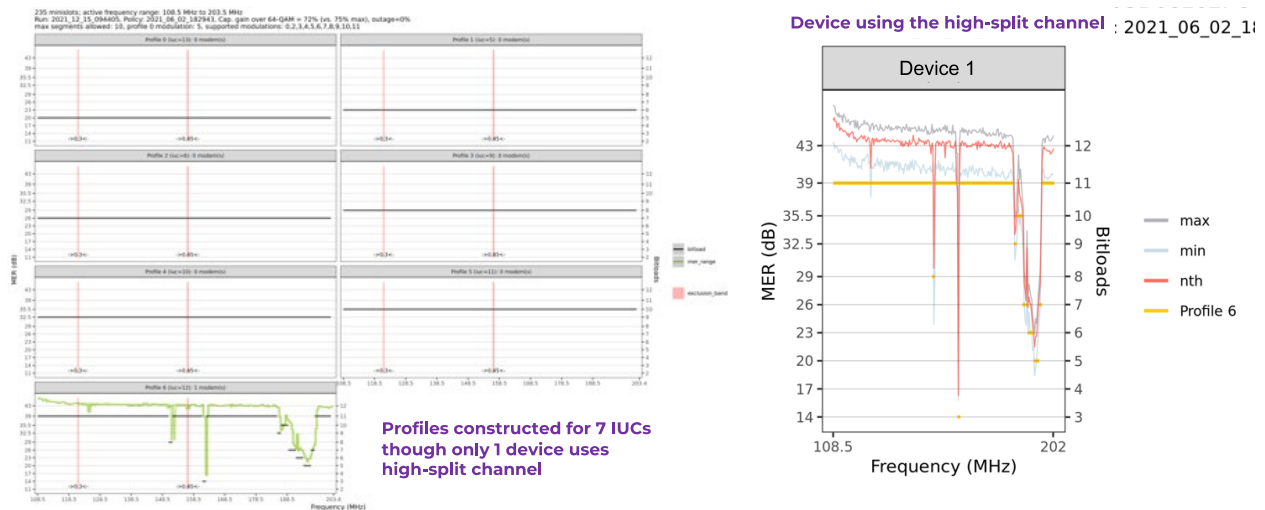

Figure 14. Example PMA design for the high-split channel in Figure 10. Left panel shows the 7 constructed profiles. Since only 1 cable modem is bonded to the channel, 6 profiles were configured with flat modulation. The right panel shows the profile tailored to the noise detected on the channel.

Figures 16 and 17 are dashboard type charts that track various metrics of interest relating to PMA performance. These include device counts, capacity, and traffic metrics both at the channel level (first row) and the IUC level (second row), as well as normalized traffic by IUC and MER statistics (last row). The first example shown in Figure 16 is for a field node with relatively clean spectrum. For this node, traffic is flowing mostly through IUC 12—the highest capacity profile at ~ 400 Mbps. MER statistics

show levels that are consistently above 41 dB and the uncorrectable codeword rate is extremely low. As a result, profile switches by PMA are minimal (indicated by vertical solid lines).

Figure 15. Example MS PMA performance charts for a clean spectrum.

In contrast, Figure 17 is for a node that exhibits variation in MER level within the 34-43 dB range. For this node, the internal PMA function responds by moving devices to suitable profiles. In this example, the dip in MER correlates with the shift of traffic from IUC 12 to lower capacity profiles. The PMA system is also responding by reconstructing the profiles in response to the dynamic nature of the noise. While the uncorrectable codeword rate is higher than the clean spectrum node, it is kept under 0.2%.

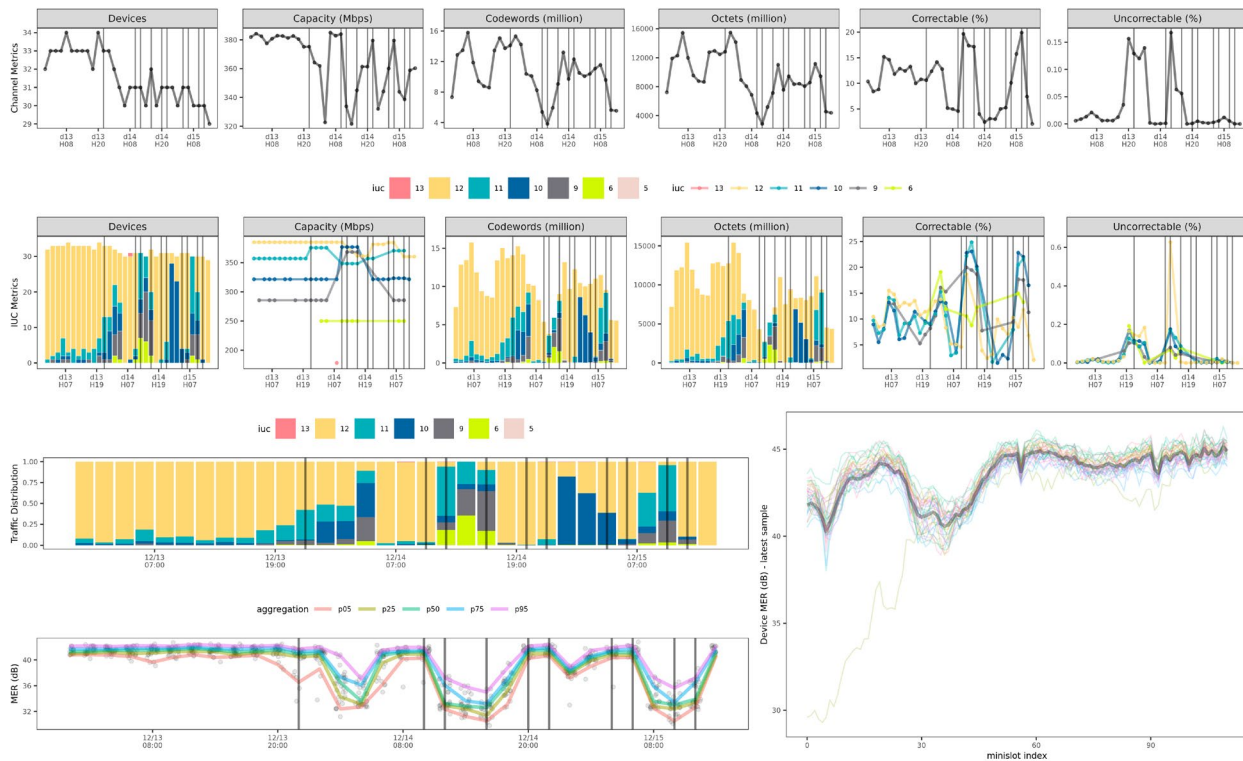

Figure 16. Example MS PMA performance charts for a noisy spectrum.

5.4. State of the Upstream Spectrum

While many of these ingress sources are problematic, the network is generally in great shape and easily supports the capacity and product speed expectations for the MS and OFDMA. Figure 18 describes the network from one of our very first OFDMA trials across 100 nodes in challenging RF environments. Even in these nodes it can be seen that:

- ~50% of network supports 4096-QAM US OFDMA based on DOCSIS PHY spec MER requirement.
- The IUC selection in the vCMTS is actually 3 dB better, implying that ~85% of OFDMA traffic can flow on 2048-QAM. This is consistent with lab testing that shows the OFDMA receiver performs at least 3 dB better than the CableLabs DOCSIS 3.1 PhHY specification requirements in the MER range of interest.
- The forecast is for ~70% of OFDMA traffic to use 4096-QAM based on this early data when that feature is available from the vCMTS.
- This performance exceeds our initial capacity models for both mid-split and high-split that were created to set goals for new product speeds.

Figure 17. (Top panel) MER cumulative distribution from early trials on ~100 nodes shows that ~85% of mini-slots can support 2k-QAM. (Bottom panel) Actual traffic stats confirm this picture.

While Figure 17 was from an initial small trial, the network performance trend is improving now that we are delivering OFDMA to hundreds of thousands of CMs with OFDMA activated. Figure 18 shows the distribution of MER per minislot over 2 days of time across tens of thousands of modems early in the writing of this paper. Several key points to note include:

- MER Performance statistics are very promising; against specification thresholds, ~90% of mini-slots show 4096-QAM speeds.
- Lab and field testing of OFDMA PMA indicates we have 3 dB more additional margin relative to specifican thresholds.
- Even at specification thresholds, this distribution represents an average of ~520 Mbps US capacity per MS SG.
- Work is ongoing to tune the OFDMA PMA, once deployment challenges are stabilized.

Figure 18. MER per minislot aggregated across tens of thousands of modems at 1-hour samples over 48 hours across varied network locations.

6. Mid-Split Ingress

6.1. VHF TV Ingress

VHF over the air (OTA) ingress is one of the more common ingress sources we discovered in our initial OFDMA deployments. As shown above this ingress can be problematic without a PMA solution. To understand how it might affect capacity, Comcast did an analysis of power levels expected at homes and within nodes. The analysis was based on a Federal Communications Commission (FCC) spectrum database for VHF transmitters and a propagation model informed by measuring actual ingress using our full band capture function. The bands evaluated are shown in Figure 19.

Channel Number	Frequency in MHz
Channel-2	54-60
Channel-3	60-66
Channel-4	66-72
Channel-5	76-82
Channel-6	82-88
FM Broadcast	88-108

Figure 19. One primary source of ingress which impacts mid-split is the lower VHF OTA television broadcast. The channels of interest are 2-6 and FM broadcast

A sample of VHF transmitters was selected and the overlapping channel power for devices at various distances from these transmitters was measured. Figure 21 shows the variation in channel power as a function of distance from the VHF transmitters. Key points to note include:

- Impact reduces as the distance from the VHF transmitter increases and it appears to follow a power trend line.
- The impact appears to vary across device types. A potential explanation for this variation may be due to shielding improvements in newer devices.
- Device Type 3 filters channels below 108 MHz and hence is minimally impacted.

Figure 20. Variation in channel power vs distance for VHF transmitters for different device categories

6.2. Interesting Impairments to Keep in Mind for PMA

The impairment in Figure 22 was seen in several nodes and diagnosed to see if it was distortions from DS signals. After investigating we believe these narrow-band ingressors are an old VCR, video game (i.e., Atari) or the wrong connector on an older set-top-box connected to an outlet in the home. This is the signature and power levels that would be generated from a channel 3 amplitude modulation (AM) modulator at 61.25 MHz.

Figure 21. Example video modulator in home transmitting into OFDMA spectrum

While stabilizing the OFDMA technology deployments we have observed several cases of high tilt compensation across the OFDMA channel. Some of these responses affected MER of the OFDMA channel resulting in some compensation by the PMA solution. Examples of these are shown in Figure 23. Some of these were due to network devices that were not replaced in the mid-split upgrade process, such as inline equalizers in the lower half of Figure 23 that were tuned for a low-split network. Other cases were from equalization optimization issues requiring a periodic unequalized probe to reset the equalizer and interaction with upstream transmit powers. Other cases were a result of incorrect use of upstream conditioning in new mid-split amplifiers.

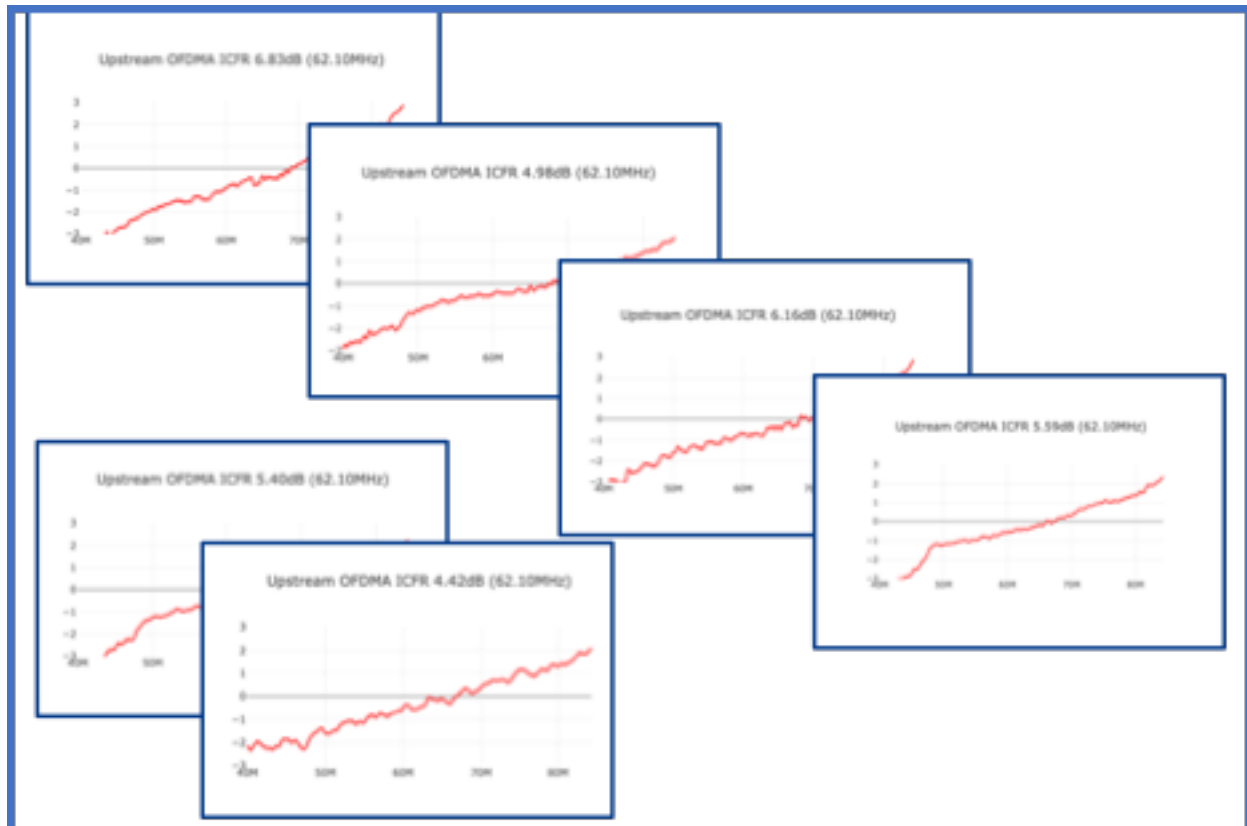

Figure 22. Various Pre-EQ responses for OFDMA channel showing tilt.

7. Conclusion

The paper details some insights into the challenges of deploying OFDMA technology. As part of the deployments and trials over the last 18 months we have shown the benefits and success of the OFDMA technology for delivering hundreds of Mbps of US speeds in MS networks and 1 Gbps US speeds in high-split networks with a positive customer experience. Comcast has determined that an OFDMA PMA solution is essential in delivering these new higher speed products. The PMA solution is essential because of the ingress and distortion challenges we have identified in a very small percentage of nodes that changes over time. Primary ingress sources include over-the-air broadcast transmission. These ingress sources are easily handled by a dynamic modulation profile management application that is an incremental evolution to the platform.

Abbreviations

AM	amplitude modulation
CM	cable modem
CMTS	cable modem termination system
D3.0	Data Over Cable Service Interface Specification 3.0
D3.1	Data Over Cable Service Interface Specification 3.1

DOCSIS	Data Over Cable Service Interface Specification
DS	downstream
FCC	federal communications commission
FDX	full duplex
FM	frequency modulation
HFC	hybrid fiber coaxial
HS	high-split
IUC	interval usage code
MER	modulation error ratio
MS	mid-split
NOAA	National Oceanic and Atmospheric Administration
OFDM	orthogonal frequency division multiplexing
OFDMA	orthogonal frequency division multiple access
OTA	over the air
PMA	profile management application
PNM	proactive network maintenance
PPOD	physical pod
RF	radio frequency
SCTE	The Society of Cable Telecommunications Engineers
vCMTS	virtual cable modem termination system
US	upstream
UVHF	Upper VHF band, Low VHF can be used to refer to channels 2-6, Upper VHF for channels above channel 6
VHF	very high frequency

1. Introduction

Network security has been one of the top priorities for the industry since the transition from analog to digital. It is a combination of prevention, mitigation, remediation, and customer notification technologies that help reduce the risk of data loss, theft, and sabotage. [1] The landscape has also changed drastically recently due to the pandemic, geo-political instability, and evolving federal and state regulatory requirements and standards. Network security threats are constantly evolving as well with threat actors looking to exploit vulnerabilities to gain the initial access required to laterally move across the network, and ultimately exfiltrate sensitive information or impact the environment. The recent CISA alert AA22-158A [2] of state-sponsored cyber actors exploits of network providers and devices is an example of such threats potentially targeting modern networks. These actors exploited known vulnerabilities, primarily common vulnerabilities, and exposures (CVEs) associated with network devices to target and compromise major telecommunications companies and network service providers since 2020.

Often the response to widely impacting cyber threats is to deploy additional security safeguards across the network and its devices; initially at the perimeter and down through its many additional security layers (network, endpoint, application, and data) as well as externally to the subscriber premise devices. Patching and end-of-life infrastructure replacement can also be conducted, but these are usually reactive measures to exploits that are already utilized and potentially costly to remediate.

A security controls framework approach facilitates the proactive measurement of existing and implemented protections required to minimize risks across an organization's people, processes, and technologies safeguarding a 10G network. Network security threats such as DDoS attacks, fraud and phishing, and data breaches are top priorities for any organization requiring the ability to continuously measure control effectiveness and risks with an automated and scalable solution. The design and implementation of continuous monitoring for security controls is often a complex and challenging task requiring subject matter expertise, alignment across multiple organizations, and data aggregation and correlation to enable effective risk management. This whitepaper will elaborate on a unique strategy that showcases the best practices for design, implementation, and operation of a controls framework for a 10G network aligned with a risk management approach.

2. Methodology

To establish the continuous measurement and monitoring of security controls requires the implementation of a controls framework that is adaptable and customizable to the technologies, processes, policies and standards, and expertise of each individual organization. Many security frameworks exist where an assessment is required to determine the best fit in alignment to organizational cybersecurity goals and its risk management strategy.

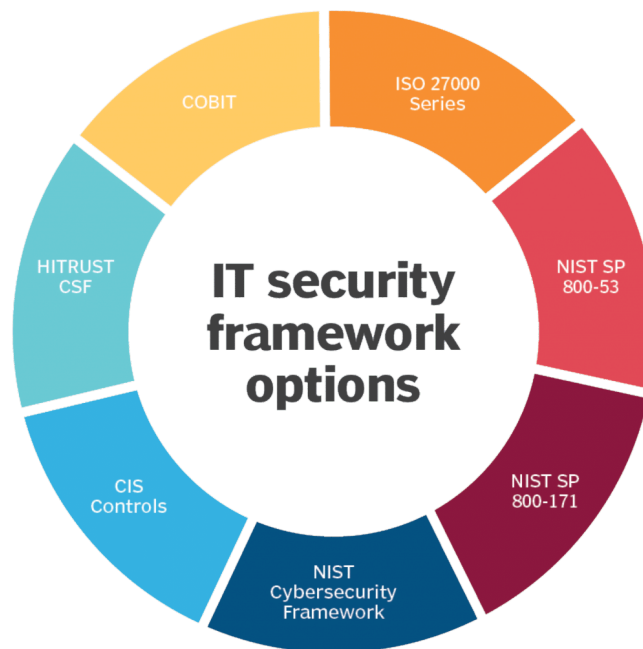

Figure 1 – Common Cybersecurity Control Frameworks

The cybersecurity framework utilized in this whitepaper to illustrate the design and implementation of continuous controls monitoring is NIST SP 800-53 [3]. The National Institute of Standards and Technology (NIST) is a non-regulatory agency of the United States Department of Commerce, where the NIST Cybersecurity framework was introduced in 2014 with revisions released to domains, controls, and enhancements (currently in Revision 5). The NIST Cybersecurity Framework is centered around five essential domains:

- **Identify (ID):** Determines an organization’s critical functions and the risks that could disrupt those functions. Identifying organizational systems and assets, information types, policies and procedures, risk management strategy, and roles and responsibilities are essential elements of this domain.
- **Protect (PR):** Defines the relevant safeguards required to deliver critical protective services by establishing priorities and cybersecurity efforts. Protection of organizational systems, assets, and information via access controls, awareness and training, data security, information protection processes and procedures, maintenance, and protective technology management are essential elements of this domain.
- **Detect (DE):** Implementation of an organization’s detective capabilities to promptly identify cyber risks and incidents. Event logging, anomalous activity detection, security continuous monitoring, and detection processes are essential elements of this domain.
- **Respond (RS):** Execution of measures related to a detected cybersecurity incident and an organization’s ability to manage its impact. Response planning, communication strategy, analysis procedures, mitigation, and application of improvements are essential elements for this domain.
- **Recover (RC):** Restorative capabilities to impacted systems and services as the consequence of a cybersecurity incident. Recovery processes and procedures, application of improvements, and cross organization collaboration are essential elements of this domain.

Taking into consideration an organization's goals, policies and standards, technologies, and processes are key in the successful implementation of a control monitoring framework. An organization's goals define its objectives, policies and standards provide governance and management, technologies illustrate its capabilities, and processes allow enablement. The domains in NIST 800-53 serve as the guidelines to be implemented concurrently to form an operational culture that addresses cyber risk. Within the domains are controls that provides the protective measures for systems, organizations, and individuals. The controls allow specification and customization to an organization's objectives allowing enablement of a continuous controls monitoring culture.

Table 1 illustrates how a series of controls can be customized to the specificity of a 10G network.

Table 1 – Example of NIST 800-53 Controls for a 10G Network

ID	10G Network Specific Controls
ID.AM	Network Inventory Management in defined source system, automated discovery, completeness of key attributes like Serial Numbers, Location for all key assets that encompass the 10G Network.
ID.BE	Alignment of the organization's mission, objectives, stakeholders, and activities with cybersecurity roles, responsibilities, and risk management of the 10G Network.
ID.GV	The policies, procedures, and processes alignment with regulatory, legal, risk, environmental, and operational requirements for the 10G Network.
ID.RA	Understanding of the 10G Network related cybersecurity risk to operations (including mission, functions, image, or reputation), organizational assets, and individuals.
ID.RM	The organization's priorities, constraints, risk tolerances, and assumptions are established and used to support operational risk decisions as they relate to the 10G Network.
PR.AC	Identity Management, Authentication and Access Control for physical and logical assets and associated facilities for authorized users managing and monitoring the 10G Network.
PR.AT	Providing personnel and partners the cybersecurity awareness education to perform their cybersecurity-related duties and responsibilities for the 10G Network.
PR.DS	Protecting Information and records (data) in transit and at rest in 10G Network against data leaks separating production and test environments.
PR.IP	Processes are in place for Software Development Lifecycle (SDLC), secure configuration, backups, vulnerability management and incident response for the 10G Network.
PR.MA	Maintenance and repairs of industrial control and information system components of the 10G Network are performed consistent with policies and procedures.
PR.PT	Audit Logging, media protection, control plane protection, load balancing are in place to ensure security and resiliency of the 10G Network.
DE.AE	Detecting Anomalous activity against a baseline and creating incidents for necessary events by correlating from multiple sources and sensors within the 10G Network.
DE.CM	Continuous monitoring and vulnerability scanning to identify cybersecurity events, malicious code, unauthorized access etc.
DE.DP	Detection processes and procedures are maintained and tested to ensure awareness of anomalous network events.
RS.RP	Response processes and procedures are executed and maintained, to ensure response to detected cybersecurity incidents.

RS.CO	Response activities are coordinated with internal and external stakeholders (e.g., external support from law enforcement agencies, vendors, etc.).
RS.AN	Analysis and forensics are conducted to ensure effective response and support the network recovery activities.
RS.MI	Activities are performed to prevent expansion of an event, mitigate its effects, and resolve the network incident.
RS.IM	Organizational response activities are improved by incorporating lessons learned from current and previous detection/response activities.
RC.RP	Recovery processes and procedures are executed and maintained for restoration of 10G network sub-systems or assets affected by cybersecurity incidents.
RC.IM	Recovery planning and processes are improved by incorporating lessons learned into future activities.
RC.CO	Restoration activities are coordinated with coordinating centers, Internet Service Providers, owners of attacking systems, victims, and vendors).

The rest of the whitepaper will discuss the process of designing the controls mentioned above, implementing related KPIs that can be matured over time, onboarding various teams running the parts of the 10G network, and setting up continuous monitoring of these controls aligned with a risk management approach.

3. Control Design

The number of devices connected to a subscribers' network continues to increase across variety of industries (e.g., healthcare, education, private and public sectors, etc.) requiring connectivity to reliable network services. Speed, capacity, reduced latency, enhanced reliable and security are all advancements that make 10G transformational in how people and industries operate in a multi-gigabit reality. "The 10G platform is a combination of technologies that will deliver symmetric multi-gigabit Internet speeds with a vision toward enabling symmetric 10 gigabits per second (Gbps) services. 10G will be significantly faster than what most consumers currently experience, and will offer lower latencies, enhanced security, and greater reliability" [4].

These advancements are examples of organizational 10G goals that are foundational to control design and the successful implementation of a security controls framework. The definition of these business objectives enables an organization to establish its scope of controls, prioritization of related security efforts, organizational adoption, and the measurability of control performance. With the organization objectives defined, an iterative approach to control design can be applied to establish a framework that is aligned to organizational goals, policies and standards, technologies, and processes.

3.1. Identify Risks

Development of the organization's holistic view of critical business functions starts with the identification of its assets, risks, policies, and owners. Identification of these aspects determines an organization's critical functions and the risks that could cause disruption to key network components or infrastructure. Identifying organizational systems and assets, information types, policies and procedures, risk management strategy, and roles and responsibilities are essential elements for a risk managed network.

The path to 10G and its network transformation to a distributed access architecture has required the controls framework to further adapt in the identification of risks in a virtualized and digital environment. From the virtualization of the cable modem termination system (CMTS) to the delivery of broadband signals across the network to the subscriber premise, the traditional approach to protect physical assets and key infrastructure has now expanded to the virtual environment.

Figure 2 illustrates an example of a virtualized CMTS network. [5] (Source: Cable Labs Data-Over-Cable Service Interface Specifications for DOCSIS[®] 4.0, MAC and Upper Layer Protocols Interface Specification CM-SP-MULPIv4.0-105-220328)

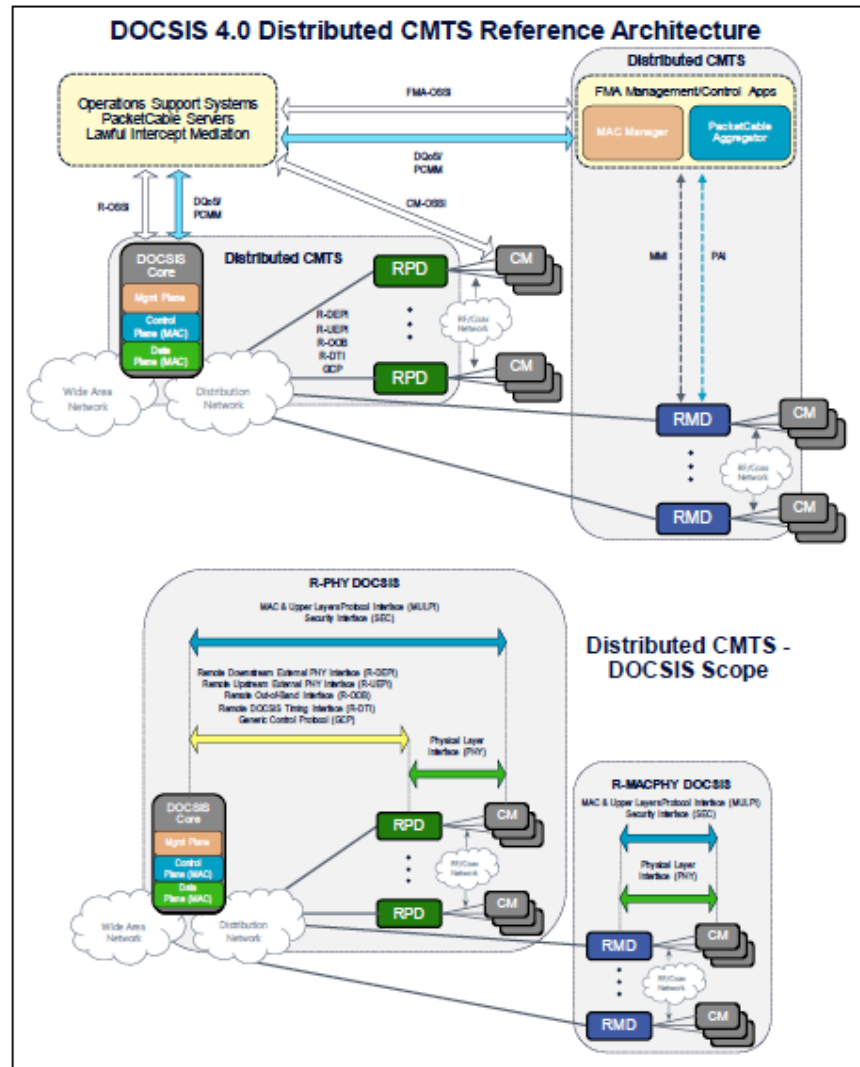

Figure 2 – DOCSIS 4.0 Distributed CMTS Reference Architecture [5]

Therefore, controls such as asset identification should be expanded to ensure coverage of the virtual environment, along with the design and implementation of policies and standards relevant to the security of a 10G network to ensure broader risk coverage. Similarly, with further reliance on automation to manage distributed and virtualized environments, traditional identity and access management risks should

be expanded to ensure appropriate coverage. Risks related to change management are also important to consider ensuring various teams involved in building and operating the 10G network are appropriately reviewing and approving deployments. Version control tools are appropriately configured and managed in alignment to organizational standards, along with the secure storage of secrets in organizational vaulting solutions and not present in source code.

Risk assessment and third-party management are additional critical aspects of risk identification in a 10G network. These areas allow a 10G network provider to understand the cybersecurity risks to organizational operations, priorities, and risk tolerance.

- **Risk Assessment:** Asset vulnerabilities to core 10G infrastructure are identified and documented; Cyber threat intelligence is received potentially impacting network providers (e.g., implementation of a Threat Intelligence Platform); Potential business impacts and likelihoods are identified; Threats, vulnerabilities, likelihoods, and impacts are used to determine risk; Risk responses are identified and prioritized
- **Third Party Management:** Cyber third party risk management processes are identified, established, assessed, managed, and agreed to by organizational stakeholders and network management teams; Suppliers and third party partners of information systems, components, and services are identified, prioritized, and assessed; Contracts with suppliers and third party partners are used to implement appropriate measures designed to meet the objectives of an organization's cybersecurity program; suppliers and third party partners are routinely audited to confirm they are meeting contractual obligations

3.2. Identify Framework and Controls

Identified internal and external risks require the implementation of controls within a framework that aligns best to organizational objectives. Frameworks such as NIST 800-53, NIST CSF, ISO 27001, etc. provide specific scope and functions where the selection may be based on various frameworks that align to the organization's goals and regulatory requirements (e.g., GDPR, CCPA, PCI DSS, etc.). Often, the legal team within the organization provides consultation on the framework selection to ensure appropriate coverage is provided to identified risks and specific regulatory requirements. Once the approach to framework selection is completed, the process to control identification can begin mapped to the identified risks.

Below details the best practices for control selection, design, and implementation:

- Mapping of controls to policies and standards, assets, risks, owners, and organizational data allows the ability to successfully design a control for implementation and measurement
- The management of controls is best accomplished utilizing domains (e.g., asset management, risk management, identity & access management, etc.) with mapping to controls for an organized implementation which avoids duplication of controls
- Each control should be paired with a specific process owner that has defined the scope of the control, designed and implemented the control, continuously supports the control and its system and users, and can accurately report on control performance
- Control design logic and requirements should be formally documented and continuously maintained with updates and changes. Additionally, a control maturity model should be considered and formally documented as the selection and implementation of a control may require multiple phases based on enhancements by the process owners

Another key aspect in the selection, design, and implementation of a control is the organization's data. The availability of control data allows the ability to measure control performance, identify risks, and enables the business to establish a continuously control monitoring culture. A data strategy should be designed based on organizational capabilities to ensure data ingestion, quality, transformation, analytics, sharing, and governance is appropriately and efficiently conducted.

Figure 3 illustrates both the upstream and downstream control mapping based on organizational data.

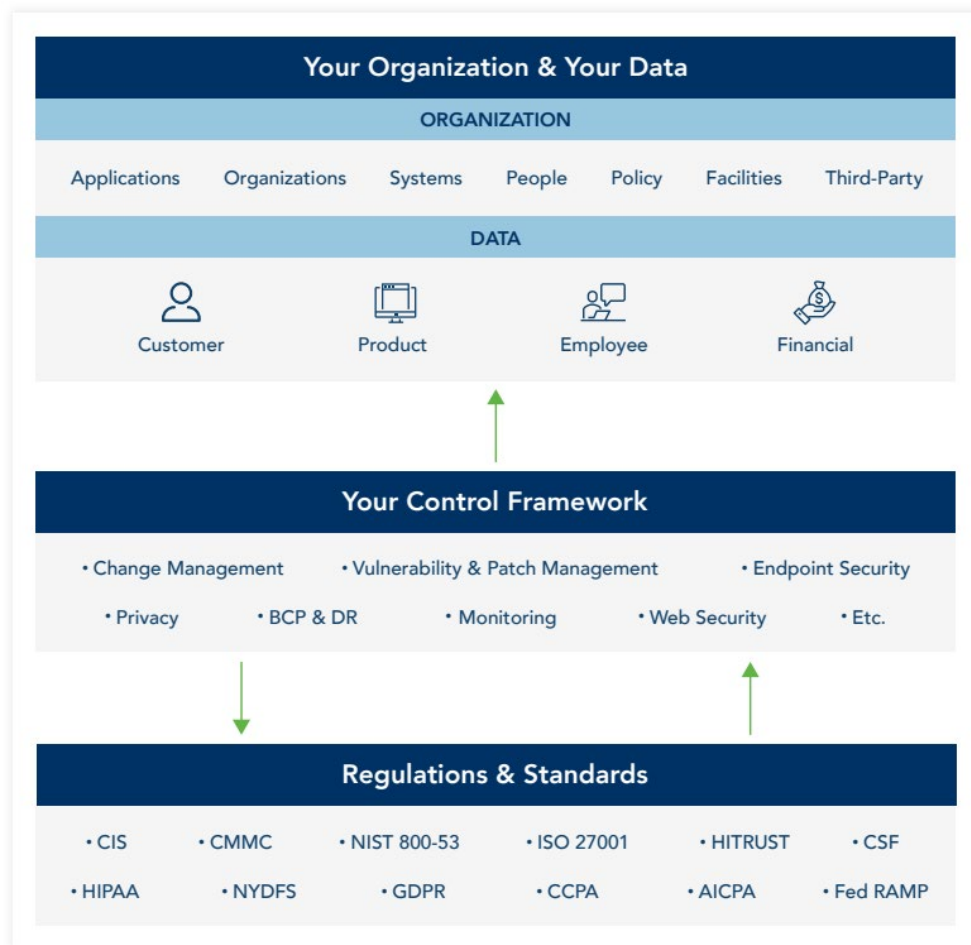

Figure 3 – Organizational Data Mapping to Controls [6]

3.3. Principles for Control Monitoring

Establishing principles for control monitoring is essential to ensure the implementation of controls meets the objectives for a 10G network. Following a set of defined and agreed upon principles allow the implementation, adoption, and support of the controls to be sustainable with roles and responsibilities clearly defined in the controls end-to-end process.

Figure 4 defines a set of principles that can be utilized to meet an organization's control monitoring objectives and requirements.

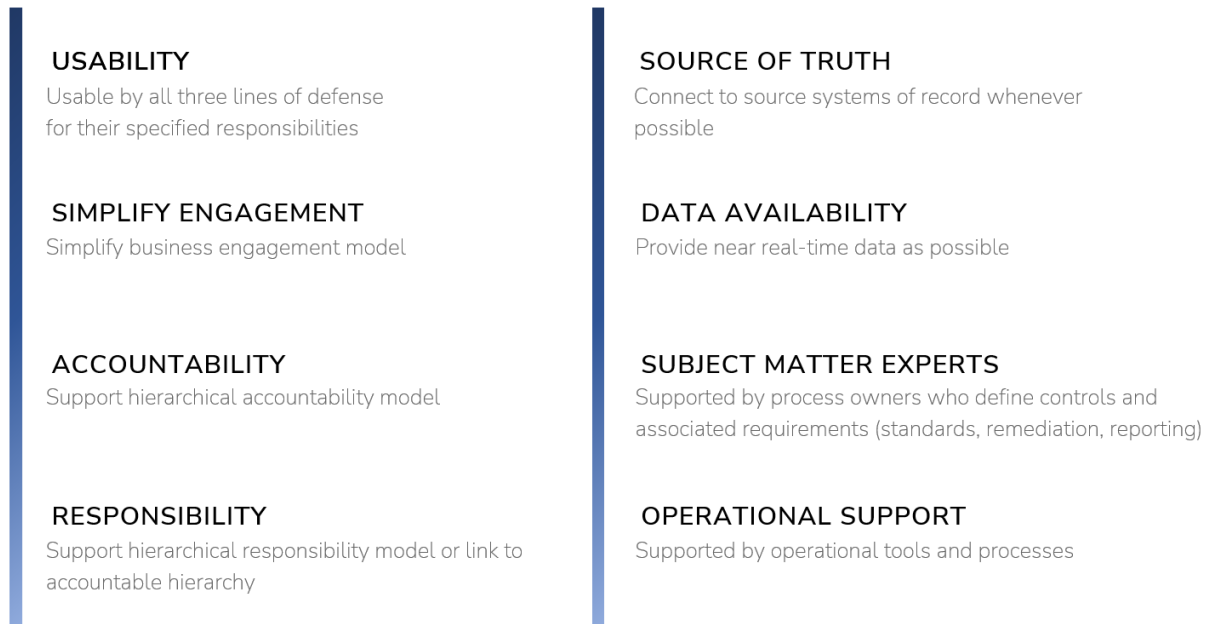

Figure 4 – Principles for Control Implementation and Monitoring

3.4. 3 Lines of Defense Risk Management

The concept of the 3 lines of defense in risk management is a term often utilized in the cybersecurity compliance and audit sector. It is essentially a model that provides guidance for effective risk management and governance for an organization with distinct roles and responsibilities across all 3 lines.

Figure 5 illustrates and details the 3 lines of defense and their responsibilities across an organization.

Figure 5 – 3 Lines of Defense

4. Measurement and Reporting

The representation of the control performance and analytics is key in the organizational adoption of the controls framework. The development of the control performance measurement is often accomplished utilizing a visualization tool (e.g., Tableau, Power BI, Splunk, etc.) that best fits organizational capabilities and skills. Prior to development, steps should be taken to gather and define development requirements which includes the determination of control metrics and thresholds, data source identification, and 1st and 2nd line defense views that demonstrate risk and control performance progress.

4.1. Defining Control Metric and Thresholds

Once the controls are defined, attention can be focused on the control metrics. Below are a few principles to consider in building the insights necessary for successful utilization:

- Understand your audience, identify their analytical capabilities and what best complements their visualization needs
- Define the appropriate control numerator and the denominator that provides the risk coverage and measures progress accurately
- Take a risk driven approach to prioritization of control measurements as opposed to easily available metrics in the data set and keep in mind the total risk posture (total attack or risk surface)
- Business Unit actions vs. Process Owner actions to maintain the accountability and responsibility for remediations
- Time-bound activities and their proper representation in the metric to measure SLAs and quarterly breakouts. Also consider the re-certification of a metric after an elapsed time
- “Keeping it simple but effective”. This adage still serves well for these metrics that can get very granular and detailed and could take a life of their own
- Ensuring that thresholds are defined in consultation with internal risk management teams and legal teams so internal and external compliance requirements are met

4.2. Identifying sources of reliable and scalable data

Following the control metrics definition, the next step is to look at various systems that source the data and build the data pipelines to integrate into the control monitoring dashboard. A few aspects to consider in this step:

- Secure interfaces and methods to integrate the data at the source
- Determine the frequency of the updates and apply automation where possible
- Ensure quality and accuracy of the data and its useability in the control metrics build out
- Deidentify the data to remove any Personal Information (PI)

Figure 6 illustrates a general inventory of an organization's data required to build the controls metrics dashboard and the lines of defense that utilizes its insights to perform risk identification and mitigation.

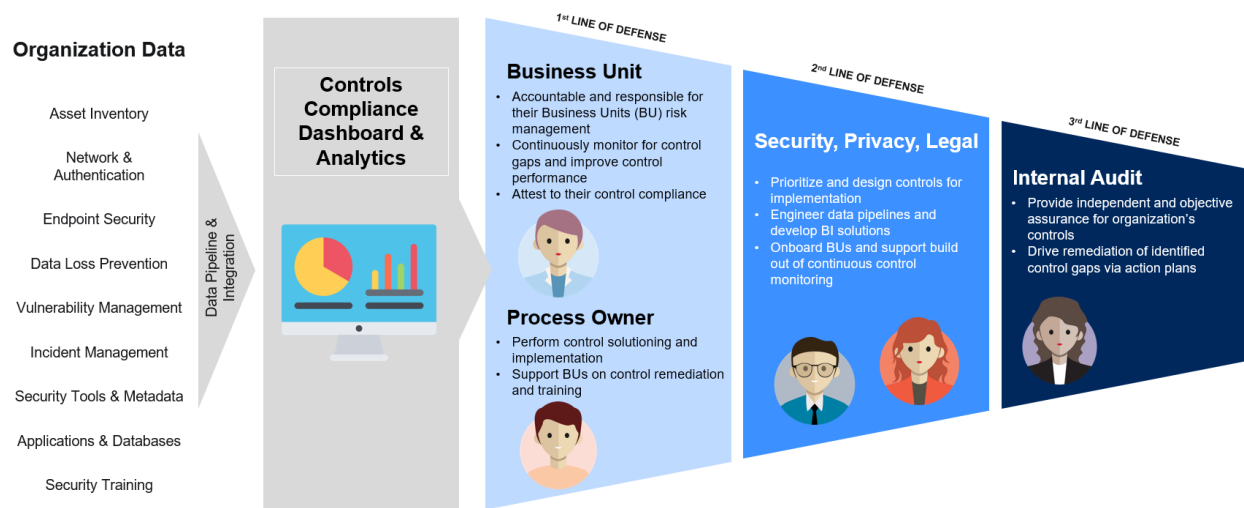

Figure 6 – Identification of Reliable Organizational Data and Insights Utilization

4.3. 1st line and 2nd line of defense dashboards

In line with the risk management framework, it is advisable to create dashboards that serve specific purposes to highlight risk for its intended use. The 1st line of defense dashboards provides the ability to highlight risk for the Business Unit to focus on control performance, gap remediation, and enablement to continuously monitor control performance. Ease of use, data accuracy, and alignment to the analytical capabilities of its audience is key in its adoption to drive enablement for the Business Unit.

The 2nd line of defense dashboards provides a risk view of the network across the entire organization with the ability to focus in on specific control risk areas requiring intervention or support. Also has the capabilities of highlighting the risk management maturity of a Business Unit with the added ability to assess progress via trending and identify additional risk areas. The 3rd line of defense is also able to utilize this view to support internal audits with the benefit of reducing the manual efforts associated to

identifying risks, driving remediation via action plans, and the validation required to confirm risk mitigation.

4.4. Accountability Summary and Responsibility Views

As the controls framework and its controls contain multiple and at times complex metrics, it is recommended to provide separate views that are related to accountability (the executive view) and responsibility (the operational view). The accountability view provides an executive the visibility required to understand control compliance at the organization level, identify escalation needs when control performance is lacking or use for attestation purposes (see section 5.6 for more details on attestations). Adding trending expands the control accountability to

The responsibility view provides the operational visibility required for the remediator to identify their control gaps and perform the corrections required to reduce risk. The responsibility view should provide the details necessary to perform the remediation; data points such as control gaps, insights on risk factors supporting prioritization, distribution by owner to forecast resource demand, and drilldown details are examples of the insights necessary to quickly and easily remediate the control gaps identified.

One of the challenges often experienced is the re-factoring of the dashboards due to organizational changes which may impact the hierarchical ownership of assigned controls and associated risks for the accountability and responsibility views. Associating the business unit roll up to a control metric that can be linked to immutable data objects such as applications and vendors provides a way to keep the dashboards agile and “self-correct” when these changes occur.

5. Onboarding and Continuous Monitoring

The onboarding of users onto the security controls framework and related dashboards is key in the organization’s overall risk management strategy. The goal in onboarding of users is to ensure a continuous control monitoring process and culture can be implemented, which improves the organization’s security posture and leads to a sustainable model for gap remediation. Sustainability is also central to onboarding as teams are often challenged with priorities and resource capacity, where consultation may be required to build in continuous control monitoring processes into existing workflows.

Onboarding onto the security controls framework can be methodically accomplished in defined phases to ensure those onboarded are equipped with the knowledge necessary to take ownership of their responsibilities across all lines of defense.

Figure 7 illustrates the onboarding approach to ensure alignment across key stakeholders and application of corrections or improvements based on feedback for Business Unit (BU) onboarding:

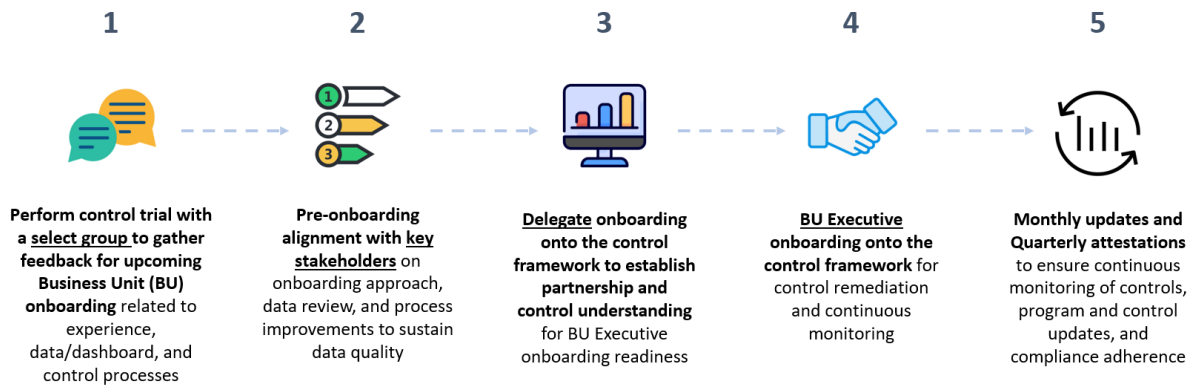

Figure 7 – Business Unit Onboarding Approach

5.1. Knowledgebase

Building a knowledgebase is key in the successful onboarding of users onto an organization's security controls framework. Depending on the size, implemented tools, and structure of the organization; control requirements and related processes may be complex. The ability for a user to understand a control, their responsibilities, and processes related to gap remediation allows the enablement necessary where accountability is taken in alignment to organizational cybersecurity goals and objectives.

A few guidelines can be followed in the development of an enablement focused knowledgebase:

- Accessibility should be considered to ensure it is usable by all users, but secured to ensure access is restricted to only those required in the organization
- Documentation is maintained periodically and expanded over time based on new control implementation, enhancements to existing controls or processes, and repeatedly asked questions
- Management of knowledgebase is simplified to ensure sustainability (e.g., links to policies and standards that can change over time)
- Control responsibilities and helpful tips for remediation are made easily available as it will drive improved adoption and understanding
- Avoid swivel where possible; if dashboards are developed measuring control performance, provide control details and remediation tips directly with the control performance metrics for users to easily address identified gaps

5.2. Control Trial Implementation

Similar to the market trials of a 10G network rollout, control implementation should be trialed with a small group of early adopters that can provide feedback on control effectiveness and design. As controls will evolve and mature over time, feedback is key in ensuring the effectiveness of controls and new features can be tested in alignment to its design and implementation. The trial goals should also be defined for the early adopters and can be targeted to specific goals during the testing period.

Figure 8 illustrates the trial control goals in preparations for a production implementation:

Control Trial Goals for Onboarding Readiness

Figure 8 – Trial Goals for Onboarding Readiness

An added benefit of implementing a trial model for future control implementation allows the ability to establish a release strategy following a control development lifecycle from start to end, while allowing the early adopters to address their control gaps early in the control implementation process.

Figure 9 illustrates the control lifecycle for new control implementation and existing control enhancements from intake to production release:

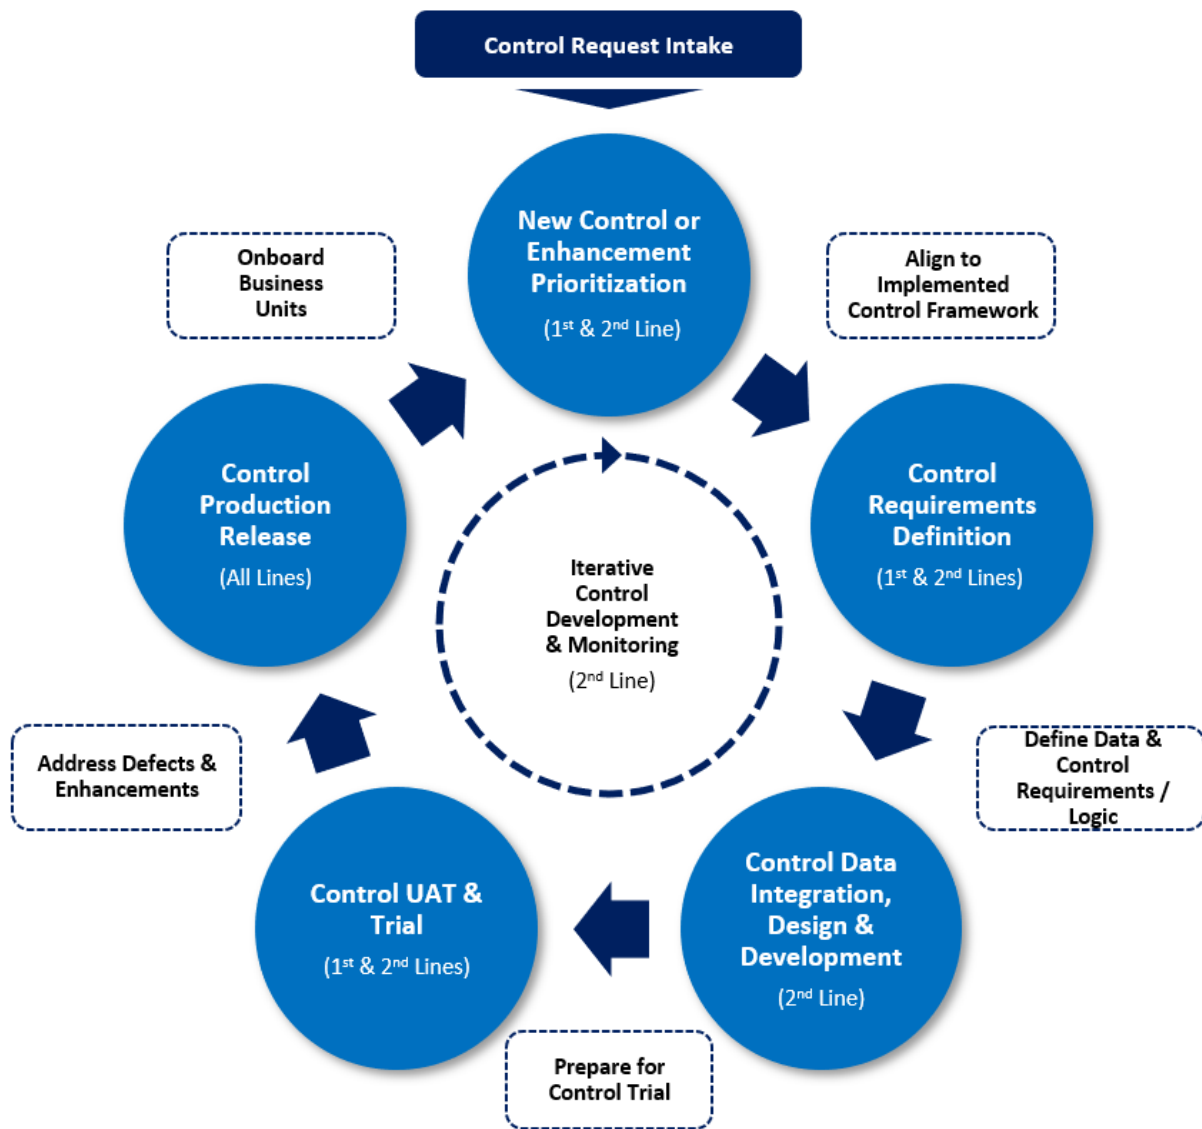

Figure 9 10– Control Lifecycle

5.3. Stakeholder Alignment

A key dependency in the success of a security controls framework implementation is the alignment established between key stakeholders. A 10G network implementation will require partnerships across many teams across engineering, field operations, to customer services. Similarly, a security controls framework requires partnerships with cybersecurity, privacy, and engineering counterparts to ensure the implementation of controls is in alignment to organizational goals and objectives. An example would be the partnership between the network engineering and cybersecurity teams in the establishment of access event logs to critical 10G network components. With access management policies and standards in place, the ability to measure control compliance via access event logs would be critical to proactively identify risks and gaps requiring remediation from both an engineering and process perspective.

5.4. Compliance Delegate Identification

Champions for a security controls framework implementation are instrumental in ensuring a continuous control monitoring culture can be adopted and implemented across the organization. These champions operate as delegates on behalf of the cybersecurity team, provide guidance on the implementation strategy for their respective teams, provide subject matter expertise to their teams related to control processes, and influence the change necessary to implement a continuous control monitoring mindset. As the delegate function in most situations are not always a part of their defined role, it is important to ensure that professional and personal growth related to this type of role is transparent for their active participation and partnership. This type of role often leads to increased visibility across the organization, with key leadership groups, and the ability to expand their knowledge as a subject matter expert in security.

5.5. Continuous Monitoring

The goal in the implementation of an effective security controls framework within an organization is to establish a continuous control monitoring process. This requires the ability to shift the cultural mindset from a traditional burndown approach to control gap remediation, to one that is proactive and continuous. Success should be measured not only in the control performance, but also with an organization's ability to shift security and privacy to the left early on in their internally processes. Only then will the security controls framework become sustainable, built in culturally across the organization, and a mechanism to ensure an initiative such as the design and implementation of a 10G network can be appropriately secured and risks mitigated.

Figure 10 illustrates the comparison between the reactive and proactive approach to control monitoring.

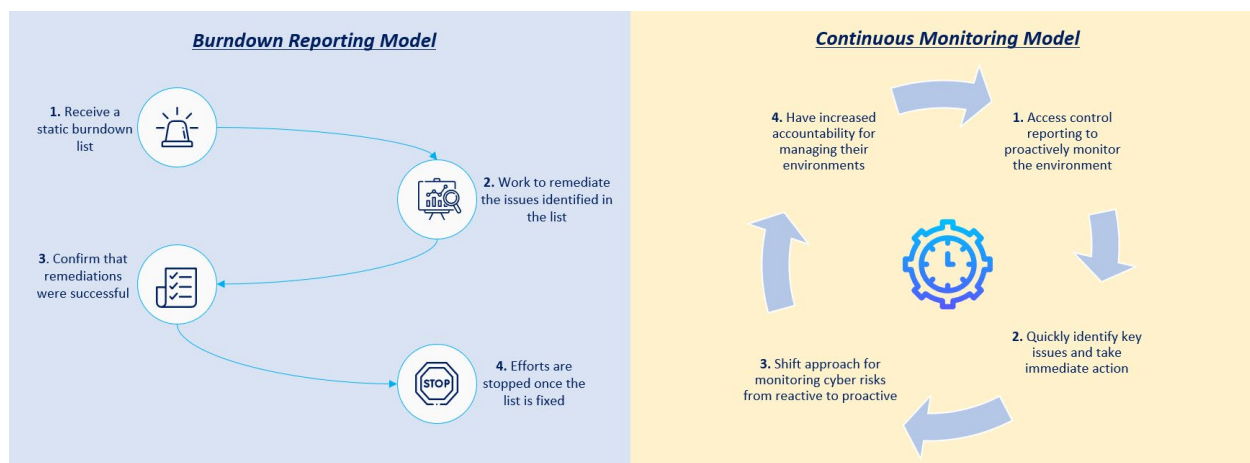

Figure 11 – Shift to Continuous Control Model

The benefits to proactive control monitoring are:

- Provides teams with the tools needed for holistic monitoring of control progress
- Promotes ongoing identification and remediation of cyber risks
- Enables teams to improve processes and go-forward strategy

5.6. Optional Attestation

In the past few years, attestations have grown in popularity to provide assurance over financial, security, and privacy related controls as required by compliance, regulators, or service clients. Adding a layer of formal attestations on quarterly basis provides the ability for companies to now gain confidence in the controls they have implemented in a method that is monitored by the financial, government, and regulatory agencies.

6. Conclusion

Establishing the foundations of a security controls framework for a 10G network provides the ability to proactively monitor implemented control effectiveness as well as identify risks in an environment that is continuously changing along with its attack surface. While it may seem challenging to implement a comprehensive framework such as NIST 800-53, it is possible to take a phased approach focused on risks with the highest impact to the network and organization. Engaging the Cybersecurity, Risk Management, and Compliance teams early on can ensure the appropriate controls are identified aligned to organizational goals and its risk strategy. The insights gained from a successful implementation can also start to showcase the security posture of the various organizational units managing the 10G network, establishing the accountability and responsibility necessary for continuous control monitoring. Securing a network is no small feat, making the right investments in security strategy and ensuring its measurable effectiveness provides the cyber protections necessary to deliver the transformative capabilities of a 10G network.

1. Introduction

As the ADKAR Model - Awareness, Desire, Knowledge, Ability, Reinforcement - states “organizational change can only happen when individuals change” (Hiatt, 2006). Organizations within our industry are now challenged with creating in-person and virtual development opportunities for their employees that are both productive and inclusive. It is more important than ever that we create engaging, actionable, and accessible learning experiences for our entire workforce. This is especially important as the cable-tech industry focuses on creating a culture that celebrates inclusion in all aspects, from customer interactions to creating innovative new products.

Learning experiences designed with an inclusive mindset can increase the value of training through innovative uses of existing technology and drive the workforce’s adoption of accessibility practices and guidelines. This includes being intentional in framing disability within the Dimensions of Diversity (Loden, 1991) and making training actionable and accessible. In this paper we will explore how this can be done by using the lessons learned when creating new Accessibility training content and how this has made a larger impact on the business and workforce.

2. Background

2.1. Inaccessible Accessibility Training

The Comcast Accessibility team and Comcast’s learning and development team (L&D), called ULearn, originally started their partnership to create accessibility focused learning journeys in 2018. The intent was to create training for Comcast technologists that focused on accessibility awareness and outlined employee responsibilities in making products and experiences inclusive. While the two training modules developed were launched in 2019, they did not come without their own challenges. Not only were we asking a large portion of the workforce to change their mindset, accounting for accessibility in their work for the very first time, but we were using development tools to create this training that weren’t in line with Comcast accessibility standards. At the time, ULearn was only starting conversations on inclusive design, building in key components like alt text or video descriptions. We were also using tools that were not fully compatible with screen readers. In our original awareness training, learners were forced to toggle back and forth between browse mode and application mode, the second being a mode not widely used by many people who use screen readers. The reality was that we had unfortunately launched accessibility training that wasn’t accessible for all learners.

2.2. An opportunity to create something new

In 2020, ULearn and the Accessibility team at Comcast took the opportunity to improve on the work started in 2018, setting out to create role specific training for our technology department and solving for the accessibility issues discovered previously. Our goal was not only to create new Accessibility training content, but to use this content as a framework to make all future training content at Comcast accessible. This, in turn, will help create better training products overall while teaching our workforce how to create inclusive experiences at work and for our customers. As we launch the newly created Accessibility and Inclusive Experiences program (AIX) in 2022, we have influenced all designers and developers to begin thinking about accessibility at the beginning of product design, rather than try to retrofit solutions after a product launches. Using existing and past products as case studies, we have developed instructional templates that meet accessibility requirements and the needs of our users to shorten the development time and increase speed to market for our products.

3. Problem Statement

Our teams' reimagination of the accessibility content led us to some key questions: **How can we increase the value of learning experiences by designing them with an inclusive mindset? What change do we want to see because of these learning experiences?**

To solve for this and deliver content that makes an impact, we sought to achieve the following:

1. Be intentional in framing accessibility within the dimensions of diversity
2. Create actionable and accessible learning experiences using the tools currently available
3. Determine how we can measure the success of the learning experiences delivered

4. Accessibility and Inclusive Experiences (AIX) Principles

We start with framing accessibility within the dimensions of diversity. The Accessibility and Inclusive Experiences (AIX) Principles, developed by Comcast's Accessibility team and co-author Joel Moffatt (Principal Product Manager, Accessibility), are the pillars we used to create our learning products and the inspiration behind all of the content included.

4.1. Why do we need AIX Principles? Mindset.

Before we jump into the AIX Principles, we need to define some key terms. First, diversity is the set of characteristics — whether inherited or gained by experience — that make you uniquely you. This can include gender, sexual identity, race, religion, ability, age. At its core, inclusion is about allowing seats at the table for each of these dimensions of diversity while also hearing and valuing those voices because of, and not in spite of, those differences.

The nuances of diversity, equity, and inclusion can't be fully appreciated simply through repetition. Learning about and truly understanding cultural perspectives of others requires not just a learning posture, but an openness to the value of lived experiences other than one's own. For many learners, the idea of diving in and understanding the full cultural context of many different dimensions of diversity can be daunting. This need not be the case. Across those dimensions, there are many commonalities: in the way language is used, the value of empathy and understanding the experience of others, the function and role of allies, and so on. In other words, people don't need to start from scratch when embarking on a journey of learning about a particular dimension of diversity. An inclusive mindset is all anyone needs to get started.

4.2. Why do we need AIX Principles? Skillset.

Disability differs from other dimensions of diversity because there are some hard skills needed to succeed when delivering accessible employee and customer experiences. To be effective in gaining and employing those skills, learners need to understand the context of disability as a culture, the different methods and technologies people with disability may use to interact with content, spaces, and products. Once there's an understanding of why inclusion and accessibility are important, the workforce becomes more motivated to learn how they can create inclusive experiences and build accessibility into all they do.

In web and mobile development, developers adhere to W3C's Web Content Accessibility Guidelines (W3C, 2018), WCAG 2.1 Level AA. In learning and development settings, Universal Design for Learning principles (CAST, 2018) help educators meet students where they are by allowing for different means of expression and reception, like project based learning. For design, there are the Inclusive Design

principles. In the built world, the Americans with Disabilities Act (1990) codifies the minimal requirements to make a space accessible. Chances are, there are physical and digital aspects and platform and content considerations involved in everything you work on. And of course, you want to deliver the best experience possible for everyone who might engage with your product. And “product” here can be just about anything: email blasts, slide presentations, video entertainment, remote controls, theme park rides, apps, workspaces, and virtual learning.

4.3. AIX Principles defined

Instead of creating a curriculum that exists in a silo of disability and accessibility, we grounded the entire curriculum in Comcast’s Accessibility and Inclusive Experience principles. These AIX principles intentionally cut across all dimensions of diversity and take into consideration mindset and functional solutions. The principles are the initial lens you can look through to evaluate any project, product or other work right from the outset. They are:

INTEGRAL

“Inclusion and Accessibility are in our company’s DNA.”

Foster a culture of diverse teams, like-minded partners, and accountable leaders driven by inclusive policies.

RESONANT

“Diversity is represented in our content, products and workplace.”

Customers see themselves positively reflected in content and their needs met by our products. Use Inclusive language, cultural context, and accessible platforms.

EQUITABLE

“The experience accommodates the customer, not the reverse.”

Offer choice and control over settings, formats, and means of participation to create equitable experiences, whether physical or digital.

SITUATIONAL

“Combinations of where and how users do things are endless.”

Consider variables like venue, experience level, modes of interaction, and cultural context.

CONSISTENT

“Respect the user’s expectations and knowledge.”

Use familiar design and content conventions to make it easy to focus and understand the message and available actions.

VALUABLE

“Unnecessary features can break the experience.”

Add value rather than complexity and novelty, considering actual customer needs and preferences.

5. Making training actionable and accessible

Using the Accessibility and Inclusive Experiences (AIX) principles as the foundation to create inclusive training solutions, we began evaluating our tools. Developing learning solutions is divided into two groups: the learning strategy and the technology platform. The learning strategy is the core of

Instructional Design, outlining the who, what, when, where, why, and how. The technology is used to deliver the strategy to users. Combining the two creates an experience that should meet the user's needs.

5.1. Understanding learners and learning strategy

To fully understand how to meet the user's needs we need to understand who the users are, or the 'who' in the learning strategy, which is the most important part. The challenge we faced was that, while everyone can benefit from different aspects of inclusive design, how do we systematically incorporate elements of inclusive design into all of our content and processes? How do we create a product that meets the needs of an entire workforce?

This is where the AIX principles and WCAG guide our strategy when creating inclusive learning products. When designing the Accessibility and Inclusive Experiences program, we created a multi-part learning journey that introduces new users to the concepts of inclusion and accessibility. It also includes role specific training to help users put these principles into action. When asking our technologists to comply with certain standards it was instrumental to lead by example and ensure the design of our content was resonant, equitable, and situational.

To apply and demonstrate the use of the AIX principles and WCAG, we implemented the ULearn L&D Accessibility design standards. This included:

1. High contrast between text and background of at least 4.5:1
2. Closed captioning for video content
3. Do not use color alone to convey any information
4. All content is accessible when using keyboard only
5. Provide text alternatives for all non-text content

While these are the five core standards used on all ULearn L&D content, it was important to show our learners the impact of doing more than just the minimum required standards. Working within the capabilities of the eBook tools available to our design team, we set out to demonstrate how making a product accessible can be both simple and innovative. One solution was to create audio transcriptions for each page in a course eBook (Figure 1). By recording the text included on each page as an audio file, we used the following principles of Universal Design for Education referenced in the AIX principles section of this paper:

1. **Equitable use:** this feature is useful to people with diverse abilities
2. **Flexibility in use:** this feature accommodates individual preferences or abilities, for example, a learner may prefer to listen to learning content as opposed to reading it
3. **Simple and intuitive to use:** the feature is easy to understand with written directions on what the feature is used for and how to play the audio transcription

Figure 1 – Audio Transcription Example

While this solved for the content of the design, we needed to evaluate the technology used while creating an inclusive and accessible learning program to ensure it supports an inclusive experience for our learners.

5.1. Evaluating technology platforms

After discovering more about our learners and determining a learning strategy based on those findings, we needed to understand the tools and technology our learners use to interact with our training experiences. Partnering with the Comcast Accessibility Team, ULearn explored how to apply WCAG standards to develop equitable training experiences using industry instructional design tools that currently exist. Using those tools to help create speed to market, save resources, and save time, we learned that many instructional design tools used at Comcast had limited capabilities when it came to accessibility. The Comcast ULearn L&D team primarily uses two industry tools to create eBooks and interactive content. Those two tools have updated several times since 2019 to allow more control over the accessibility of the products we create for our users. However, these tools and most of the ones available in the industry, still don't have all the capabilities to create a fully accessible learning product. We have partnered with our vendors, especially providers of our development tools, to help them identify where they can improve their software.

Since these industry tools do not give us full control over the accessibility of the products we create with them, we often need to use features of these tools in non-traditional ways to meet the needs of our users. For example, we used an audio block within the eBook tool to allow users to listen to the page instead of reading it. While this isn't the expected use of the block, it fits the needs of our users. By using the tools in a different way we provide learners an equitable experience where they can choose to either read or listen.

In another example of how our tools restrict our capabilities, we can't access the code level of the products in a "What you see is what you get" WYSIWYG environment, since these tools are designed for people to create products without coding knowledge. However, since the tools don't provide the functionality to create a fully accessible experience for our learners, we now modify the output to include accessibility "fixes". This makes product maintenance more difficult. When a new version of the product is released, we implement the same fixes repeatedly. However, providing these fixes is still the better alternative for our users. As a short-term solution, we have templated our fixes to allow developers to copy and paste them throughout similar applications.

As we know this isn't a long-term solution, our ULearn Design team is adding to our current set of standards to help instructional developers interpret WCAG standards in order to create instructional experiences. Before any products go to market we include full quality assurance documentation.

6. Determining value and impact

6.1. What demonstrates the value of training?

When determining the factors that measure the success of our created learning journeys we had to answer a key question: **How do we determine the impact of building accessibility into our training programs when one of the primary goals is to create a mindset shift?**

As learners begin their accessibility training journey, the initial indicator of program success is learner feedback and course ratings. We also determined that success was measured in our own ability to create training products that follow the standards outlined in the content, allowing us to “lead by example.” Success can also be determined by recognizing new programs or opportunities that exist now, either as a direct result of the training or as a result of the company mindset shift that was influenced by developing inclusive accessibility training.

6.1.1. Learner feedback and ratings

Below are two examples of the initial feedback we gain from learners: anonymous quotes provided by the learner and a star rating, ranked on a scale between 1 (very dissatisfied) and 5 (very satisfied).

Table 1 shares just a sample of the quotes received, but they are a reflection of the actionable takeaways and mindset shift our learners gained as a result of the training content:

Table 1 – Learner Feedback

Anonymous quotes from learners		
"Very informative and helpful in terms of takeaways, specifically, terminology and mindful inclusion"	"Enlightening subject"	"This lesson really opened my eyes to how I can be more inclusive in ways that never occurred to me"

Figure 2, the Accessibility Course Star Rating, demonstrates that overall the content was well-received. Of the 13 courses launched as part of the accessibility programs, two of the 13 have received scores of 4 out of 5, while 11 of the courses have received 5 out of 5 stars, to date:

Figure 2 – Accessibility course star rating

The courses included in this data were released between November 2021 and May 2022 with a completion date of September 2022 for all learners assigned each course.

6.1.2. What exists now that didn't before?

One of the questions posed earlier in this paper was: **What change do we want to see because of these [inclusive] learning experiences?**

As we look towards the future, it's important to understand how the culture of our company has evolved since our original training content for Accessibility was launched in 2019. We have seen an increase in the number of programs and initiatives with a focus on accessibility and inclusion as more individuals have developed an inclusive mindset. They are also a direct result of the partnerships developed between the Comcast Accessibility Team and ULearn. This includes, but is not limited to:

1. The [Innovation for Inclusion of Diversity and Accessibility](#) conference, presented by Comcast Labs Connect and includes a partnership between ULearn and the Comcast Accessibility team. This conference focuses on the collaboration, culture and experiences of diverse teams driving the growth of accessible technology.
2. A Community of Practice, comprised of learning professionals and accessibility champions, this group comes together to discuss best practices in creating inclusive and accessible experiences for all
3. Focused effort between Accessibility, ULearn, leadership, and the business on implementing accessibility standards and practices
4. Peer learning and speaker series offerings with a focus on accessibility content

6.2. Value to business

By focusing on innovation with existing tools, we were able to create content using our own internal design and development resources. This gave our team control over the project timeline, cost, and to the best of our ability, the accessibility standards built in to the training created. We saved money by using existing platforms. Engaging a third party vendor to create the content can sometimes cost tens of thousands of dollars per eLearning module.

As is the case with most businesses, one of Comcast's most valuable resources is time. By using our own design teams we created accessible content without the extended lead times needed to secure contracts or onboard the right tools. As many know too well, the procurement process is one that can often take many month to complete.

7. Where do we go from here?

The experiences outlined in this paper have provided a better understanding of what we need to do in the future to create inclusive and valuable learning experiences. Our goal should be to create content that empowers our workforce without having to retrofit solutions using technology that isn't fully accessible.

7.1. Inclusive tools and vendors

The work we've already done to create inclusive training content provides a better understanding of what we need to do in the future to avoid retrofitting solutions.

This starts with the vendors we partner with and the tools we use to create content. Moving forward we need to ensure every vendor we engage with follows our own accessibility standards and policies,

including the Web Content Accessibility Guidelines. Over time, and with a commitment to changing our mindset and culture to one of inclusion, it should become apparent that we're working with a vendor that is compliant or inclusive. This standard should be met by any existing vendor or any new partnership we take on, starting immediately.

As discussed earlier, the tools and platforms we use are instrumental in creating accessible learning experiences for our workforce.

7.2. Learning design standards

Earlier in this paper we mentioned the five ULearn L&D design standards included in each of our learning products. As we move towards the future, it's important to note that our need for inclusion and standards are constantly evolving. We need to be open to that change, constantly re-evaluating our standards while providing our workforce the resources needed to feel confident in applying these standards. Our ULearn design team is currently working on updated design standards to align with newly implemented Accessibility Policies and Guidelines launched at Comcast this year. This includes PDF Accessibility standards, Office Documents (Word, Excel, PowerPoint, and Email) Accessibility Standards, and Instructor led guidelines for inclusive facilitation (both in-person and virtual), to name a few. ULearn L&D, in partnership with the Comcast Accessibility team, are launching these standards in 2022 with the goal of 100% compliance by 2024 for anyone creating content, including our instructional designers, developers and product managers.

7.3. A mindset established through the lens of the AIX Principles

Accessibility training at Comcast has two main objectives. First, teach individuals the skills they need to build accessibility into all they do. Second, the training must change the learner's mindset so that they are receptive to the content and understand why it's important. With the mindset established through the lens of the AIX Principles, individuals in any role can readily assess the inclusivity of their work and why building inclusive products or experiences benefits everyone.

The guidelines for living up to the AIX Principles are found in WCAG for web content, in the ADA for the built environment, in Universal Design for Learning Principles, and in the associated best practices for executing on each of those. Success looks like:

INTEGRAL

"Inclusion and Accessibility are in our company's DNA."

Example: Your company has established a policy on inclusive media, has tools and resources in place to make it easy to make content inclusive and accessible, and has training in place to enable employees to reliably adhere to that policy.

RESONANT

"Diversity is represented in our content, products and workplace."

Example: inclusive media guidelines call for diversity in casting and using inclusive language in scripting and copy. Customers and employees see their culture reflected in our content and messages.

EQUITABLE

"The experience accommodates the customer, not the reverse."

Media player controls include closed captions, audio description and alternate languages. Content includes those options across all asset versions at time of delivery.

SITUATIONAL

“Combinations of where and how users do things are endless.”

Experiences are evaluated across many display types and designed and built to work well on small as well as large screens.

CONSISTENT

“Respect the user’s expectations and knowledge.”

Media player controls use expected conventions. Player options are found in the same location and identified with the same iconography across platforms.

VALUABLE

“Unnecessary features can break the experience.”

Media player controls are not cluttered with niche options, e.g. too many caption font options, including illegible ones.

8. Conclusion

As we mentioned in the beginning, the ADKAR model states that “organizational change can only happen when individuals change” (Hiatt, 2006) This became apparent through the development and launch of the AIX learning journeys as we discovered more people than ever before are open to embracing an inclusive mindset. As we see more individual champions of accessibility within the cable-tech industry, there’s an opportunity to continue the conversations that will drive change within our industry. With the support of our leaders and peers, we can engage with the resources available and proactively create inclusive experiences. This includes a keen focus on how the Comcast Accessibility and ULearn Learning & Development teams can partner together to develop our workforce, how we can lead by example and build upon the accessibility standards we have already implemented. We can empower our learners and each other by being intentional in framing disability within the dimensions of diversity, basing our work on the Accessibility and Inclusive Experiences principles, and making training actionable and accessible for all.

1. Introduction

Home coaxial wiring and drop cable are expected to contain corrosion diodes created between dissimilar metals and metal oxides. Generally, corrosion diodes have not been a serious problem up to this point because continuous composite downstream radio frequency (RF) levels inside homes were not sufficient to force the corrosion diodes into hard conduction, which would create nonlinear distortion. DOCSIS[®] transmitted signals can be strong enough to force the corrosion diodes to conduct, but due to sub-split upstream frequencies, damage to downstream signals has been limited. It should be technically possible to automatically detect passive intermodulation (PIM) products at the headend due to their correlation with the main transmission and the spectral location of the nonlinear distortion. This paper discusses the mechanism for creating PIM in sub, mid and high split plant using orthogonal frequency division multiple access (OFDMA) transmissions. The paper also reports on PIM impairments created in our lab and analyzed using digital signal processing (DSP), discusses the potential impact of nonlinear noise on full duplex (FDX), and provides techniques to tackle this until now invisible plant impairment.

2. Background

2.1. Background on Nonlinear Distortion

Plant distortions can be separated into two categories: linear and nonlinear. Linear distortions consist of group delay, echoes, and channel ripple/tilt to name a few. Nonlinear distortions are created by mixing signals with themselves or other signals, and this mixing process creates energy at new frequencies. This distortion is also called intermodulation distortion (IMD). Cable plants have both types of distortions, and while linear distortion can generally be remedied with equalizers, nonlinear distortions are much harder to remove. Generally, it is best to avoid generating nonlinear distortions in the first place, if possible.

Mathematically, the input-output relationship of many devices can be described as a polynomial or Taylor series as shown below. More is explained in Appendix 8.3.

$$E_{out} = A \cdot E_{in} + B \cdot E_{in}^2 + C \cdot E_{in}^3 \dots \quad (1)$$

E_{out} is the composite output signal, E_{in} is a composite input signal, A is the gain, B is a coefficient for the second order distortion, and C is a third order coefficient. Additional higher-order coefficients typically exist and may not be ignored if input signal levels are large.

Figure 1 illustrates a transfer function modeled as a third order Taylor series. An input sine wave passes through a device with third order distortion, such as a push-pull amplifier. Most cable amplifiers are a push-pull design to cancel 2nd order distortions. In the figure, the resulting distorted output wave is illustrated as a red curve, while a desired undistorted amplifier waveform is black. The distance between the red curve and the black curve is the voltage of the distortion energy.

Figure 1 –Sine wave input applied to nonlinear circuit produces a distorted sine wave.

Figure 2 is a spectral plot of 2nd and 3rd order output products created by two sine waves, f_1 and f_2 . Consider an input signal E_{in} comprised of just two sine waves, f_1 and f_2 . They are mixed in a circuit with a transfer function with only 2nd and 3rd order distortions. Equation (1) may be expanded using trigonometric identities. Second order distortion products will be created at $2f_1$, $2f_2$, f_1-f_2 , and f_1+f_2 . Third order distortion products will be generated at $3f_1$, $3f_2$, $2f_1-f_2$, $2f_2-f_1$, $2f_1+f_2$, and $2f_2+f_1$.

Figure 2 – 2nd and 3rd order spectral components created by sine waves at f_1 and f_2 .

Generally, higher order distortions than the 3rd order should be considered at high composite RF signal levels.

System designers use an intercept point diagram, as illustrated in Figure 3, to model nonlinear components. A plot is made of input signal level vs. output signal level, and the fundamental slope of that plot is the amplifier's gain. A second plot is made of 2nd order distortion level vs. input signal level, and that plot has a slope twice as steep as the fundamental due to the squared term in the Taylor series. Likewise, a third order distortion plot has a slope three times as steep as the fundamental due to the cube term in the Taylor series. If the 3rd order distortion line is extrapolated (red lines), it crosses the fundamental line at a point called IP3, or the 3rd order intercept point. This key number is used to predict expected distortion levels, and usually is specified on amplifier and mixer data sheets. Another point of interest on data sheets is the 1dB compression point, where the fundamental signal's output falls 1dB below its ideal level.

Figure 3 – Plots of fundamental, 2nd and 3rd order distortions vs fundamental RF levels.

In Figure 3, fundamental and 3rd order plot can be projected to find a third order intercept point. This method can be used to predict distortion levels in amplifiers or other nonlinear components. This projection graphing method applies also for corrosion diodes and shows how higher RF fundamental levels produce higher levels of nonlinear distortions.

For test purposes, cable engineers and technicians sometimes raise (or lower) plant levels by a decibel to identify if resulting nonlinear distortion energy goes up by 2 or 3 dB, identifying the distortion as 2nd or 3rd order. To properly perform this test, pilot signals must be held constant because amplifier automatic gain controls (AGCs) will attempt to change gain.

Typically, digital cable signals being transported have a flat spectral energy with an approximately rectangular spectral shape. An analysis method for nonlinear distortion is to use a double or triple frequency-domain convolution of the input signal with itself. This method is used because a convolution in the frequency domain is mathematically equivalent to a multiplication (e.g. squaring or cubing) in the

time domain, and vice-versa. Figure 4 illustrates the creation of 2nd and 3rd order nonlinear distortion products. The convolution of a rectangular spectrum with itself produces a triangular shape on a linear vertical scale occupying twice the original rectangular spectrum, while a triple convolution of a rectangular spectrum with itself produces a “haystack” shaped spectrum occupying three times the original rectangular spectrum. Figure 4 illustrates a relatively narrowband input OFDMA signal 70 MHz to 100 MHz (red) which creates 2nd and 3rd order distortion products. Distortion products are not drawn to scale for the sake of clarity. The more convolutions a rectangular signal undergoes, the wider its resulting nonlinear distortion spectrum gets.

Figure 4 – Non linear distortion

The spectral plot in Fig. 4 shows how a rectangular-shaped block of spectrally-flat energy, such as an OFDMA or OFDM spectrum (in red) produces nonlinear distortion products (in black). The vertical scale is linear. The 2nd order products employ as double convolution, producing a triangular-shaped spectrum. 3rd order distortion products create haystack-shaped spectral energy. Occupied bandwidth increases linearly with each higher order distortion coefficient and the distortion takes on a relatively “flat” spectrum. This is particularly true for wide transmitted rectangular (bandwidth) blocks.

The spectral photo in Figure 5 explains why we generally have not been affected by nonlinear distortion products with a sub-split frequency plan inside home wiring up to this point. If, for example, an ATDMA upstream single carrier transmission at 30 MHz is 6.4 MHz wide, the second order difference term is 0 MHz to 6.4 MHz yet cable upstream amplifiers do not pass energy below 5 MHz. The second order sum products will be 12.8 MHz wide centered at 60 MHz, so 2nd order distortion can affect downstream signals located between 53.6 MHz and 66.4 MHz but received signal degradation occurs only for the duration of a burst upstream transmission.

Figure 5 – Schottky Diode distortions

Figure 5 is a lab experiment of a single carrier 6.4 MHz signal at 33.8 MHz being distorted by a Schottky diode producing 2nd and 3rd order distortions (lower plot). LeCroy DSO digital oscilloscope has a horizontal frequency range of 0 MHz to 200 MHz, and 10 dB/div is vertical scale. Upper plot is voltage vs. time, captured at 500 Msamples/second.

2.2. Background on CPD and PIM

CPD has long been a known impairment source for downstream cable plant. The distortion is created by corrosion diodes in cable plant, usually located in hard line plant where signal levels are large due to nearby line amplification. High level downstream signals produce nonlinear distortion in all bands, but the distortion is visible in the upstream band. [9]

PIM is a well-known impairment in wireless systems also caused by corrosion, and it sometimes occurs on RF feedlines. Because bandpass filtering is possible, the biggest concerns are third order distortions located just above, just below, and on the carrier. Both CPD and PIM are caused by corrosion diodes, and result in nonlinear distortions in RF. Therefore, CPD can be considered a subvariant of PIM, which is a generic term.

A question arises why CPD only seems to affect upstream signals, while it appears to have relatively flat spectral content. See Figure 6, which shows typical upstream and downstream carrier levels (per 6MHz) at the output of a downstream amplifier, which is also the input of an upstream amplifier. Assuming CPD is spectrally relatively flat, with a -40dBc distortion relative to downstream carriers each at +50 dBmV, upstream signals experience a 18dB carrier-to-noise ratio. This ratio is below the threshold for a 64-QAM upstream receiver.

Figure 6 – CPD non linear distortions in downstream

Figure 6 is a diagram explaining why CPD nonlinear distortion is seldom observed on downstream channels. As an example, in a 6 MHz band, if a downstream signal is at 50dBmV and creates a spectrally-flat CPD distortion -40dBc relative to the downstream carrier level at the output of a downstream amplifier, distortion power level is -10dBmV. So, it is relatively harmless to a downstream carrier. But an upstream carrier, attenuated by a flat loss of a 32dB tap, suffers a modulation error ratio (MER) degradation of only 18dB (28dB-10dB). This is below threshold and is a continuous impairment to all upstream signals in the node due to noise funneling.

One advantage that coaxial cable signals have over long term evolution (LTE) signals is cable composite signal levels are much lower, such as approximately 1-2 watts for cable versus 20 watts for cellular transmissions. However, cable plant has many more connectors relative to a cellular feedline and antenna. Cable downstream also employs uptilt, placing more energy into the higher frequencies. This design will cause some distortion components to land at higher frequencies, which hopefully are out of band.

3. Lab Experiments

It has been observed in lab experiments that a wide OFDMA transmission can produce relatively flat distortion energy over a wide band. If a strong signal, such as a wide OFDMA transmission, mixes with itself in a corrosion diode, a difference product will start at DC (0 HZ) and extend to the bandwidth of the OFDMA carrier with a triangular-shaped spectrum (viewed on a linear display). This is a 2nd order difference mixing product. However, if the OFDMA transmission mixes with another strong signal, such as a MoCA[®] transmission or a citizen band (CB) transmission ingress signal, a difference product will not be centered at direct current (DC), but at a difference frequency, as expected. For example, an OFDMA transmission centered at 200MHz can mix with a MoCA signal centered at 1150 MHz and produce interference centered at 950 MHz, which is in a downstream frequency band. The 2nd order interference will be a convolution of the MoCA signal's spectrum with an OFDMA signal's spectrum.

A first test was to pass an ATDMA single carrier 6.4 MHz signal through a corrosion diode simulator circuit, with a Schottky diode. The spectral plot was previously illustrated in Figure 5, showing the

expected 2nd and 3rd order distortion products. This plot can be compared to Figure 4, which illustrates frequencies at which distortion products are expected.

The circuit used is illustrated in Figure 7 was used to produce upstream-only FDD distortion products. This circuit simulates corrosion in the outer conductor of a coaxial connection, such as a ground block. A shunt resistor's value was varied to increase the amount of distortion caused by the nonlinear 1N5711 Schottky diode with a given RF drive level. Two duplex filters were used to prevent downstream nonlinear distortion, which can potentially cause interference with the cable modem's (CM's) reception. The optional inductor was used to prevent DC bias on the diode and has very large inductive reactance at test frequencies.

Figure 7 – Circuit simulation of corrosion in a drop.

Figure 7 is a circuit used in the lab to simulate corrosion in a drop. Two mid-split diplexers were used with a mid-split diplexer to limit the effects of distortion to only the upstream signal. The CM operates on a mid-split frequency plan. The shunt resistor (R=) is varied to increase or decrease MER caused by the nonlinear diode. The meter function (M), which may be located at the headend, samples upstream energy which is distorted.

Figure 8 is a pair of plots obtained from a LeCroy HDO 6104-MS digital oscilloscope. The top plot is voltage vs. time, and the lower plot is a fast Fourier transform (FFT) of the time samples. The sample rate was 500 M-samples per second. The corrosion diode is shunted with 0 ohms and thus had no effect. The OFDMA transmission was almost continuous due to heavy data loading, and the occupied bandwidth was 40 MHz to 80 MHz. Note that there is negligible nonlinear distortion.

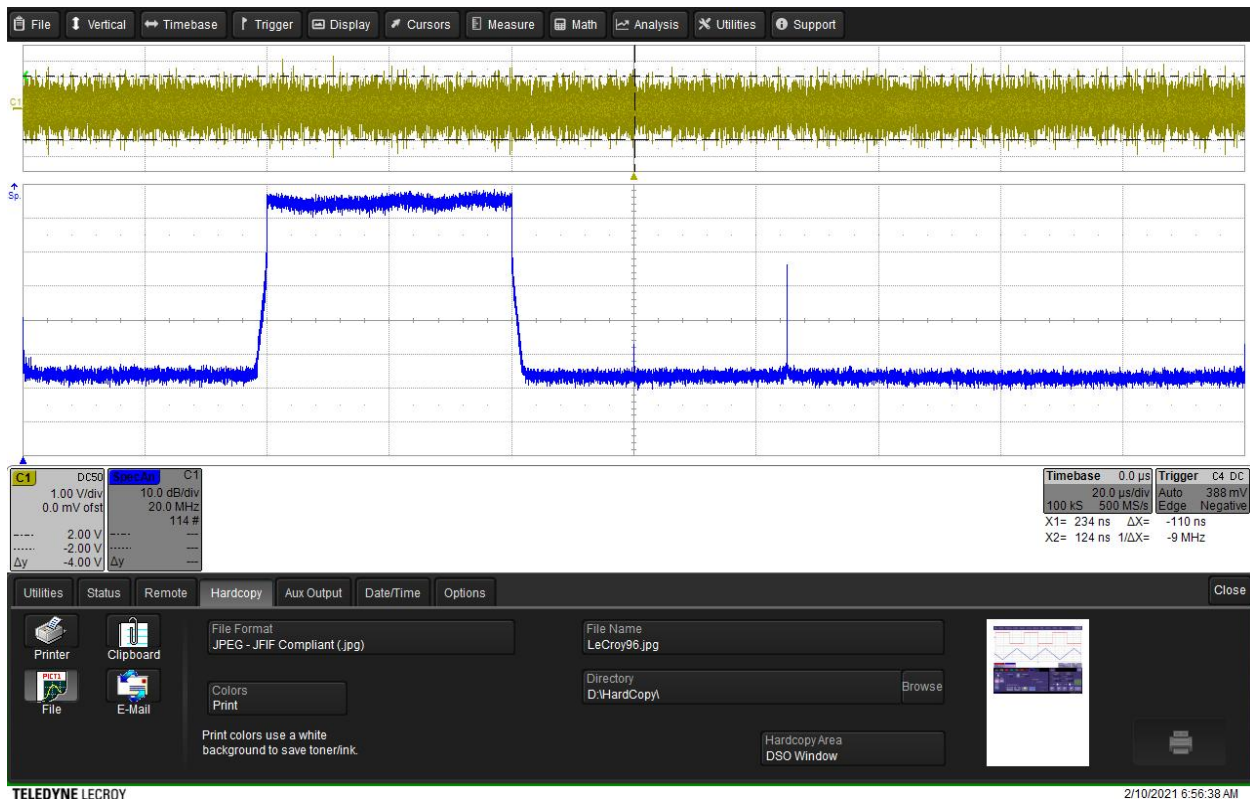

Figure 8 – OFDMA spectral plot

Figure 8 is a spectral plot of 40 MHz to 80 MHz OFDMA signal with $R = 0$ ohms (no corrosion diode effects). Top trace is voltage vs time, and bottom trace is dB magnitude vs. frequency. MER of 64-QAM OFDMA signal was an excellent 48.7 dB.

Figure 9 is a spectral plot with a shunt resistor value of 39 ohms, showing broadband distortion, notably sum and difference 2nd order.

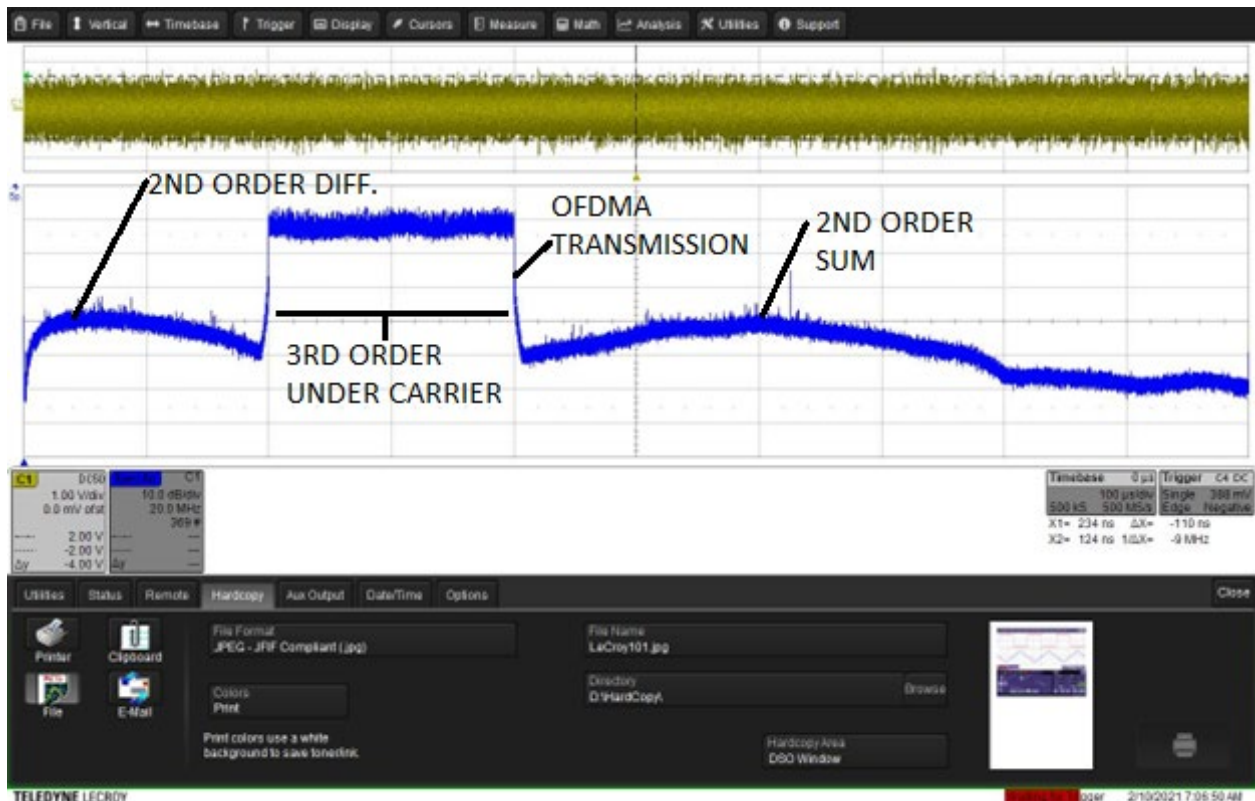

Figure 9 – OFDMA spectral plot (Shunting corrosion diode)

Figure 9 is a spectral plot of 40 MHz to 80 MHz OFDMA signal with $R = 39$ ohms (shunting corrosion diode). Transmit power was approximately 47 dBmV, and a MER of 64-QAM signal was 36.5dB. Observe wide spectrum of 2nd order distortion of difference products (on left) and sum products (on right). 2nd and 3rd order distortions overlap with a wideband transmission.

Figure 10 is a cross correlation plot of 2nd order measured lab distortion with ‘manufactured’ distortion. This method was published in 2013 [6]. It uses the received OFDMA carrier to manufacture a 2nd order distortion signal. That distortion energy is cross correlated with the filtered received energy at a frequency where 2nd order distortion is expected. This testing method is practical because upstream triggered upstream spectrum capture (UTSC) can capture a signal with nonlinear distortion. This cross-correlation method can be used for 3rd order distortion but works best where the cross-correlation capture is performed in a vacant band, such as with an active-quiet probe measurement.

Figure 10 – Cross -correlation plot

Figure 10 is a cross-correlation plot of the filtered signal time domain signal (measured) illustrated in Figure 8 with a mathematically-created signal (manufactured) created by squaring the filtered time domain signal illustrated in Figure 8, top trace. See 2013 technical paper [6]. An impulse at zero time offset indicates significant energy is 2nd order distortion.

Figure 11 is a plot of modulation error ratio (MER) on a 40 MHz to 80 MHz, 64QAM OFDMA transmission vs. shunt resistor value. Shunting the Schottky diode with a lower value resistor reduces distortion.

Figure 11 – MER of OFDMA signal

Figure 11 is a plot of MER of an OFDMA signal vs. shunt diode resistance, illustrated in Figure 6. When the shunt diode approaches zero, the corrosion diode is still present, but has no effect. A low value shunt resistance across a shunt diode is achieved by a high clamping force, achieved, for example, by a tight seizure screw or properly torqued housing bolts.

3.1. FDX

The process of PIM creation in FDX is going to be similar to FDD, but the lack of a duplex filter in the 108 MHz to 684 MHz FDX band means that distortion products can affect both upstream and downstream signals simultaneously.

Another concern is the adaptive equalizer in the fiber node won't be able to equalize non-linear distortion: it is designed to equalize linear distortion.

3.2. PNM

UTSC is essential in detecting anomalous US noise and distortion. Currently not all vendors implement this feature. Data should be in complex format for DSP. Furthermore, a UTSC capture needs to occur while a specific CM is transmitting at high power.

4. Field tests

CMs and cable modem termination systems (CMTSs) today are in some cases able to capture frequencies outside of their receiving ranges. Some CMs can capture low frequencies, and others can work in sub split mode on a mid-split or high split plant, etc. CMTSs can in some cases provide spectrum capture data (free run mode of upstream triggered spectrum capture or other means) for the downstream as well as upstream bands.

5. Detection Methods for Corrosion Diodes

Nonlinear distortion detection is a difficult problem because, in normal operation, upstream CM transmissions are brief RF bursts which are difficult for test equipment to capture (trigger on), and a source of which is generally difficult to identify.

A first detection method is to observe the MER for a particular CM's transmissions and compare them to the MER in transmissions from other CMs in the same node in approximately a same time period. Because of additive noise funneling, it is expected that all CMs in a fiber node should be experiencing a common noise background. However, a common noise background can vary with time. On the other hand, nonlinear distortion instantaneously follows the RF level of a transmission. A worse MER (relative to other subscribers in the node) could indicate nonlinear energy contamination in a signal path that a CM is using, but variable common background noise must be considered. An upstream MER test can be made on several CMs with nearly simultaneous upload speed tests at high RF power levels. This approach should yield a good indicator of homes with nonlinear distortion.

A second method is to look for distortion energy above the transmitter's frequency as a sum product or as harmonics. A challenge with this method occurs when the harmonics land in the downstream spectrum, which propagates away from the headend. Detection of nonlinear distortion in a CM on downstream caused by a CM's upstream transmissions may be considered a self-inflicted wound. However, using full band capture (FBC), if a CM can be forced into a speed test at a predictable transmit frequency, distortion energy may be observed either in a vacant band, or in the spectral null between two adjacent RF carriers. 2nd and 3rd harmonics can be observed with this method. A delta FBC plot can be made between CM transmitting and CM not transmitting.

A third method is to look for distortion energy below the transmitter's frequency, as a difference product. This method looks promising, but a UTSC needs to be done while a CM is at transmitting at high composite power levels. Testing needs to be initiated with a process such as a speed test, concurrent with a UTSC trace capture. It is expected that UTSC traces will contain 4096 in-phase and quadrature time samples.

A fourth method is to look for out-of-band energy that "follows" an RF transmission in time. Nonlinear distortion is created simultaneously with a transmission, so detection can be done in the time domain.

A fifth method is to plot a histogram of time domain voltage samples and look for non-symmetry, indicating signal clamping by a corrosion diode conducting. This method requires relatively severe clipping (distortion).

A sixth method is to analyze the MER error vectors in the OFDMA signal and correlate them with 3rd order distortion created from the error-free symbols. This requires the symbols in the OFDMA signal to not cross decision boundaries. [7]

Another method involving bonded upstream ATDMA signals is to get multiple upstream channels to transmit simultaneously from a single CM at high power. A block of three or four 6.4 MHz wide carriers can be approximately treated as one wide OFDMA-like block of random energy.

Distance ranging can be done to facilitate locating a corrosion diode in house. For example, the Optus (Australia) method using DSP can be employed using a test waveform such as a chirp signal. A display can show a technician TDR results for both linear and nonlinear distortions on the same screen. If timing matches, a linear discontinuity is the source of nonlinear distortion. This will speed troubleshooting.

The cable industry desperately needs functional, consistent, correct, upstream triggered spectrum capture capabilities. We don't yet generally have the ability to trigger an upstream spectrum capture for say a particular CM, which would be very helpful for finding PIM. Lacking that, we need alternate methods to identify and localize nonlinear impairments caused by upstream signals. Campos, Hamzeh, and Williams created a solution in 2013 [1]. Ultimately, capturing spectrum from a single CM transmitting would allow us to look for that PIM signature. If we are able to use UTSC to capture that signal, we could identify the distortion by the harmonics. If two narrow frequencies are transmitted, then a mixing product would reveal PIM if it appears. Note that two CMs transmitting at the same time, on two frequencies, could potentially create a mixing product in the plant, though that is less likely due to transmission loss leading to lower energy levels at potential points of corrosion diodes. Still, it may be possible, and may be found.

6. Conclusion

The question plant engineers have been asking is where are the corrosion diodes in my plant? A better question to ask is “where are the high value shunt resistors?” as very many junctions in the cable plant are candidates for a corrosion diode. A loose seizure screw is an example of how a shunt resistor may be created.

Calling a distortion-producing diode a PIM diode or a CPD diode is a relatively arbitrary distinction, as a single diode can be both a CPD diode producing upstream distortion, or a PIM diode producing downstream distortion. CPD is viewed as a subvariant or type of PIM.

For wide bandwidth transmissions, nonlinear distortion, particularly 3rd order, can be detected in adjacent frequency bands using UTSC, aided by a command to a CM to transmit a powerful signal, such as a speed test. An UTSC signal, captured as in-phase and quadrature component signals, can be processed to detect the presence of nonlinear distortions.

Clamping screws need to be correctly tightened to keep corrosion diodes shunted with low value resistors.

7. Appendix

7.1. Appendix A Diode Equation for a I-V Curve

The I-V curve (diode characteristic curve) can be found by the following nonlinear equation. The equation is also known as ideal equation of a diode or diode law:

$$i = I_s(e^{\frac{qv}{kT}} - 1)$$

Where

i = Current flowing through the diode

I_s = Reverse or dark saturation current (Typical value for silicon is 10⁻¹² amperes)

e = Base of the natural logarithm (2.71828)

q = Charge on electron (1.602 x 10⁻¹⁹) in coulombs, which the absolute value of an electron charge.

v = applied voltage across the diode

k = Boltzmann's constant (1.380 x 10⁻²³ joules/kelvin)

T = Absolute temperature in degrees Kelvin (room temperature is about 300 kelvin)

7.2. Throbbing CPD Caused by Loose Seizure Screws.

In Williams and Rupe, "Common Path Distortion in Cable Networks," [8], CPD is studied.

Instead of using two fixed CW carriers to implement the SCTE-109 CPD lab test procedure, if one (or both) of the two carriers is made tunable, the frequency of a returning CPD CW difference beat will also vary. The two downstream CW carriers are combined at the headend (or node insertion point) to make a headend 2-CW test signal. CPD in plant is revealed by the presence of the difference signal in the return band.

The difference signal is a 2nd order impairment and was observed in 7 out of approximately 70 nodes. 3 of the nodes had a static difference product (CW), but 4 were dynamic.

In [8], dynamic upstream CPD on a sub-split plant was observed to go up and down in power level at a 120 Hz rate. This was observed in four nodes in the hub site containing approximately 70 nodes, so dynamic throbbing was about a 5.7% problem, and static CPD was also about a 4.3% problem. Two CW signals, one at 800 MHz and one at 840.5 MHz, were applied at analog video carrier level into the downstream, and a modulated difference product at 40.5 MHz was observed. Figure 12 is a plot of RF level in dB vs. time, and repetition rate was 120 Hz. The spectrum analyzer's span was set for 0 Hz.

Fortunately, currently available CPD location gear detects both throbbing and static CPD.

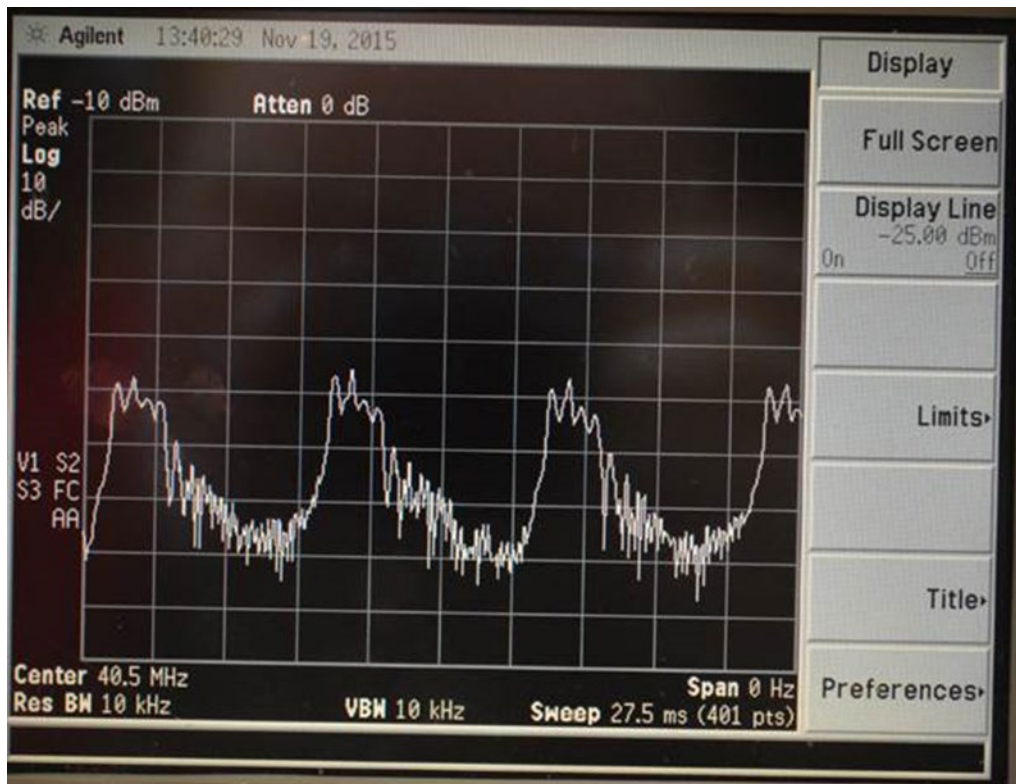

Figure 12 – 120 Hz CPD level vs. time.

In the field the level of a 40.5 MHz CW distortion (difference) signal at was observed to vary at a 120 Hz rate. The 40.5 MHz CPD signal is a distortion product created by mixing 800 MHz and 840.5 MHz CWs.

Figure 13 is a diagram of a seizure mechanism, which is one possible way that 120 Hz modulated CPD can be created. At point “A,” a resistive connection is made from a loose seizure screw, and several amperes of AC current are flowing to power amplifiers. This condition causes an AC voltage difference between the seizure screw and coax center conductor that is proportional to AC current. Nearby, at points “B,” corrosion diodes are present. The corrosion diodes can only actively mix downstream signals while the AC voltage difference is small. Increasing clamping force makes the distortion disappear.

Figure 13 – Shunt resistance-nonlinear distortion

A diagram showing how a loose seizure screw creates a high value shunt resistance, which enables nonlinear distortion to occur.

7.3. Mathematics of nonlinear signals

To evaluate non-linear behavior up to a third order we represent the composite input E_{in} as:

$$E_{in} = \sin(\omega_1 t) + \sin(\omega_2 t) = \frac{e^{i\omega_1 t} - e^{-i\omega_1 t}}{2} + \frac{e^{i\omega_2 t} - e^{-i\omega_2 t}}{2}$$

where $\omega_1 = 2\pi f_1$ and $\omega_2 = 2\pi f_2$.

The composite output E_{out} is defined in equation 1 as:

$$E_{out} = A \cdot E_{in} + B \cdot E_{in}^2 + C \cdot E_{in}^3$$

Expanding the composite input signal

$$A \cdot E_{in} = A(\sin(\omega_1 t) + \sin(\omega_2 t)) = \frac{A}{2}(e^{i\omega_1 t} - e^{-i\omega_1 t} + e^{i\omega_2 t} - e^{-i\omega_2 t})$$

Expanding the square of the composite input signal

$$B \cdot E_{in}^2 = B(\sin(\omega_1 t) + \sin(\omega_2 t))^2 = B((\sin(\omega_1 t))^2 + 2 \sin(\omega_1 t) \sin(\omega_2 t) + (\sin(\omega_2 t))^2)$$

$$4E_{in}^2 = (e^{i\omega_1 t} - e^{-i\omega_1 t})^2 + 2(e^{i\omega_1 t} - e^{-i\omega_1 t})(e^{i\omega_2 t} - e^{-i\omega_2 t}) + (e^{i\omega_2 t} - e^{-i\omega_2 t})^2$$

$$4E_{in}^2 = (e^{i2\omega_1 t} - 2 + e^{-i2\omega_1 t}) + 2(e^{i\omega_2 t} e^{i\omega_1 t} - e^{i\omega_2 t} e^{-i\omega_1 t} - e^{-i\omega_2 t} e^{i\omega_1 t} + e^{-i\omega_2 t} e^{-i\omega_1 t}) + (e^{i2\omega_2 t} - 2 + e^{-i2\omega_2 t})$$

$$4E_{in}^2 = (e^{i2\omega_1 t} - 2 + e^{-i2\omega_1 t}) + 2(e^{i(\omega_1+\omega_2)t} - e^{-i(\omega_1-\omega_2)t} - e^{i(\omega_1-\omega_2)t} + e^{-i(\omega_1+\omega_2)t}) \\ + (e^{i2\omega_2 t} - 2 + e^{-i2\omega_2 t})$$

Expanding the cube of the composite input signal

$$C \cdot E_{in}^3 = C(\sin(\omega_1 t) + \sin(\omega_2 t))^3$$

$$E_{in}^3 = (\sin(\omega_1 t))^3 + 3(\sin(\omega_1 t))^2(\sin(\omega_2 t)) + 3(\sin(\omega_1 t))(\sin(\omega_2 t))^2 + (\sin(\omega_2 t))^3$$

$$8 \cdot E_{in}^3 = (e^{i\omega_1 t} - e^{-i\omega_1 t})^3 + 3(e^{i\omega_1 t} - e^{-i\omega_1 t})^2(e^{i\omega_2 t} - e^{-i\omega_2 t}) \\ + 3(e^{i\omega_1 t} - e^{-i\omega_1 t})(e^{i\omega_2 t} - e^{-i\omega_2 t})^2 + (e^{i\omega_2 t} - e^{-i\omega_2 t})^3$$

$$8 \cdot E_{in}^3 = e^{i3\omega_1 t} - 3e^{i\omega_1 t} + 3e^{-i\omega_1 t} - e^{-i3\omega_1 t} + 3(e^{i2\omega_1 t} - 2 + e^{-i2\omega_1 t})(e^{i\omega_2 t} - e^{-i\omega_2 t}) \\ + 3(e^{i\omega_1 t} - e^{-i\omega_1 t})(e^{i2\omega_2 t} - 2 + e^{-i2\omega_2 t}) + e^{i3\omega_2 t} - 3e^{i\omega_2 t} + 3e^{-i\omega_2 t} - e^{-i3\omega_2 t}$$

$$8 \cdot E_{in}^3 = e^{i3\omega_1 t} - 3e^{i\omega_1 t} + 3e^{-i\omega_1 t} - e^{-i3\omega_1 t} \\ + 3(e^{i\omega_2 t}e^{i2\omega_1 t} - 2e^{i\omega_2 t} + e^{i\omega_2 t}e^{-i2\omega_1 t} - e^{-i\omega_2 t}e^{i2\omega_1 t} + 2e^{-i\omega_2 t} - e^{-i\omega_2 t}e^{-i2\omega_1 t}) \\ + 3(e^{i\omega_1 t}e^{i2\omega_2 t} - 2e^{i\omega_1 t} + e^{i\omega_1 t}e^{-i2\omega_2 t} - e^{-i\omega_1 t}e^{i2\omega_2 t} + 2e^{-i\omega_1 t} - e^{-i\omega_1 t}e^{-i2\omega_2 t}) \\ + e^{i3\omega_2 t} - 3e^{i\omega_2 t} + 3e^{-i\omega_2 t} - e^{-i3\omega_2 t}$$

$$8 \cdot E_{in}^3 = e^{i3\omega_1 t} - 3e^{i\omega_1 t} + 3e^{-i\omega_1 t} - e^{-i3\omega_1 t} \\ + (3e^{i(2\omega_1+\omega_2)t} - 6e^{i\omega_2 t} + 3e^{-i(2\omega_1-\omega_2)t} - 3e^{i(2\omega_1-\omega_2)t} + 6e^{-i\omega_2 t} - 3e^{-i(2\omega_1+\omega_2)t}) \\ + (3e^{i(2\omega_2+\omega_1)t} - 6e^{i\omega_1 t} + 3e^{-i(2\omega_2-\omega_1)t} - 3e^{i(2\omega_2-\omega_1)t} + 6e^{-i\omega_1 t} - 3e^{-i(2\omega_2+\omega_1)t}) \\ + e^{i3\omega_2 t} - 3e^{i\omega_2 t} + 3e^{-i\omega_2 t} - e^{-i3\omega_2 t}$$

Therefore, by expressing ω as $2\pi f$ and analyzing the first second and third order distortion, we have that the frequency components in E_{out} are:

$f_1, f_2, 2f_1, 2f_2, 3f_1, 3f_2, f_1+f_2, f_1-f_2, f_2-f_1, 2f_1-f_2, 2f_2-f_1, 2f_1+f_2, 2f_2+f_1$

DOCSIS 4.0 Security: A Comprehensive Guide to Successful Deployments

1. Introduction

DOCSIS[®] 4.0 security introduces several important enhancements when compared to previous generations of the protocol [SECv4.0]. To better understand the impact and use of DOCSIS 4.0 new features and how they relate to today's deployments and practices, let's start from reviewing the history of DOCSIS security and its evolution.

The first version of the Data Over Cable Service Interface Specification or DOCSIS[®] was released in 1997. The document specified the first standard approach to providing Internet access to subscribers over a cable operator's shared-access Hybrid Fiber-Coaxial (HFC) network (i.e., cable network).

The initial DOCSIS security architecture supported two major schemes: the Baseline Privacy Interface (BPI) and the Full Security (FS), a Security System with a removable security module. These two schemes specified the requirements to implement DOCSIS' two main security goals of protecting users and operators from data privacy issues and theft-of-service. The DOCSIS 1.0 specification eventually dropped FS due to a lack of support from the community. DOCSIS 1.1 strengthened BPI with its implementation of BPI+, which later evolved into the DOCSIS Security Specification in DOCSIS 3.0 and 3.1.

1.1. DOCSIS 3.0 and The Enhanced Secure Provisioning (ESP)

The DOCSIS 3.0 Security Specification [SECv3.0] introduced several new components that built upon the BPI+ (V1) Specification such as the Enhanced Secure Provisioning (ESP), extended support for Revocation Status Checking, and PKI Updates.

The Enhanced Secure Provisioning, or ESP, refers to securing the cable operator's operational support systems (e.g., the CM provisioning process, including Dynamic Host Configuration Protocol (DHCP), Time of Day (ToD), and TFTP). Securing these processes played a critical role in protecting the CM and the cable network from unauthorized access and theft-of-service attacks that cable operators were experiencing. Specifically, it prevented hacked modems from requesting unauthorized services.

DOCSIS 3.0 Security Specification also introduced a very important tool: certificate revocation status checking. Specifically, DOCSIS 3.0 supported two standard methods of certificate revocation: Certificate Revocation Lists (CRLs) and Online Certificate Status Protocol (OCSP). DOCSIS 3.0-compliant CMTS-es support configuration of none, one, or both certificate revocation methods.

On the PKI side, DOCSIS 3.0 Security leverages the same infrastructure (PKI) and the same authentication protocol that was used in the previous version of DOCSIS, but it introduces a new CVC infrastructure that supports a three-tier certificate chain architecture (i.e., Root, Intermediate, End-Entity). The support for the new CVC SubCAs was actually employed later in DOCSIS 3.1 security specification as part of the 2nd Gen DOCSIS[®] PKI, namely the "New PKI".

1.2. DOCSIS 3.1 and The Second Generation DOCSIS[®] PKI (The New PKI)

The new DOCSIS 3.1 Security Specification [SECv3.1] was introduced to strengthen the cryptographic parameters used during authentication. While DOCSIS 3.1 retains all the DOCSIS 3.0 Security features, it upgrades the PKI to a new infrastructure (2nd Gen DOCSIS[®] PKI) and increased the allowed size of cryptographic keys for both authentication and encryption.

On the PKI side, for DOCSIS 3.1, CableLabs defined an entirely new PKI hierarchy. The legacy PKI was halfway through its 30-year lifecycle, and it was starting to show its age with key sizes that needed

increasing and Hash Algorithms (i.e., SHA-1) whose use was being deprecated by NIST due to discovered weaknesses in the algorithm. To address this problem, the new PKI introduced the use of SHA-256 for digital signatures.

The overview of the security features of DOCSIS (1.0-3.1) are summarized in Table 1.

Table 1 - DOCSIS Security Evolution (1.0-3.1)

DOCSIS 1.0-3.1 Security Overview					
		DOCSIS 1.0	DOCSIS 1.1 & 2.0	DOCSIS 3.0	DOCSIS 3.1
Baseline Privacy Key Management (BPKM)	CM Public Key	768-bit key, 1024-bit key	768-bit, 1024-bit	768-bit, 1024-bit	768-bit, 1024-bit, 2048-bit key
	Authorization Key (AK)	64-bit key	160-bit key	160-bit key	160-bit key
	AK Generation	Random key generated by the CMTS and sent to the CM			
	AK Encryption	RSAES-PKCS1-v1_5	RSAES-OAEP	RSAES-OAEP	RSAES-OAEP
	KEK	64-bit Key	128-bit key	128-bit key	128-bit key
	KEK Generation	Both CM and CMTS derive KEKs from a function using the Authorization Key and the SHA-1 Hash Algorithm.			
	TEK	64- bit key	64- bit key	64- bit key, 128-bit key	64- bit key, 128-bit key
	TEK Generation	Random key generated by the CMTS and sent to the CM			
	TEK Encryption	56-bit DES	56-bit DES, 112-bit DES	56-bit DES, 112-bit DES	56-bit DES, 112-bit DES
	Message Authentication Key (MAK)	160-bit key	160-bit key	160-bit key	160-bit key
	MAK Generation	Both CM and CMTS derive MAKs from a function using the Authorization Key and the SHA-1 Hash Algorithm.			
	Hash Algorithm	SHA-1	SHA-1	SHA-1	SHA-1
MIC	MIC	HMAC-MD5	HMAC-MD5	MMH-MAC	MMH-MAC
Data	Traffic Encryption	56-bit DES, 40-bit DES	56-bit DES, 40-bit DES	56-bit DES, 40-bit DES, 128-bit AES	56-bit DES, 40-bit DES, 128-bit AES
Auth	CM Authentication	MAC Address	X.509v3 RSA certificate	X.509v3 RSA certificate	X.509v3 RSA certificate
Code	SSD	Proprietary	1024-bit CVC, 1536-bit CVC, 2048-bit CVC	1024-bit CVC, 1536-bit CVC, 2048-bit CVC	1024-bit CVC, 1536-bit CVC, 2048-bit CVC
ESP	ESP	No	No	Yes	Yes

1.3. Distributed Access Architectures and New Security Needs

Since DOCSIS 4.0 relies on the use of distributed architectures to deliver increased speeds both downstream and upstream, it is important to assess and understand the boundaries of this new attack surface and the associated threats.

Distributed Access Architecture (DAA) is an evolved cable network architecture that decentralized the headend network functions by moving the PHY and/or MAC layer functions to the remote node of the access network, while other functions remain in the Converged Cable Access Platform (CCAP). Currently, there are three types of DAA networks: (1) the Remote PHY or R-PHY (2) Remote MACPHY architecture or R-MACPHY, and (3) Flexible MAC Architecture or FMA.

In R-PHY and R-MACPHY, the MSO network is split into “trusted” and “untrusted” domains. The RPD/RMD, coax access network and edge devices (e.g., CMs) are in the “untrusted” domain (i.e., either in the customer’s premises or deployed in the field). On the contrary, the CCAP core, authentication server and provisioning servers are located in the “trusted” domain that is usually under strict MSO physical control and where only authorized employees are allowed access (e.g., NetOps and NetSecOps).

With the introduction of FMA, virtualization and containerization techniques are used to ensure service availability and to optimize resource allocation for enhanced services capability. In FMA, the security boundary between trusted and untrusted domains is even more blurred, and, therefore, the need to verify the identity of all elements that are present in the network is critical and necessary. This approach to network security is referred to as Zero Trust Security. Operators may find themselves facing difficult choices when considering tradeoffs between security and service availability: strict revocation checking, frequent software updates, or unnecessarily short certificates’ validity periods can cause unexpected service availability issues, while loose security controls and exceptionally long certificate validity periods can put customer and organization assets under the potential risk of compromise.

The original threat model used to design the DOCSIS security protocol did not incorporate or anticipate the kinds of security issues introduced by distributed architectures and without specific hardware protections (e.g., secure key storage), it’s still possible to maliciously modify or replace device software and credentials, which might enable attacks such as Modem Cloning or Service Uncapping. For example, attackers could exfiltrate the device’s credentials or install malware (e.g., backdoors, bot agents, etc.) to perform active attacks such as ***Denial-of-service*** or ***Man-in-the-middle*** that can have very disruptive effects for the operator’s network.

To mitigate the possibility to carry out these new class of attacks, DOCSIS 4.0 introduced two new security controls that are meant to work together: device physical security and network identities.

On the physical security side, the new requirements are described in section 15 of [SECv4.0] and mandate for increased security of stored secrets (keys) (see Section 15.1 of [SECv4.0]) and the use of secure boot processes for CMs (see Section 15.2 of [SECv4.0]). The use of such measures is aimed at reducing the risk of unexpected/malicious changes in the software running on CMs.

When it comes to network identities, before DOCSIS 4.0, only the CMTS could verify the Cable Modem’s certificate, not the other way around. In fact, since no verifiable identity is used on the server side (CMTS) in BPI+ V1, an attacker may be able to intercept CMTS functionalities and redirect the messages to its own device or service by targeting, for example, fielded RPDs or RMDs. In this scenario, it is easy to show how an attacker could completely take over large amount of internet connections via malicious network configurations (i.e., DHCP, DNS, etc.) and services (i.e., Web, Mail, etc.). Similarly,

passive attacks are also possible where the customer's session is not actively modified but it is just monitored for "interesting" data.

As discussed in great detail in the next section, DOCSIS 4.0 supports a new version of the authentication protocol, namely BPI+ V2, that greatly reduces the possibility to carry out such attacks by requiring both the CM and the CMTS to verify each other identities before establishing a connection.

2. DOCSIS 4.0 Security Principles

One of the challenges faced in designing DOCSIS 4.0 was how to integrate the needed new security features such as Mutual Authentication or Perfect Forward Secrecy in a minimally disruptive fashion. The answer to this challenge was twofold: (1) provide support for the same BPI+ (V1) authentication protocol in use in previous version of DOCSIS (1.1-3.1) and, (2) introduce a new version of BPI+ (V2) that encapsulate the needed security enhancements.

Figure 1 - BPI+ Authentication Messages (V1 and V2)

Figure 1 provides an overview of the BPI+ authentication process (common across BPI+ V1 and V2) where the Auth Request and Auth Reply messages are used to establish a common encryption key (i.e., AES) between the CM and the CMTS.

To better understand the differences between the security features supported in the two versions of BPI+, let's compare their security features and how they relate to and solve the new threat model.

Message Authentication and Integrity. This security principle is related to protecting the integrity and providing verifiable origin information for exchanged messages during authentication. In BPI+ V1, neither the CM nor the CMTS authenticate (sign) the messages they generate. In BPI+ V2, the CMTS uses the public key of the CM's Device certificate to encrypt the authorization key for the destination CM. The lack of authentication is the source of many possible security vulnerabilities that can lead to very disruptive attacks (i.e., modifying exchanged messages, spoofing device identities, etc.). In BPI+ V2, both the CM and the CMTS are required to sign outgoing authentication messages sent to the other party and authenticating their peer's messages before processing them.

Perfect Forward Secrecy or PFS. This security principle is related to protecting data across sessions. Specifically, when PFS is supported, its use protects against the decryption of pre-recorded data even when the target Cable Modem (CM) private key has been compromised. In BPI+ V1, the session encryption key is directly encrypted under the public key of the CM certificate and an attacker can decrypt any prerecorded sessions between the CM and the CMTS by compromising the certificate's private key at some date in the future. In BPI+ V2 the encryption key is negotiated when establishing a new session by using a Diffie-Hellman key exchange over finite field or Elliptic curves. This prevents an attacker from decrypting previously recorded traffic that was protected under BPI+ V2 even if/when an attacker compromises the CM's private key.

Mutual Authentication or MA. This security principle is related to guaranteeing that no malicious entity is able to impersonate the other party when establishing/authenticating the communication session between the CM and the CMTS. This type of attack is usually referred to as a "Man-In-The-Middle" (MITM) attack and requires the ability to manipulate the traffic on the network. Because BPI+ V1 does not secure the CMTS (or network) identity (it does not provide certificate during connection initiation), BPI+ V1 is vulnerable to such attacks. Malicious actors could impersonate a CMTS without the CM being able to distinguish between the real CMTS and the attacker. In BPI+ V2, the CMTS provides a certificate to prove its identity and the CM can, in this case, easily identify the real CMTS by validating the CMTS' message signature and certificate. The incorporation of this CMTS certificate-based identity allows the CM to properly authenticate the CMTS via a digitally signed Auth Reply, thus preventing any non-authenticated or modified messages to be ignored.

Algorithm Agility. This security principle is related to the possibility to execute the authentication protocol independently from the underlying cryptographic algorithms selected for proving identities (e.g., RSA, Falcon, Dilithium, etc.). In BPI+ V1, as mentioned when describing PFS, the CMTS directly uses the RSA public key associated with the CM's certificate to secure (encrypt) the authorization. In BPI+ V2 the authorization exchange enables a variety of methods to determine an authorization key. This mechanism provides a path for enabling post-quantum-safe cryptography and classic/post-quantum hybrid identity certificates.

Increased size of encryption keys. This security principle is related to the normal evolution of cryptographic algorithms over time where it is understood that larger keys are needed to keep the same level of confidentiality. In BPI+ V1, although there are few options when it comes to negotiating line-rate symmetric ciphers (encryption algorithms), AES-128 is the only supported option that is considered secure according to today's best practices. DOCSIS 4.0 introduces support for negotiating larger key sizes (AES-256) to encrypt user-data traffic that aligns with current best practice and provides the same level of protection against quantum attacks that users enjoy today against classic ones.

Downgrade Protection. This security principle is related to protecting against malicious actors trying to negotiate a more vulnerable version of a protocol when multiple versions are supported. This is a very difficult problem to solve that generally affects Access Networks architectures such 3GPP networks. Since DOCSIS 4.0 supports two different versions of BPI+, without providing any protection, DOCSIS 4.0 could suffer from vulnerabilities similar to ones observed in mobile networks. To address this issue, DOCSIS 4.0 introduces the concept of Trust on First Use (TOFU) that requires a CM to store the minimum allowed version of the BPI+ protocol for subsequent authentications, as indicated by the CMTS, in a secure memory location on the CM after successful authentication. For example, a CM that authenticates with BPI+ V2 can be signaled by the CMTS to only communicate using BPI+ V2 for subsequent sessions – preventing an imposter CMTS from downgrading to BPI+ V1 on a subsequent connection.

In the rest of the section, to better understand the differences and similarities of DOCSIS 4.0 and 3.1, we provide a summary about what changes and what does not change when it comes to deployments.

2.1. From DOCSIS 3.1 to DOCSIS 4.0 Security: What Does NOT Change?

DOCSIS 4.0 supports two versions of the BPI+ authentication protocol: BPI+ V1 and BPI+ V2. While the latest version of the protocol (BPI+ V2) is only available in DOCSIS 4.0 mode, the first version of the protocol, i.e., BPI+ V1, is shared across almost all versions of DOCSIS, including DOCSIS 4.0 (1.1-4.0). A first advantage for retaining support for BPI+ V1 in DOCSIS 4.0 is the possibility to deploy new DOCSIS 4.0 devices without the need for updating existing procedures, thus reducing the extra overhead of deploying new technologies that might come with new requirements. A second advantage is related to the fact that since in BPI+ V1 the CMTS does not need a device certificate, deploying DOCSIS 4.0 with BPI+ V1 does not introduce new requirements (for security) when compared to previous versions of DOCSIS such as DOCSIS 3.0 or DOCSIS 3.1. However, as discussed previously, with the introduction of distributed nodes outside the operator's trusted domain, the attack surface has increased. When enhanced authentications are needed, BPI+ V2 can be enabled to address the new security risks (see Section 2.3 for more details).

From the *Secure Software Download (SSD) standpoint*, DOCSIS 4.0 design applies the same principle that was used for the authentication protocol: keep support for current procedures and provide the possibility for upgrading to a more efficient one when needed. In fact, in DOCSIS 4.0 *there are two different mechanisms that can be used to enable SSD on a device*. The first one is the same leveraged in DOCSIS 3.1 where the use of a Manufacturer's CVC and/or an Operator's co-signer CVC certificate(s), in the config file (or via SNMP SET), triggers SSD procedures. The second mechanism that directly use the Firmware Authentication Header (FWAH) is detailed in the next section.

Another important similarity between DOCSIS 3.1 and DOCSIS 4.0 is *the use of the same PKI*. Differently from the previous DOCSIS update (DOCSIS 3.0 → DOCSIS 3.1), DOCSIS 4.0 uses the same Root of Trust that is used in DOCSIS 3.1. This means that DOCSIS 4.0 can use the same procedures and Trust Anchor used in DOCSIS 3.1 to validate device certificates.

When looking at the *backward compatibility with previous versions of DOCSIS*, it is important to understand what type of certificates might be needed. Specifically, while DOCSIS 4.0 devices use a single certificate to connect to both DOCSIS 4.0 and DOCSIS 3.1 CMTS¹ by using a *Common Cable Modem* certificate profile, they will still need a DOCSIS 3.0 CM certificate to be able to connect to pre-3.1 CMTS. The reason for this is that DOCSIS 3.0 and DOCSIS 4.0 do not share the same Root of Trust and, therefore, separate certificates are still needed, exactly as for DOCSIS 3.1 devices.

Support for revocation also remains untouched from D3.1 and D3.0 specifications. In fact, besides the use of CMTS-related revocation information when BPI+ V2 is enabled, the validation of CM certificates is delegated to the CMTS. During this process the CMTS can use CRLs or OCSPs to check the status of the CM's certificate and take proper action about it (or just report it). Support for revocation status checking for the network (CMTS) certificate is discussed in the next section.

What about EAE? DOCSIS 4.0 support for EAE is backward compatible with previous versions of DOCSIS where the CMTS support for EAE is advertised via TLVs in downstream MDD messages. In DOCSIS 4.0, the usual TLV Type 6 that is used to advertise support for EAE for BPI+ V1 is joined by the

¹ DOCSIS 4.0 certificates are different from DOCSIS 3.1 ones, and a software upgrade might be needed for D4.0 devices to be supported by DOCSIS 3.1 CMTS.

new TLV (Type 23) that allows to specify additional options for BPI+ V1 and BPI+ V2 as described in the next section.

In summary, the security features and operations that remain common to both D3.1 and D4.0 are:

- DOCSIS 4.0 can use the same authentication protocol in use for DOCSIS 3.1 (BPI+ V1)
- DOCSIS 4.0 can use the same PKI in use for DOCSIS 3.1 (2nd Gen DOCSIS[®] PKI)
- DOCSIS 4.0 can use the same SSD procedures in use for DOCSIS 3.1
- DOCSIS 4.0 devices require, exactly as D3.1 devices, an additional certificate from the 1st Gen DOCSIS[®] PKI (“legacy” PKI) to authenticate in DOCSIS 3.0 networks (if the device supports D3.0 environments).
- DOCSIS 4.0 supports the same revocation options available in DOCSIS 3.1 and DOCSIS 3.0.

In the next section we look at the aspects that have changed and their impact on DOCSIS 4.0 deployments.

2.2. From DOCSIS 3.1 to DOCSIS 4.0 Security: What Changes?

While support for BPI+ V1 is shared across almost all versions of DOCSIS (1.1-4.0), DOCSIS 4.0 is the first version of DOCSIS to support BPI+ V2 that delivers new and enhanced security controls. Since BPI+ V2 introduces the most profound changes in DOCSIS security since the introduction of digital certificates in DOCSIS 1.1, a detailed description is provided in the next section while here we focus on the rest of the differences with DOCSIS 3.1.

On the certificate side, there are four important changes that need to be discussed.

First, although DOCSIS 4.0 uses the same PKI as DOCSIS 3.1, the contents of CM certificates for the two environments are different. In fact, while DOCSIS 4.0 uses the same algorithm (RSA) and key sizes (2048 bit) already in use in DOCSIS 3.1, certificates for D4.0 CMs are larger than their DOCSIS 3.1 counterpart because of the introduction of several standard extensions that deliver new security controls. The first change to notice is the use of the Authority Information Access (AIA) extension to carry the location of the authoritative OCSP server that the CMTS can use to check for the revocation status of certificates. This change fixes the status of revocation in D3.1 and D3.0 where the absence of such data makes revocation checking very hard in practice. Another important change in the certificate profile is related to the introduction of a new concept in DOCSIS: **roles or functions**. Indeed, D4.0 certificates use a well identified set of Object Identifiers or OIDs inside the Extended Key Usage (EKU) extension that allow the verifier to check, based on the presence of specific values in the extension, if the connecting device is authorized (or not) to provide specific services. DOCSIS 4.0 defines two OIDs to identify CMTS functionality (`svcCMTS`) and CM functionality (`svcCM`) respectively. For example, when a CM is validating the CMTS certificate, it will look for the `svcCM` value in the EKU extension of the certificate and, if not found, rejects the connection if the `svcCMTS` value is not present in the certificate (i.e., the device was not authorized to provide CMTS services). In other words, in DOCSIS 4.0 not all certificates are created equal to prevent attacks where a legit certificate (e.g., a CM certificate) would be used to impersonate different roles (e.g., a CMTS). Table 2 provides the list of the EKU values supported in DOCSIS 4.0.

Second, before the operator enables BPI+ V2, the CMTS needs to be provisioned with a DOCSIS certificate. As we discussed earlier, the availability of CMTS credentials enables the CMTS to authenticate its own messages and, therefore, turning on BPI+ V2 not only lowers the risks of network compromise, but it also enables the possibility for Trusted Services from the network enabled by the

possibility to validate, and subsequently trust, the CMTS identity. The provisioning and management of CMTS certificates (i.e., renewal and installation) is a very new process for the DOCSIS community and it is expected to require dedicated support and/or automation. CMTS certificates have a validity of up to five years.

Four, DOCSIS 4.0 CMs use a single certificate to authenticate in both DOCSIS 4.0 and DOCSIS 3.1 modes. This means that D4.0 devices connecting to existing D3.1 networks will use certificates that although compatible with the DOCSIS 3.1 environment (i.e., same algorithm and key sizes), they may be larger in size than the D3.1 ones because they contain new standard extensions that are not present in D3.1 certificates.

Table 2 - Object Identifiers for EKU enabled functionalities in DOCSIS 4.0

Short Name	Name	Value	Description
svcCMTS	id-cl-pki-eku-CMTS	1.3.6.1.4.1.4491.2021.2.1.1	CMTS functionalities
svcCM	id-cl-pki-eku-CM	1.3.6.1.4.1.4491.2021.2.1.2	CM functionalities

On the CVC side there are some important changes. Differently from the DOCSIS 3.1 environment, DOCSIS 4.0 does not support CVCs from the 1st Gen PKI (or “legacy PKI”) when it comes to Secure Software Download and Firmware signing. Because the validation of “legacy” CVCs does not require to check expiration times against the current time, retaining support for “legacy” CVCs would introduce the possibility to modify the code loaded onto D4.0 devices with CVCs that use outdated (and possibly weak) cryptographic parameters such as 1024-bit keys and the SHA-1 algorithm for signatures (any time in the future). To eliminate the security risk, differently from D3.1, DOCSIS 4.0 devices only support CVCs from the 2nd Gen DOCSIS[®] PKI (i.e., the “modern” PKI). Additionally, a new mechanism to initiate the SSD process has been introduced that optimized validations of the firmware by directly supporting the use of the Firmware Authentication Header (FWAH) in config files or via SNMP SET (see Section 14.2 of [SECv4.0]).

On the revocation side there are also some changes. Although when BPI+ V1 is used there are no changes in how revocation works since D3.0, when BPI+ V2 is enabled and revocation checking is desired there is a new certificate to be validated, the CMTS one. Indeed, in BPI+ V2, the CMTS MUST transmit the OCSP response related to the status of its own certificate in the Auth Reply or Auth Reject message. The CMTS’s OCSP response can be cached by the CM and the CMTS for its entire validity time, to minimize the load on revocation infrastructures.

In the previous section we mentioned **some changes on the EAE side**. Although support for TLV Type 6, i.e., the EAE Enabled/Disable TLV (see Section 6.4.28.1.6 of [MULPIv4.0]), is maintained for backward compatibility, DOCSIS 4.0 devices use the new TLV of Type 23, i.e. BPI+ Supported Version and Configuration (see Section 6.4.28.1.22 of [MULPIv4.0]), to discover which BPI+ versions are enabled on the CMTS and what services are available with each one. This new TLV is a compound TLV that uses two bytes to indicate (a) the enabled version of BPI (i.e., 1-byte integer value), and (b) the associated enabled features (i.e., bitmask where Bit 7, when set to one, indicates EAE support). Multiple TLV 23 can be used to announce the enabled features for each BPI+ version that is enabled on the CMTS.

On the BPKM layer side, DOCSIS 4.0 introduces an important update: enabling fragmentation support to extend the supported maximum size of BPKM payloads to ~28 Kb. This change is implemented by introducing two new MMM messages (i.e., the BPKM-REQ5 and the BPKM-RSP5) in [MULPIv4.0] that leverage MMM V5 (instead of V1 as used in BPI+ V1) to support large BPKM

messages that may span more than one frame (i.e., up to 16 fragments). This solution not only enables the use of extra cryptographic material in the Auth Request / Auth Reply process without the need to add new messages and states in the State Machine, but it also opens up future paths for the deployment of new cryptographic algorithms such as Kyber (for key exchange) and Dilithium (for public/private keys), or even hybrid approaches that combine RSA with new types of algorithms [Pala21].

In summary, the security features and operations that change between D3.1 and D4.0 are:

- DOCSIS 4.0 supports multiple versions of BPI+ (i.e., BPI+ V1 and BPI+ V2)
- DOCSIS 4.0 can use advanced authentication features when enabling BPI+ V2
- DOCSIS 4.0 devices use certificates that are larger in size than D3.1 certificates
- DOCSIS 4.0 can use updated SSD procedures that optimizes early error detection
- DOCSIS 4.0 introduces two new approaches for delivering SSH access to devices without static secrets on devices
- DOCSIS 4.0 can enable or disable, for each enabled BPI+ version, the use of EAE independently.
- DOCSIS 4.0 introduces fragmentation support for BPI+ V2 messages

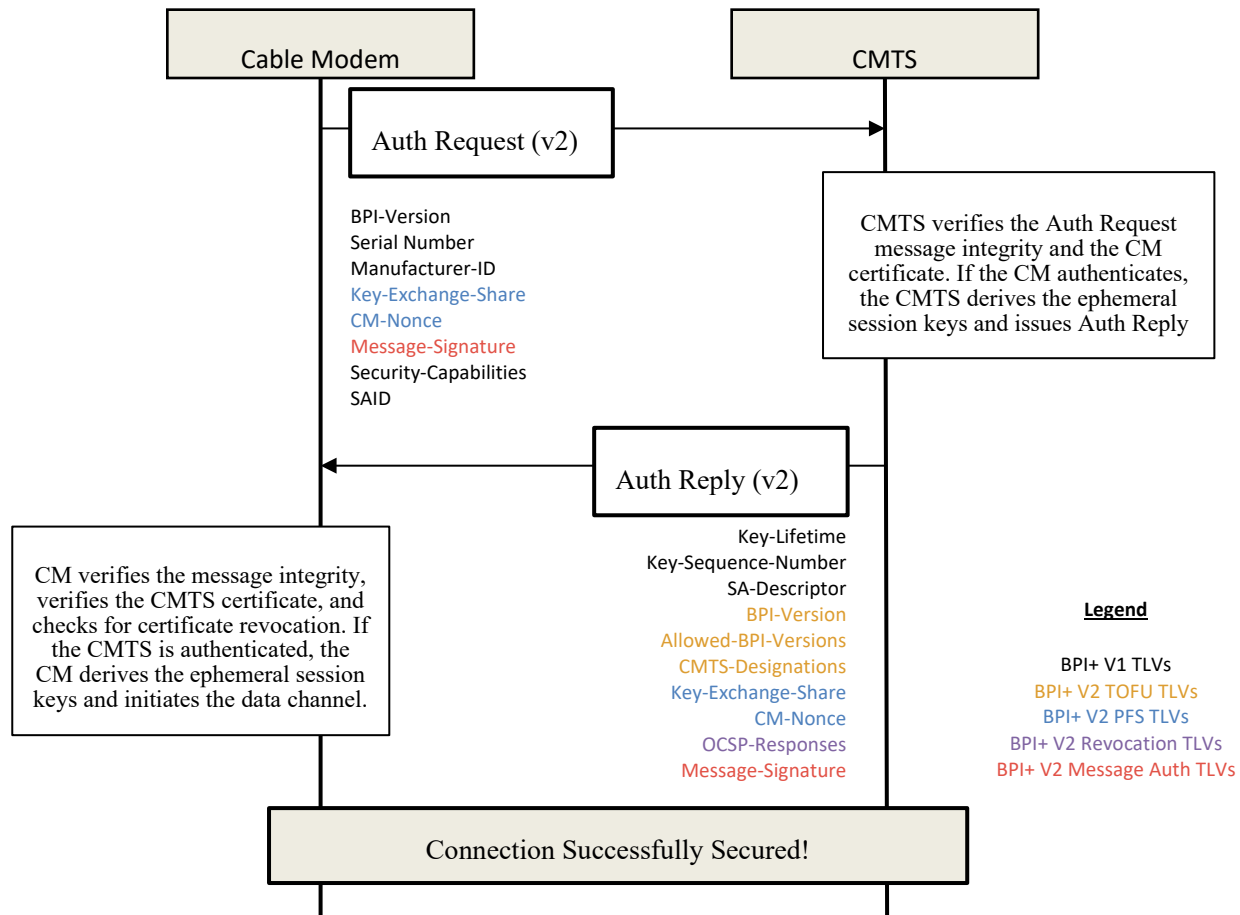

Figure 2 - BPI+ V2 authentication process

2.3. A New Authentication Mode (BPI+ V2)

The new version of the BPI+ authentication protocol supported in DOCSIS 4.0 is called BPI+ V2. Although this new version has the same structure of its predecessor (i.e., it still uses only two (2) messages to establish a secure connection between the CM and the CMTS and there is no change in the state machine), the security properties offered by BPI+ V2 are very different from the ones offered by BPI+ V1. Figure 2 depicts a BPI+ V2 message exchange where the newly defined TLVs are detailed.

A first fundamental difference between BPI+ V1 and V2 is the use of different versions of Mac Manager Messages (MMM) to encapsulate the protocol. In fact, while BPI+ V1 use MMM V1 messages that are limited in size to a single frame, BPI+ V2 defines two new messages, the BPKM-REQ5 and BPKM-RSP5, that leverage version 5 of the MMM headers. The new version of the messages supports payload fragmentation for up to 16 different fragments, thus pushing the maximum supported size for BPKM close to ~28Kb. This change allows for the deployment of larger cryptographic material that may require larger data structures during transport such as post-quantum keys, certificates, and signatures.

A second important feature of BPI+ V2 is the use of digital signatures to authenticate BPKM messages. The Message-Signature TLV, depicted in red color in the figure, carries a DER representation of a Cryptographic Message Syntax (CMS) data structure together with the signer's certificate and stores a

detached signature that is calculated over the entire BPKM message (i.e., the code, length, and payload up to, but excluding, the Message-Signature TLV itself). The use of this TLV implements the Message Authentication and Integrity principle. Moreover, the use of message authentication on both sides of the communication reflects a very important paradigm shift in DOCSIS security where, up to DOCSIS 3.1, the primary focus has been the authentication of Cable Modems only. As the deployment models for DOCSIS have become more distributed, the new BPI+ V2 introduces the support for Mutual Authentication principle via the presence of the Message-Signature TLV in both the Auth Request and Auth Reply (or Auth Reject) messages.

Another important enhancement introduced with BPI+ V2 is the use of the Diffie-Hellman (DH) key exchange mechanism to provide support for Perfect Forward Secrecy (PFS). Indeed, differently from BPI+ V1 where the authorization key is directly encrypted with the RSA public key of the CM's certificate, BPI+ V2 use the Key-Exchange-Share TLV to carry the cryptographic material to derive a common key across the CM and the CMTS. This new key exchange mechanism prevents the decryption of pre-recorded traffic for a CM even when the private key of the CM has been compromised, thus implementing the PFS principle.

The combination of Message Authentication and Mutual Authentication principles (implemented in BPI+ V2 via the Key-Exchange-Share and Message-Signature TLVs), enables a third one, i.e., Algorithm Agility. In fact, because of the separation of the algorithm used for the public key in the certificate and the algorithm used for key exchange, BPI+ V2 is algorithmically agile with respect to the device certificate, thus being able to support not only RSA-based certificates but other classic (e.g., ECDSA), post-quantum (e.g., Dilithium or Falcon), or hybrid (e.g., Composite-Crypto) algorithms.

With the introduction of multiple versions of the BPI+ protocol, a Downgrade Protection mechanism (TOFU) was introduced to provide protection against unauthorized downgrades. To support TOFU, BPI+ V2 uses two TLVs during the authentication process: the BPI-Version and the Allowed-BPI-Versions whose value can be used to manage which version of BPI+ should the device use after an initial successful connection. For example, during a BPI+ V2 authentication, the CMTS can use the Allowed-BPI-Versions TLV with the value of (1) to indicate that the CM can still use BPI+ V1, if needed, for subsequent authentications (i.e., legit downgrades).

In the rest of the section, we focus on the different options available for managing revocation status checking, an important aspect of successful deployments when it comes to security.

2.4. Certificate Revocations Updates

Support for checking the status of revocation for DOCSIS devices has been integrated into the specifications since DOCSIS 3.0 where both CLRs and OCSF checking were introduced to lower security risks associated with providing services to potentially compromised devices.

In DOCSIS 4.0, there are two main changes in the protocol that affect revocation checking procedures: the introduction of the CMTS (or network) identity, and the updating of certificate profiles.

The first change, the introduction of the network identity, required the definition of a new security control that would allow Cable Modems to know when (or not) to demand OCSF responses from the CMTS (i.e., in DOCSIS 4.0, CMs do not perform OCSF queries directly), and when they can ignore it. Since malicious attackers would try to remove checking of revocation information to make it easier to use compromised credentials, DOCSIS 4.0 does not leverage the usual control interface for configuring CM revocation checking requirements (i.e., config file TLVs or SNMP SETs), but the certificates itself.

Indeed, when CM revocation checking is desired, operators should use CMTS certificates that contain the URL of the OCSP responder (i.e., the Authority Info Access extension with the OCSP access method): when the URL is embedded in the certificate the CM understands that revocation status checking is required and will reject messages that do not carry the needed OCSP responses for the CMTS certificate. Vice versa, when revocation checking is not desired on the CM, operators should install CMTS certificates that do not contain the OCSP URL in them: when the URL of the OCSP responder is not embedded in the CMTS certificate, the CM understands that revocation checking is not required and, therefore, OCSP responses are not needed in the CMTS' messages. CMTS certificates that do not carry any OCSP revocation information are referred to as NRI certificates or No-Revocation Information certificates.

In other words, *the protected value, i.e., the extension, inside the certificate is the secure equivalent of configuring revocation checking on CMs via SNMP or configuration file options* since the presence of the extension in the certificate is protected by the CA signature on the device certificate itself (i.e., even the CMTS cannot lie about the requirement).

In this view, CMTS vendors should consider the possibility to support a dual-certificates configuration for their devices: one certificate for when CMTS certificate revocation checking is enabled and one certificate for when CMTS certificate revocation checking is disabled.

Figure 3 - Integrated BPI+ and Revocation Checking Flow

Figure 3 provides an overview of the generic workflow for the BPI+ protocol basic authentication messages when combined together with the revocation information checking process. We will use this figure throughout this section of the paper to discuss the details of the different deployment options available in DOCSIS 4.0.

As depicted in Figure 3, the retrieval of the revocation information can be triggered by new Authorization Requests coming into the CMTS, however it might be a good practice to keep a caching mechanism on the CMTS to allow for faster authentications (and re-authentications) and reduce the number of external

requests the CMTS issues (and rely upon) to complete the authentication. This is particularly true in the context of OCSP processing when a CMTS is rebooting and, in general, for CRL-based revocation checking where usually the validity period of CRLs is quite long (days or weeks). Since DOCSIS 4.0 explicitly allows for caching the revocation information for their entire validity period, it is important to leverage this option on the CMTS to deliver fast and efficient revocation status checking.

Another important consideration is related to the ability of the CMTS to directly connect to resources on the internet (not directly available on the operator's network). Usually, because of security concerns, CMTS-es are not allowed to access any resource on the Internet. When this is the case, the CMTS would not be able to query CRLs repositories or OCSP responders unless some "intermediary" is used. For example, operators can route all requests for revocation information via an HTTP proxy, thus allowing for easier monitoring (and restrictions) for which resources the proxy can access (e.g., only official OCSP repositories). When OCSP validity period and HTTP caching headers carry the same values, the HTTP caching mechanism can be used for both OCSP and CRLs.

However, when HTTP proxy services are not enough and operators would like to take control over the revocation information for the devices deployed in their own network, operators should consider the possibility to deploy local OCSP servers that can provide OCSP responses (locally) and, moreover, override revocation status (locally). The deployment of such services in the operator's network can enable the possibility to manage the revocation status of device certificates locally. For this option to be enabled, the operator needs an OCSP responder certificate from the DOCSIS infrastructure (for each D4.0 issuing CA) that can be used to setup the local service. Efficient open source implementations for in-line OCSP responders are already available (e.g., OpenSSL [OSS] or OpenCA OCSPD [OCAOD]).

In the rest of this section, we examine different deployment scenarios for enabling revocation checking on the server side, on the client side, or both.

2.4.1. Enabling Mutual Authentication without Revocation Checking

The simplest and most common deployment model is the one where there is no support for revocation status checking. This is the default deployment scenario in today's DOCSIS network where revocation checking is disabled or practically very difficult to implement because of the lack of OCSP URLs inside D3.0 and D3.1 certificates.

In this authentication mode, when BPI+ V1 or V2 are executed, the CMTS (in both BPI+ V1 and BPI+ V2) does not download any Certificate Revocation List (or CRL) nor any OCSP Responses to validate the revocation status of the device certificate. This means that authentications only rely on the information presented by the device (or the network) to decide if to allow the connection with the device (or the network). This means that the extra steps $\{1.a, \dots, 1.f\}$ from Figure 3 are not needed and will not be executed in both BPI+ V1 and BPI+ V2.

To achieve this configuration, the CMTS must be first configured to disable CRL and OCSP response (both). Changing the CMTS configuration is sufficient when only BPI+ V1 is enabled. However, to correctly handle the BPI+ V2 case, the CMTS must also be provisioned with a CMTS NRI certificate: the absence of the OCSP URL inside the certificate is used as the security control to communicate to the CM that no revocation checking is needed on this certificate when executing BPI+ V2 only (i.e., BPI+ V1 does not use any network identity and, therefore, there is no CMTS certificate to validate).

2.4.2. Enabling Mutual Authentication with CM's Certificate (client-side) Revocation Checking

Similarly, to D3.0 and D3.1, DOCSIS 4.0 supports checking the revocation status of connected devices when using either BPI+ V1 or BPI+ V2. Similarly, to the previous case, only when executing BPI+ V2 the CMTS NRI certificate is needed to be installed on the CMTS. In this configuration, OCSP responses are not sent inline from the CMTS to the CM during BPI+ authentications (i.e., because NRI certificates do not carry the URL of the OCSP responder), thus limiting the dependencies on the availability of revocation information to the CMTS only.

Since the CMTS is the ultimate controller that can allow or reject a CM during authentication, CMTS vendors have the possibility to implement different authorization policies can be enabled to better accommodate NetOps needs. For example, CMTS vendors could provide the possibility to have strict or permissive policies for allowing devices on the network only after passing revocation checking (strict policy) or allowing them even when revoked and, in that case, report it for monitoring or investigative purposes (permissive policy). Although a strict revocation is the most secure option (e.g., not allowing compromised devices to access any service), permissive policies might be implemented to monitor for potentially compromised or otherwise misbehaving devices. This approach allows for decoupling the decision to provision services to devices from the certificate revocation status (i.e., the revoked status becomes a factor in the decision, not the decision itself).

In this case, although both OCSP and CRL mechanisms can be used for checking the status of devices, it might be more efficient to enable CRL-based validation since a single CRL carries all relevant revocation information for all the certificates issued from the CA while OCSP responses are related to a single certificate entry. When using OCSP, individual request/response roundtrips have to be used for each CM the CMTS needs to validate the revocation status for, while a single CRL can be used to lookup the revocation status of all certificates issued from a CA (with the downside of being quite large if many certificates have been revoked).

2.4.3. Enabling Mutual Authentication with CMTS' Certificate (server-side) Revocation Checking

On the opposite side of the spectrum, this deployment model enables the revocation status checking for the CMTS certificate to authenticate the network. This use-case, because it involves the CMTS certificate, it is relevant only for BPI+ V2 authentications.

To achieve this configuration, operators must disable revocation checking on the CMTS, both CRL-based and OCSP-based mechanisms for the client side. By disabling revocation checking on the CMTS, the CMTS will not execute steps {1.a, ..., 1.f} from Figure 3 to validate the CM's certificate.

However, the CMTS still need to procure the OCSP response for its own certificate and send it to the CM in Auth Reply messages during BPI+ V2. Therefore, in this case, the CMTS still needs to execute steps {1.d, 1.e, 1.f} to be able to retrieve the OCSP response from the server (if not cached).

Differently from the two previous use-cases, the CMTS certificate must carry the URL of the OCSP responder in it to communicate to the CM that OCSP responses validation is required for this certificate. CMTS certificates that contains revocation information are referred to as "Full" or "Full CMTS" certificates.

As described in Section 2.3, that when validation checking is to be performed by the CM, the CMTS must provide the OCSP response inline during BPI+ authentications and that means that if a response cannot be fetched (or the cached version is expired), the CM will reject the CMTS certificate.

2.4.4. Enabling Mutual Authentication with Mutual Revocation Checking

The last use-case we want to explore is the scenario where both the client-side (CMs) and the server-side (CMTS-es) are required to check the validation status of the other party. This setting, as the previous one, is only relevant when BPI+ V2 is used.

To achieve this setup, the CMTS must be configured to enable the revocation checking of CMs' certificates (either via CRLs or OCSP) must be enabled on the CMTS. Moreover, the CMTS, exactly as the previous case, must be provisioned with a Full CMTS certificate to enable revocation checking on the CM.

In this configuration, the authentication message flow will actually use steps {1.a, 1.b, and 1.c} to validate the CM's certificate when the CRL mechanism is used or steps {1.d, 1.e, 1.f} to validate the CM's certificate when the OCSP mechanism is enabled. Additionally, steps {1.d, 1.e, 1.f} must be repeated to gather the revocation information of the CMTS certificate that needs to be sent inline when executing BPI+ V2.

3. Deployment Examples

As we have seen, DOCSIS 4.0 offers a series of new security features that can be independently enabled to lower the network's security risks. This section provides an overview of one of the possible paths to DOCSIS 4.0 deployment. We start by providing considerations on how to support D4.0 devices in existing networks (such as DOCSIS 3.1 or earlier) and then we focus on the impact of enabling the new security features when deploying new DOCSIS 4.0-enabled networks. The envisioned architecture is depicted in Figure 4 where it is assumed that the CMTS (i.e., or where the functionality is provided such as the CCAP Core or MAC-NE elements in distributed architectures) does not have direct access to external services. In this architecture, the CMTS can route all the HTTP request for CRLs and OCSP processing via the HTTP Proxy where strict access rules can be easily enforced.

Additionally, to improve network reliability, operators may deploy local OCSP Proxies and/or responders that can directly sign (or cache) valid responses locally. This solution can be used not only to improve the network reliability, but also to provide support for locally managed revocations that are specific for the operator's ecosystem such as tracking (permissive policy) or reject (strict policy) cloned or otherwise potentially compromised devices.

Figure 4 - Example Deployment with revocation checking support and local overrides

3.1. Preparing Your Networks for D4.0 CMs

To prepare the network for operating with DOCSIS 4.0 devices, there are important details that operators need to be aware of for successful deployments planning.

In Section 2.2, we discussed the additions made to DOCSIS 4.0 certificates when compared to DOCSIS 3.1 or earlier profiles (or configurations). It is therefore evident why DOCSIS 4.0 certificates are bigger in size than their DOCSIS 3.1 equivalent.

Because of the increased size of the certificates, even BPI+ V1 messages might hit the software limit imposed on the size of BPKM messages (1490 bytes)². The relaxation of the software limitation on BPKM messages is needed to enable the use of a common certificate when operating in DOCSIS 4.0 and DOCSIS 3.1 modes. Although this choice lowers devices cost because of the use of a single certificate, in some cases DOCSIS 3.1 CMTS-es might require a software update to enable processing BPKM messages that are larger than 1490 bytes. It is important to notice that the same issue does not affect pre-D3.1 backward compatibility: the common certificate cannot be used in this case, and, exactly as for DOCSIS 3.1 devices, a separate certificate issued from the 1st Gen DOCSIS PKI (i.e., the “legacy” PKI) is still needed

When operators are ready to offer higher speed tiers and additional services that come with it, networks can be upgraded by deploying new DOCSIS 4.0 CMTS (or their DAA equivalent), thus enabling new speeds and the possibility to upgrade the security features, if needed, at a later time. Let’s see how.

² The software limit stems from limitations in the frame size of DOCSIS 3.0 MAC and Phy layers that was wrongly directly imported in the DOCSIS 3.1 specifications without any update.

3.2. Upgrading Speeds, Not Security

When the time is right for a network upgrade, new DOCSIS 4.0 CMTS services can be enabled on the network. Besides the needed work to configure and upgrade the PHY layer to be able to deliver the new speeds, DOCSIS 4.0 does not require any changes from the currently used deployment model when it comes to security.

In previous Sections of the paper, we have shown how DOCSIS 4.0 networks can be configured to leverage the same authentication protocol used in DOCSIS 3.1 (and previous) networks (i.e., BPI+ V1) and how, additionally, it is possible to duplicate the existing networks configuration for revocation checking in the new environment. The combination of these two controls allows DOCSIS 4.0 deployments to leverage new speeds without requiring changes in NetOps because of security: a feature aimed at ease the transition, on the operator's time, to more secure options.

In other words, only when and if new security features are needed (i.e., PFS or MA), operators may decide to enable the use of BPI+ V2 according to their own deployment plans and schedule.

3.3. Enabling Advanced Security Features With BPI+ V2

During the development of DOCSIS 4.0, the need for providing trusted networks where the identity of the network is validated was quite evident: not only the use of a network identity enables more secure authentication and privacy options, but it also introduces the concept of authenticated and trusted networks that is the basis on top of which networks can offer trusted services. The need for trusted networks, combined with the need to mitigate new attack vectors related to new distributed deployment models, are some of the core reasons for enabling the new BPI+ V2.

When the new authentication protocol is enabled, a new set of controls is available to the operator via the configuration of the Persistent Security Attributes (PSAs). PSAs are stored in the secure memory of the CM and allow operators to further restrict accepted network/CMTS identities and protocol's versions during authentications (i.e., via the `Allowed-BPI-Versions` TLV) and are used to implement the downgrade protection mechanisms for BPI+. Additionally, PSA attributes are used to restrict what is considered valid with respect of network identities by requiring, in the CMTS certificate, the presence of specific values. For example, it is possible to configure a CM to only accept "Operator A" as the Organization field (O) in the certificate's subject name by using the `CMTS-Designations` TLVs in the Auth Reply message from the CMTS.

Enabling BPI+ V2, however, requires the provisioning and management of the CMTS certificate as discussed earlier. This means that managing CMTS (only when BPI+ V2 is enabled) will require supporting a new set of operations: from requesting the initial certificate (if not already installed by the Vendor) to regularly renewing it before expiration (i.e., once every 5 years). Although not part of DOCSIS 4.0 specifications, it is expected that automated certificate renewal protocols and tools will be developed and integrated with the increased enablement of BPI+ V2 across networks.

3.4. Enabling Revocation Checking and DOCSIS 4.0

As discussed throughout the paper and specifically in Section 2.4, DOCSIS 4.0 allows for very flexible configurations when it comes to revocation status checking. In fact, it is important to notice how enabling or disabling revocation status checking can be done independently from enabling or disabling the use of BPI+ V2. This capability is the key for empowering operators to choose the deployment path that is more relevant for their networks today and their upgrade path(s) tomorrow – even if they need to change it

during execution. In other words, because of the different options available in DOCSIS 4.0, revocation checking should not be considered a limiting factor for its deployment.

This said, because revocation checking has not been widespread enabled in the broadband community, enabling support for it (especially when requiring CMs to check revocation status of CMTS certificates) should be carefully planned and might require additional infrastructure services such as HTTP proxies or local OSCP responders as depicted in Figure 3.

4. Acknowledgments

The work described in this paper is the ultimate result of the contributions to DOCSIS 4.0 design and specifications from the whole community. We would like to recognize the many great contributions from both the Operators and the Vendors community without which DOCSIS 4.0 could not have happened. We would also like to recognize the continuous support and commitment to the DOCSIS 4.0 SEC WG activities from Ali Negahdar, Colin Dearborn, Dan Torbet, David Taylor, Margo Dolas, Jeff DeMent, Jeff Finkelstein, Owen Parsons, Onur Zengin, Pawel Sowinski, Philip Anderson, Ramy Elmoneiry, Sasha Medvinsky, and Satish Mudugere.

5. Conclusion

In this paper, we provide an overview of the many new security features in DOCSIS 4.0 with particular attention to the impact of its deployment on existing and new networks.

After a brief introduction where we describe the history of DOCSIS security together with considerations about new deployment models, the paper continues with a description of the security principles adopted in DOCSIS 4.0 and how they address new possible threats when considering distributed architectures. In particular, we have seen how DOCSIS 4.0 can be deployed by using the same authentication protocol and procedures that are in use in today's DOCSIS 3.1 networks and how operators can enable existing and new features by enabling BPI+ V2.

When it comes to revocation status checking, we also provided important considerations on how to support efficient revocation checking and described how to support different degrees of enforcement (i.e., strict vs. permissive policies).

Ultimately, DOCSIS 4.0 and BPI+ V2 open new future possibilities for the broadband industry and paves the road for practical solutions to address upcoming security issues or threats (such as post-quantum cryptography deployment for DOCSIS) while providing a cost-effective and efficient path to get there (algorithm agility).

1. Introduction

1.1 What Is DTP?

Mobile networks require high accuracy time and frequency synchronization. 3GPP mandates 1.5 μ s of timing accuracy from the base stations (BSs) to a common time reference [1]. Meeting this 1.5 μ s target avoids inter-base station interference in time-division duplex (TDD) networks. In addition, inter-network synchronization is required by the FCC for Citizens Broadband Radio Service (CBRS) and is recommended for other bands. In outdoor environments, Global Positioning System (GPS) signals are reliable and can be used to derive an accurate timing signal. However, when BSs are deployed indoors where GPS signals are unreliable, BSs need an accurate timing signal delivered over the backhaul link. DOCSIS Time Protocol (DTP) is designed to provide such a high-accuracy synchronization signal on the Hybrid Fiber Coaxial (HFC) network, serving as the Xhaul (Xhaul refers to backhaul, mid-haul, or fronthaul) for mobile networks.

Figure 1 shows a DOCSIS network as mobile backhaul and DTP as the timing source for a 5G New Radio (NR) or 4G Long-Term Evolution (LTE) base station. The CMTS gets timing signals from the Primary Reference Time Clock (PRTC) using the Precision Time Protocol (PTP), also known as the IEEE 1588 Standard. PTP cannot be directly used on an HFC network (see the reason in Section 3.2). The HFC network (CMTS, remote-PHY device (RPD)/remote-MAC-PHY device (RMD), amplifiers (A) and cable modem (CM)) uses DTP instead. The CM delivers PTP timestamps to BSs using PTP, which BSs widely support. Note that the terminology of PTP/DTP master/slave was used in the IEEE 1588 standards and the DOCSIS specifications. The IEEE 1588 working group is considering using more inclusive language: PTP timeTx and PTP timeRx to replace master and slave, respectively, and we use this new terminology in this paper.

Figure 1 – DTP supports 5G NR/LTE in the field.

1.2 Where Is DTP Needed?

Table 1. Mobile Network Timing Sources.

Timing sources	Accuracy	Applications
NTP	tens of ms	Not usable for BS
PTP	< 1.5 μ s	Widely supported by LTE/NR BS, PTP OTT on the HFC network performs poorly
GPS	a few ns	For outdoor BS
DTP	< 1.5 μ s	<i>Fills the gap!</i>

Table 1 lists potential timing sources for mobile networks. The Network Time Protocol (NTP) accuracy is in the order of tens of milliseconds, which does not meet the 3GPP requirements.

PTP over-the-top (OTT) on the HFC network performs poorly. GPS signal is unreliable in indoor or urban canyon environments. Multi-Service Operators (MSOs) are interested in deploying indoor small-cell networks using HFC as backhaul, for which DTP is the only option, as summarized in Figure 2.

Figure 2 – Where Is DTP Needed?

1.3 How Does DTP Work?

The CMTS, RPD/RMD, and CM all have their local timestamp. The task for DTP is to synchronize these local timestamps. As illustrated in Figure 3, the CMTS and RPD/RMD have a fiber connection, hence, they use PTP to update their local timestamp. The RPD maps its local timestamp into the DOCSIS 3.1 timestamp that is transferred to the CM via the coaxial plant. The DOCSIS 3.1 timestamp is delayed in the downstream path. The DOCSIS ranging procedure measures the round-trip delay between RPD and CM. This round-trip delay is defined as the true ranging offset (TRO). If the downstream and upstream delays in the cable plant are the same (ideally symmetrical), half of TRO is applied to correct the downstream delay for the CM local timestamp. The CM maps its local timestamp to a PTP timestamp output for mobile networks. The DTP timeTx in the CMTS and the DTP timeRx in the CM exchange messages that include parameters of the HFC plant. The DTP timeRx also reports the real-time TRO to the DTP timeTx. The CMTS uses half of TRO and other parameters to calculate the time adjustment, t_{adj} , that is applied in the CM.

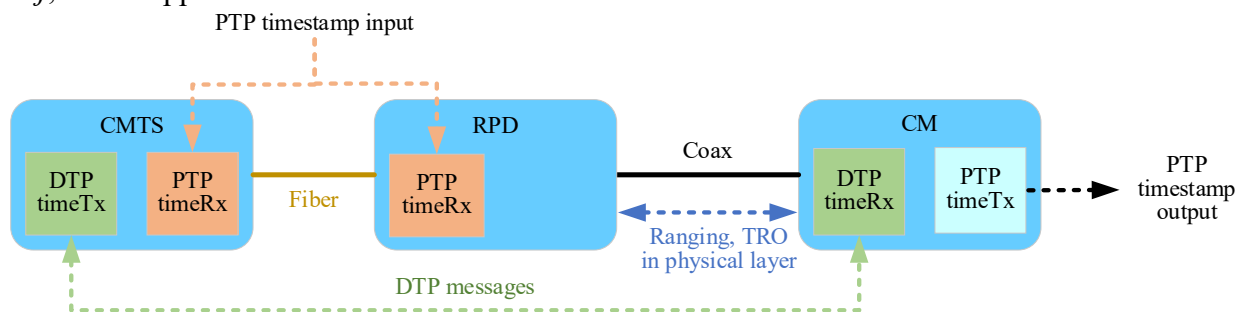

Figure 3 – How Does DTP Work?

DTP has many challenges, such as the asymmetrical delay in the HFC plant (the downstream and upstream delays in the cable plant are different, so half of the TRO cannot perfectly compensate the downstream delay), as well as some non-ideal effects in the CMTS, RPD/RMD and CM devices. A three-step DTP calibration procedure (see Section 7 in [8]) is needed to address these challenges.

1.4 DTP History and Status

DTP was invented in 2011 [2], standardized in the DOCSIS MULPI 3.1 Specification [3], and further incorporated in the DOCSIS SYNC specification [4] in 2020. DTP leverages existing DOCSIS hardware-based timestamp, accounts for path asymmetry, and provides timing performance independent of the traffic load on the DOCSIS network. DTP is being implemented in the industry. From September 2020, CableLabs, Charter Communications, Cisco, and Hitron started DTP proof-of-concept (PoC) tests. A DTP calibration procedure was designed to correct asymmetrical and other non-ideal delays in the HFC network. In December 2021, CableLabs/Kyrio developed a cloud database [5] that distributes the calibration data. The DOCSIS SYNC spec [4] was updated on July 15th, 2022, to describe the DTP calibration procedure and define the interface between the cloud database and CMTS.

1.5 DTP PoC Testing

The PoC testing was split into two phases. Phase I tests were conducted in a basic lab environment, and the results were published in an SCTE 2021 paper [5] and a CableLabs Technical Report [7]. This paper presents the phase II testing results. This second phase evaluates DTP performance in a complex environment similar to a field deployment with different downstream and upstream traffic load levels and fiber and coaxial cable lengths with multiple amplifiers. Phase II testing also considered HFC physical layer configurations such as modulation, interleaver, and cyclic prefix (CP) in the downstream orthogonal frequency-division multiplexing (OFDM) channel. In the upstream orthogonal frequency-division multiple access (OFDMA) channel, Phase II testing considered modulation, frame size, and CP. DTP PoC testing demonstrated that DTP could successfully deliver accurate timing information to end applications. TDD mobile networks successfully met the 3GPP timing accuracy specifications using DTP on the backhaul.

While working on the DTP PoC phase 1 and phase 2 testing, the group made many other contributions including designing the DTP cloud database [5], and updating the DOCSIS SYNC Specification [4].

2. DTP PoC Phase II Test Plan and Configuration

The DTP PoC phase 2 testing was conducted in Q3 and Q4 of 2021. This paper summarizes the key observations. More details are presented in [8].

2.1 Test Plan

The DTP PoC phase 2 testing aims to evaluate the DTP performance in a complex field environment. The cases listed in Table 2 cover most of the cases for MSOs' field deployment scenarios. We firstly confirmed that PTP over-the-top of HFC networks performs poorly. Then we tested DTP with different levels of traffic load in both downstream (DS) and upstream (US), fiber and cable lengths, number of amplifiers, and with different HFC network configurations at the CMTS.

The second column in Table 2 contains the baseline values that define the default test case, in which the traffic load, fiber and coax cable length and number of amplifiers are set the minimum value in our lab, and the CM and CMTS configurations capture the most commonly used values

by MSOs. Columns 3 and 4 contain comparative and extreme values that may or may not often be used in field deployments. Each case only changes one value from the default case. Several factors limit the phase 2 testing: (1) the CMTS serves as the DTP timeTx and the CM serves as timeRx (the SYNC spec also supports the CM serving as the DTP timeTx and the CMTS serving as the DTP timeRx); (2) the test bed uses the distributed access architecture (DAA) with RPD; (3) the primary upstream channel is the OFDMA channel instead of the single carrier quadrature amplitude modulation (SC-QAM) channel (SC-QAM channel has a different TRO, etc.); (4) assumes 4k fast Fourier transform (FFT) size in the US OFDMA channel and 8k FFT size in the DS OFDM channel; (5) assumes the DS OFDM channel has a flat profile; (6) PTP multicast was used between the CM and the Paragon-X and PTP unicast was used between the Paragon-X (or PRTC) and the CMTS & RPD.

Table 2. DTP PoC Phase II Test Plan [8].

Parameters		Baseline test value	Comparative test values	Extreme values (optional test)	Note
DS load impact on PTP over the top		0	25%, 50%	75%, 100%	
US load impact on PTP over the top		0	25%, 50%	75%, 100%	
DS load impact on DTP		0	25%, 50%	75%, 100%	
US load impact on DTP		0	25%, 50%	75%, 100%	
Fiber length (NCS to RPD)		90 m	5 m, 25 km		
Coax length (RPD to CM)		3 m	244 m (800 ft) 591 m (1938 ft) 835 m (2738 ft)		
Number of amplifiers		0	1, 2, 3, 4, 5		
CM configs (US)	Frame size	$K = 6$	$K = 18$, BW < 48 MHz		Assume 4k FFT size. K is number of symbols in a frame
	OFDMA modulation	256-QAM	64-QAM	1024-QAM	1024-QAM only in a clean environment with no noise
	CP	6: 256 samples	4: 192 samples		
CMTS configs (DS)	Interleaver	2	1	16	Assume 8k FFT size
	Modulation	4096-QAM	1024-QAM, 256-QAM		Assume flat profile
	CP	1 (1.25 μ s, 256 samples)	2 (2.5 μ s, 512 samples)	3.75 μ s (768 samples), 5 μ s (samples), and 0.94 μ s (192 samples)	

In addition to Table 2, we also tested three cases:

- Impact of the Cisco Network Convergence System (NCS) boundary clock (BC), see Section 3.7.
- The upstream OFDMA channel frequency range, which impacts the group delay, see Section 3.8.

2.2 Test Configuration

The lab test configuration is shown in Figure 4. Because there is no solution that can measure DTP performance directly, we used the Paragon-X to measure the PTP time error (TE) between the input of the CMTS/RPD and the output of the CM. The PTP timeTx in the Paragon-X is

connected to the Cisco NCS 55A1-24Q6H-SS that serves as a PTP BC, which provide the PTP timing source for both the integrated CMTS (I-CMTS) and RPD. The I-CMTS is the Cisco cBR-8 with software version 16.12.z1. The RPD is the Cisco SmartPHY 120 with software version v7.8.2. The CM is the Hitron ODIN1112 with software version ODIN-724GA-7.2.4.0.152 that uses MaxLinear's Puma 7 solution.

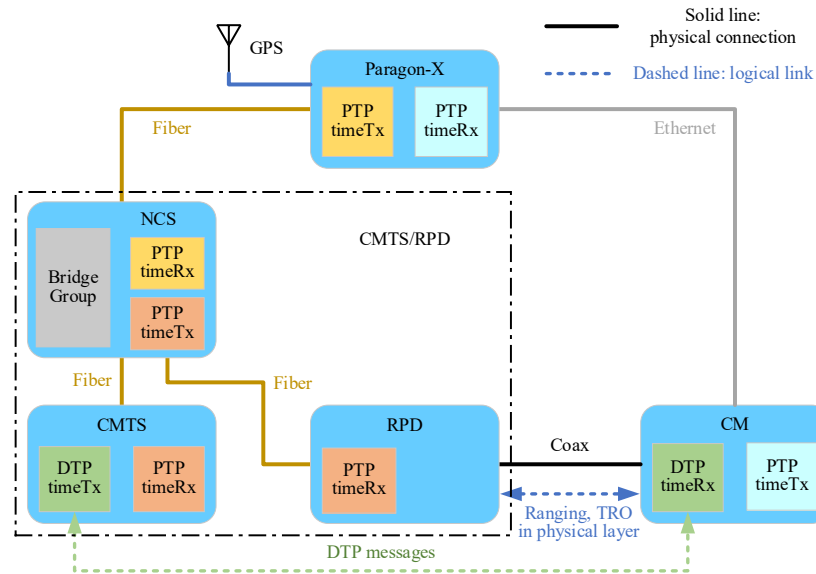

Figure 4 – DTP PoC Testing Lab Configuration.

3. DTP PoC Phase II Results and Observations

3.1 Default Case

The default case uses the baseline values listed in Table 2. Calibration was done before doing the PoC testing, as reported in Section 5.2 in [8]. Each of the phase 2 cases were run five times. Each run was one hour long. The TRO was captured on the CM before and after the run. The Paragon-X generated many statistics of the time error. In this paper we only focus on the constant TE and dynamic TE. The Paragon-X compares the PTP timestamp sent from its timeTx to the HFC network and the PTP timestamp received by its timeRx from the HFC network. The constant TE is the difference (time error) averaged over one hour and five runs. The dynamic TE is the maximum variation of the TE over a 1000 second moving window in each run, then averaged over five runs.

The default case results are provided in Table 3. The time error budget for this DAA scenario is 980 ns, see Table 4 in [7]. The time error has an average value of -35 ns and variation of up to 214 ns, which meet the 980 ns requirement.

Table 3. Default Case Results.

Case Index	Case	Average TRO (ns)	Constant TE (ns)	Dynamic TE (ns)
1	Default Setting	5,315,965	-35	214

Observation 1: DTP will work. The default test case with baseline configurations met the DTP time error budget.

3.2 PTP Over-The-Top

In this case, DTP is not running in the HFC network. PTP messages are over-the-top traffic in the HFC network. Thus, PTP messages are impacted by HFC queueing. Upstream PTP messages go through a DOCSIS upstream service flow configured with a best-effort scheduling service. Case 2 in Table 4 does not have any traffic load. The constant TE is over 3 ms. The TE varies over 4 ms. Both the constant TE and dynamic TE are multiple orders larger than the 3GPP requirement of 1.5 μ s.

Two other CMs and a tap were added after the RPD, see Figure 5 in [8]. The two CMs are controlled by a load tester (ByteBlower) to create a certain amount of traffic load either downstream or upstream. Cases 3 to 6 are with DS load from 25% to 100%, and cases 7-10 are with US load from 25%-100%. The constant TE and dynamic TE for all these cases do not meet the 3GPP requirement.

Table 4. PTP Over-The-Top Results.

Case Index	Case	TRO (ns)	Constant TE (ns)	Dynamic TE (ns)
2	No load	5,315,925	3,012,010	4,440,810
3	25% DS load	5,315,925	3,026,168	4,273,112
4	50% DS load	5,315,929	3,017,390	3,656,898
5	75% DS load	5,315,929	3,008,489	3,845,175
6	100% DS load	5,315,929	735,443	6,074,600
7	25% US load	5,315,929	3,173,979	5,383,784
8	50% US load	5,315,929	3,459,314	6,052,003
9	75% US load	5,315,917	3,807,350	5,559,820
10	100% US load	5,315,917	4,672,663	7,603,164

Observation 2: PTP over-the-top does not meet the 3GPP requirement. The dynamic TE is on the order of milliseconds with or without traffic load. The cTE changes with different levels of downstream and upstream load by multiple milliseconds.

3.3 Load Testing

Three CMs share the same channels. Two CMs generate 25% to 100% traffic load in either DS or US. The other CM runs DTP. The results are presented in Table 5. Because DTP messages are designed to be a control message, and the DOCSIS 3.1 timestamp is transferred on the physical layer link channel (PLC), neither the constant TE nor dynamic TE is impacted by HFC network traffic.

Table 5. Load Testing Results.

Case Index	Case	TRO (ns)	Constant TE (ns)	Dynamic TE (ns)
11	25% DS load	5,315,933	-58	216
12	50% DS load	5,315,933	-53	219
13	75% DS load	5,315,925	-64	215
14	100% DS load	5,315,988	-33	222
15	25% US load	5,315,941	-48	212
16	50% US load	5,315,941	-36	208
17	75% US load	5,315,996	-28	225
18	100% US load	5,315,996	-21	189

Observation 3: Neither the DS nor the US traffic load impacts the DTP performance.

3.4 Fiber and Coaxial Cable Length

The fiber length between the NCS and the RPD in the default case is approximately 90 m. Cases 19 and 20 change the fiber length to 25 km and 5 m. The TE is not impacted by the fiber length, see Table 6. Ranging and TRO between the RPD and the CM are also not impacted by the fiber length in such a DAA-RPD architecture.

Table 6. Fiber and Coaxial Cable Length Results.

Case Index	Case	TRO (ns)	Constant TE (ns)	Dynamic TE (ns)
19	25 km fiber	5,315,901	-42	223
20	5 m fiber	5,315,984	-15	215
21	244 m coaxial + 1 Amp	5,318,125	49	223
22	591 m coaxial + 3 Amps	5,320,750	185	237
23	835 m coaxial + 5 Amps	5,323,038	194	224

Observation 4: Fiber length in the DAA-RPD architecture does not impact DTP, nor does it impact TRO.

The coaxial cable length from the RPD to the CM in the default case is approximately 3 m. We replaced it with 244, 591, or 835 m long cables. To compensate high attenuation, multiple amplifiers need to be used. The TE changes slightly from the default case to cases 21-23, which is not due to the asymmetrical TE introduced by amplifiers but instead due to impact from the long cable. The TRO increases with cable length correspondingly to compensate for the additional delay introduced by the long cable.

The delay of the 244 m cable is also measured by a Vector Network Analyzer (VNA); see Table 7. The DS delay at 591 MHz is 1004 ns and the US delay at 32 MHz is 1005 ns, which are almost the same.

Observation 5: Cable length does not impact DTP. VNA measurements indicate that coaxial cable does not introduce any asymmetrical delay. The additional round-trip delay from cable length is symmetrical, and the corresponding TE is well compensated by the TRO, which is verified in the DTP measurements.

3.5 Amplifiers

The constant TE for cases 21-23 in Table 6 are slightly different. We designed cases 24-27 to further check if the additional constant TE is due to the cable length or amplifiers. Cases 24-27 use the same cable length of 3 m, but change the number of amplifiers (from QDAX) from one to four. Each of the amplifiers introduce additional TE from 38 to 83 (case 1 vs. case 24) ns with an average of 54 ns, see Table 8. The VNA measurements for the QDAX amplifiers are listed in Table 7. The QDAX amplifiers have a large asymmetrical delay between DS and US, which introduces an additional TE of 36-40 ns per amplifier. The additional TRO and TE are in the same range with the DTP results. The 591 m cable plant is built with three Arris amplifiers. The Arris amplifiers also have a large asymmetrical TE that introduce additional TE of approximately 27 ns per amplifier.

Table 7. Amplifiers: VNA Results.

VNA Measurements	QDAX Amplifier					591 m hardline cable + 3 Arris Amps	244 m RG-6 Cable
	#1	#2	#3	#4	#5		
DS delay $D_{DS'}$ (ns)	6.3	6.3	6.3	6.4	6.4	2278	1004
US delay $D_{US'}$ (ns)	81.5	79	80.9	81.3	86	2442	1005

Additional TE ($(D_{US}' - D_{DS}')/2$ (ns))	38	36	37	37	40	82	0.5
Additional TRO $D_{US}' + D_{DS}'$ (ns)	88	85	87	92	92	4720	2009

Table 8. Amplifiers: DTP Results.

Case Index	Case	TRO (ns)	Constant TE (ns)	Dynamic TE (ns)
24	3 m coaxial + 1 Amp	5,316,160	48	218
25	3 m coaxial + 2 Amps	5,316,250	101	215
26	3 m coaxial + 3 Amps	5,316,394	139	229
27	3 m coaxial + 4 Amps	5,316,480	182	217

The additional TE from amplifiers varies in the field. The MSOs need to consider this factor in the field DTP deployment. If a large number of amplifiers is used, the TE from other network elements will need to be reduced in order to meet the entire TE budget. For example, a higher class of CMTS or CM with better quality and smaller TE may be used. An alternative solution is to reduce number of cascading boundary clocks used in the DTP network. These solutions are suggested in Section 8.4.2.5 in the SYNC spec [4].

Observation 6: Amplifiers introduce an asymmetrical delay in the HFC plant and additional TE to DTP. The additional TE varies with amplifier make and model. The QDAX amplifier has an additional TE of 36–40 ns that is accurately characterized by the VNA. Such additional TE from each QDAX amplifier is, on average, 54 ns measured in the DTP testbed.

3.6 HFC Configurations

The baseline value for the US frame size is 6 symbols per frame, the US modulation is 256-QAM and the US CP is 256 samples. The US frame size is changed to 18 symbols per frame in case 28. The US modulation is changed to 64-QAM and 1024-QAM in cases 29 and 30. The US CP is changed to 192 samples in case 31. The results are provided in Table 9. The TE is not impacted by these US configurations.

Observation 7: HFC upstream network configurations of frame size, modulation scheme, and cyclic prefix do not impact DTP performance.

Table 9. HFC Configurations Results.

Case Index	Case	TRO (ns)	Constant TE (ns)	Dynamic TE (ns)
28	US frame size: 18	5,315,965	-32	212
29	US mod: 64-QAM	5,315,925	-50	221
30	US mod: 1024-QAM	5,315,933	-48	227
31	US CP: 192	5,315,941	-48	215
32	DS Interleaver: 1	5,315,968	-33	226
33	DS Interleaver: 16	5,315,992	-30	224
34	DS mod: 1024 for data 256 for control	5,315,965	-44	209
35	DS mod: 256 for data 64 for control	5,315,972	-29	225
36	DS CP: 192	5,276,152	19,898	211
37	DS CP: 512	5,475,554	-79,820	230
38	DS CP: 768	5,635,687	-159,914	228
39	DS CP: 1024	5,795,644	-239,959	221

The default case uses DS interleaver depth of 2 and DS modulation of 4096-QAM for data and 1024-QAM for the control channel. Cases 32 and 33 compare the DS interleaver depth of 1 and 16. Cases 34 and 35 compare DS modulation of 1024-QAM for data and 256-QAM for the control channel, and 256-

QAM for data and 64-QAM for the control channel, respectively. The TE is not impacted by the DS interleaver and modulation.

Observation 8: HFC downstream interleaver depth and modulation scheme do not impact DTP performance.

The baseline value of DS CP is 256 samples. Cases 36-39 compare DS CP values of 192, 512, 768 and 1024 samples. Both the constant TE and TRO are impacted significantly by the DS CP. This is likely due to a frame alignment issue at the CM. MaxLinear and Hitron are working on fixing the frame alignment issue. Before this issue is fixed, an alternative method is to have DTP devices calibrated for each individual DS CP value to compensate the impact.

Observation 9: The downstream cyclic prefix significantly impacts DTP. Every 1.25- μ s CP length reduces cTE by approximately 80 μ s. As of August 2022, this issue is being investigated by the CM vendor and chipset vendor.

3.7 NCS Boundary Clock

The PTP timeTx in the Paragon-X is connected to the PTP timeRx in the NCS, and the PTP timeTx in the NCS is connected to the PTP timeRx in the Paragon-X directly to evaluate the performance of the NCS as a boundary clock. The NCS employs a class B boundary clock with a theoretical TE of 20 ns. The measured TE is listed in Table 10. The constant TE ranges from -8 to 1 ns with an average of -3 ns. The dynamic TE is 15 ns.

Observation 10: The NCS class B boundary clock TE is between -8 and 1 ns, which is smaller than the 20-ns TE budget defined in the SYNC spec [4].

Table 10. NCS Boundary Clock Results.

Case Index	Case	Constant TE (ns)	Dynamic TE (ns)
40	NCS	-3	15

3.8 Upstream OFDMA Channel Frequency

Diplexers, amplifiers, and filters have frequency dependent group delay, which may impact DTP performance. A plant with five cascade diplexers is used to verify if the upstream OFDMA channel frequency may impact DTP. The diplexers have an upper cutoff frequency of 42 MHz. The group delay from 5 to 45 MHz for the five-cascade-diplexer plant is measured by a VNA. As shown in Figure 5, the blue curve is the group delay over frequency, which increases gradually from 115 ns at 5 MHz to 375 ns at 42 MHz, then increases dramatically after 42 MHz. Two US OFDMA channels are selected for the comparative analysis that are on the two edges of the diplexer frequency range: (1) 5-17 MHz (green box in Figure 5); and (2) 31-42 MHz (red box in Figure 5). The average group delay in the 5-17 MHz channel is 128 ns, and in the 31-42 MHz channel 241 ns. In comparison between these two channels, the impact on TRO is 113 ns, and the impact on TE is 56.5 ns (half of TRO).

Figure 5 – VNA Measured Group Delay for a Five Diplexers Plant.

This five-diplexer plant is plugged into the DTP test bed to replace the coaxial cable shown in Figure 4. The DTP measurement results are provided in Table 11. The TRO increased by 99 ns between 5-17 MHz and 31-42 MHz channels, and the constant TE increased 49 ns between the two channels. The DTP results confirmed that the group delay and US OFDMA channel frequency does impact DTP.

Observation 11: The US OFDMA channel frequency does impact DTP depending on the group delay variation over frequency.

Table 11. US OFDMA Channel Frequency Results.

	DTP Results		VNA Results	
	TRO (ns)	Constant TE (ns)	Impact on TRO (ns)	Impact on constant TE (ns)
5-17 MHz vs. 31-42 MHz	99	49	113	56.5

4. Conclusion

DTP provides an accurate timing source for mobile networks. DTP is particularly helpful for the scenarios where the GPS signal is unreliable (e.g., indoor) and the HFC network is used for mobile backhaul, where over-the-top PTP performs poorly. The PoC testing proved DTP meets the 3GPP requirement of 1.5 µs. A three-step DTP calibration procedure is required to correct non-ideal effects in the CMTS, RPD/RMD, and CM devices. Here are the observations from the PoC phase 2 testing:

Observation 1: DTP will work. The default test case with baseline configurations met the DTP time error budget.

Observation 2: PTP over-the-top does not meet the 3GPP requirement. The dynamic TE is on the order of milliseconds with or without traffic load. The cTE changes with different levels of downstream and upstream load by multiple milliseconds.

Observation 3: Neither the DS nor the US traffic load impacts the DTP performance.

Observation 4: Fiber length in the DAA-RPD architecture does not impact DTP, nor does it impact TRO.

Observation 5: Cable length does not impact DTP. VNA measurements indicate that coaxial cable does not introduce any asymmetrical delay. The additional round-trip delay from cable length is symmetrical, and the corresponding TE is well compensated by the TRO, which is verified in the DTP measurements.

Observation 6: Amplifiers introduce an asymmetrical delay in the HFC plant and additional TE to DTP. The additional TE varies with amplifier make and model. The QDAX amplifier has an additional TE of 36–40 ns that is accurately characterized by the VNA. Such additional TE from each QDAX amplifier is, on average, 54 ns measured in the DTP testbed.

Observation 7: HFC upstream network configurations of frame size, modulation scheme, and cyclic prefix do not impact DTP performance.

Observation 8: HFC downstream interleaver depth and modulation scheme do not impact DTP performance.

Observation 9: The downstream cyclic prefix significantly impacts DTP. Every 1.25- μ s CP length reduces cTE by approximately 80 μ s. As of August 2022, this issue is being investigated by the CM vendor and chipset vendor.

Observation 10: The NCS class B boundary clock TE is between -8 and 1 ns, which is smaller than the 20-ns TE budget defined in the SYNC spec [4].

Observation 11: The US OFDMA channel frequency does impact DTP depending on the group delay variation over frequency.

4.1 Suggestions for MSOs

A three-step DTP calibration procedure is required to guarantee DTP performance. The calibration test needs to be done for each pair of CMTS/RPD/RMD and CM devices. The calibration test needs to be repeated for each of the key software releases of these devices. The calibration data will be distributed by a cloud database. The CMTS will query the calibration data and apply them in the field.

DTP performance is impacted by amplifiers, diplexers, and filters, as well as the number of boundary clocks in the field plant. Each amplifier may introduce 36-40 ns additional TE to DTP due to the asymmetrical TE. When multiple amplifiers are used for a DTP CM, in order to meet the entire TE budget, a higher class (with smaller time error) of CMTS or CM may be needed, or a smaller number of boundary clocks may need to be considered [4].

The upstream channel frequency may impact DTP depending on the number of diplexers, amplifiers and filters, which change the group delay over frequency. In the case that the group delay in the upstream varies significantly over frequency, consider using the portion of the channel closest to the center of the upstream band in order to stay clear of the expected delay variation/increase at the band edges [4]. For example, the band edge frequency above 42 MHz should be avoided for the specific HFC network discussed in Section 3.8.

1. Introduction

As operators look ahead to expand their speed tiers and offerings, they will also be looking to expand their plant capacity to 1.8 GHz Extended Spectrum DOCSIS (FDD) and DOCSIS 4.0. Passives are the highest quantity device in the outside plant that limits the usable bandwidth and will take the most amount of time and energy to replace.

This paper will discuss the methods that an operator can use to replace passive equipment in their plant and examine the operational and technical benefits of each method. We will explore the considerations for evaluating passives in the plant during field trials from both plant performance and maintenance savings perspectives.

For context, the paper will present some of the advantages of having passive upgrades completed before actives, specifically around the ability for 1.8 GHz signals to pass through the plant to measure for ingress, egress, and other test signals. We will also discuss the benefits of being able to set up plant actives by already having passives upgraded to 1.8 GHz, as opposed to a partial tilt setup, which would require the identification of where rolloff exists in order to do a drop-in style upgrade.

2. Passive Replacement Programs

Before we enter in depth into a discussion around passives and how they can be operationalized in the plant, we need to ensure a consistent language is being used around the devices themselves. Passives devices are a category of devices that includes taps, splitters, couplers and power inserters. A passive is also defined as a device that operates in the plant without consuming power directly. It acts as a gateway for the signals passing through it and is designed with specific RF characteristics in mind. Passives are the most common device in the plant, with an industry average of around six passives per active device. For the purpose of this discussion, we will be using an illustration of a sample plant for the various methods of passive upgrades to outline the benefits of each method, as in the figure below.

Figure 1 – Sample Plant Illustration

As cable operators begin their planning for DOCSIS 4.0, the work begins on selection of equipment for evaluation. When an operator is looking to bring a new passive into the plant, there are several factors that need to be explored and understood before proceeding with a field trial.

The first set of considerations are around higher-level plant design requirements for the radio frequency (RF) performance of the devices. The first thing on this list is the insertion loss, or the amount of signal that is lost as the signals pass through the device. As the spectrum is expanded, and to accommodate for higher spectrum transmissions, there is potential for tradeoffs related to the RF design of passive devices. These properties are actively under development by the vendor community and will not be discussed at length in this paper. It is sufficient to understand that the caveat of this performance exists, and how it will impact the operational methodologies examined throughout.

This leads to the signal from the passives to the customer and how it feeds into drop loss. As we look at these higher bandwidths, the total composite power (TCP) of the plant to the modem—and the modem back to the plant—become more of a balancing act than ever before. (Such analysis is outside the scope of this paper but something that will need to be considered as part of the larger design considerations.) After these levels are captured and understood, the secondary RF characteristics of the passive devices must be reviewed.

As spectrum is expanded, some operators are taking a step back to evaluate their network holistically to determine what levels they should be running out of their actives, as well as what levels they would like their modems to be transmitting at. The passive evaluation needs to be included in this discussion as the expanded spectrum greatly impacts the performance achievable through a passive device—along with the design and component usage to build the device—which in turn impacts power passing capability, low-end usable frequency, insertion loss, return loss and isolation between various ports.

Once the high-level design considerations and RF performance characteristics of the passive evaluation are understood, an operator can move to the operational efficiencies and savings that can be realized by selecting the correct passive for their network. The Society of Cable and Telecommunications Engineers (SCTE) has developed a standard for 3 GHz passives (known as SCTE 265 2021) that has completed the foundational work to ensure that the options available to operators have value and longevity in the plant.

At Shaw, we have spent the last few years performing a mid-split upgrade in our plant, coupled with a downstream spectrum expansion. Part of this effort was to replace all passives in the plant from legacy, defined as sub-1 GHz passing, to a minimum of 1 GHz passing. Over the course of this exercise, we learned several operational lessons that will significantly influence our next rounds of passive evaluations and selection.

2.1. Passive Evaluation Criteria

The most immediately impactful piece of selection criteria, aside from questions around advertised spectrum bandwidth, is what the insertion is and through loss of the new device. As touched on above, once the design of the passive is enhanced for almost double the spectrum, there will be tradeoffs with RF performance in other areas of the spectrum. These will vary from vendor to vendor, but they will add up in a cascaded environment. As evidenced in the formulae below, n is the number of passives and x is the loss of the existing passives, which leads you to the legacy loss. The additional loss from the ESD passive, that is the delta from the legacy passive to the new passive, is defined by y . Once a new passive has been added to the plant, every decibel of loss that this expanded spectrum passive could potentially contribute to the overall loss is added for every tap in the run.

$$\textit{Legacy Loss} = nx$$

$$\textit{ESD Loss} = n(x + y)$$

One of the often forgotten but incredibly important considerations is the pin length required for the passive device. As the spectrum that the passive needs to transport expands, the pin length becomes much more important than legacy passives. The accuracy of the pin length creates a much tighter window from a technician craft perspective. Hardline passive connector reusability is a key factor in saving time, and in some cases, there may not be excess cable available to be re-cored and have connectors added.

Another key consideration is the dimensions of the passive devices themselves. Upgrading passives in an existing environment means that the device needs to fit into existing pedestals, into housings and on existing strands. There may not be extra room in pedestals, or enough bend radius or cable length, to implement a large change in passive housing size.

Another often neglected factor in the analysis is the availability of an upgradeable faceplate. Upgradeable faceplates are key features when considering a new passive for the plant. To remove connectors and re-install a device into the plant, rather than unscrewing a faceplate and dropping in a new one, is a massive operational difference.

Figure 2 - Faceplate Upgrade Comparison

Something that we have found over years of maintaining cable plant through all imaginable geography is the importance of the seizure mechanism. The seizure mechanism is the way that the mainline connector pin makes contact for RF and power transmission within the passive device. Fundamentally, there are two types of seizer mechanisms: one that is controlled with a technician tightened set screw and one that has an effective and often proprietary mechanism that applies constant pressure to the pin of the connector. After the initial installation, passives tend to be in the plant until they fail, or the network is upgraded. Since the passives are such long-lived devices in the plant, even the smallest design choices can have a great impact on maintenance cost over the lifetime of the device.

One item that has stood out is the seizure screw for the mainline cable entering the passive. Over the life of a passive, our analysis has shown that the seizure screw may have been forgotten and not tightened or working loose over time, which occurs in a surprisingly large number of cases. Each operator will need to apply their own cost structure to how these issues translate into cost, but each one would be a customer impacting truck roll. The self-seizing mechanism has been shown to be a key success factor in our analysis, as it not only saves the costs associated with truck rolls for set screws that have some looseness, but also speeds up installation by removing some labor and tool requirements from plant technicians.

For any operator is looking to expand their plant to enhance capacity and increase service offerings to customers, the category of equipment that will require the most upgrades is the plant passive. The scale of upgrading every passive in the plant is enormous; as previously discussed, the number of passives overshadows the number of actives in the plant. There are two main methods to operationalizing the upgrades to the plant that we will discuss in the next session: the Blanket Method and the BAU Method.

3. Operationalizaton of Passive Upgrades

For any operator is looking to expand their plant to enhance capacity and increase service offerings to customers, the category of equipment that will require the most upgrades is the plant passive. The scale of upgrading every passive in the plant is enormous; as previously discussed, the number of passives overshadows the number of actives in the plant. There are two main methods to operationalizing the upgrades to the plant that we will discuss in the next session: the Blanket Method and the BAU Method.

3.1. Blanket Method

The Blanket Method refers to the complete, targeted upgrade of plant passives in an area or region, as shown in Figure 3.

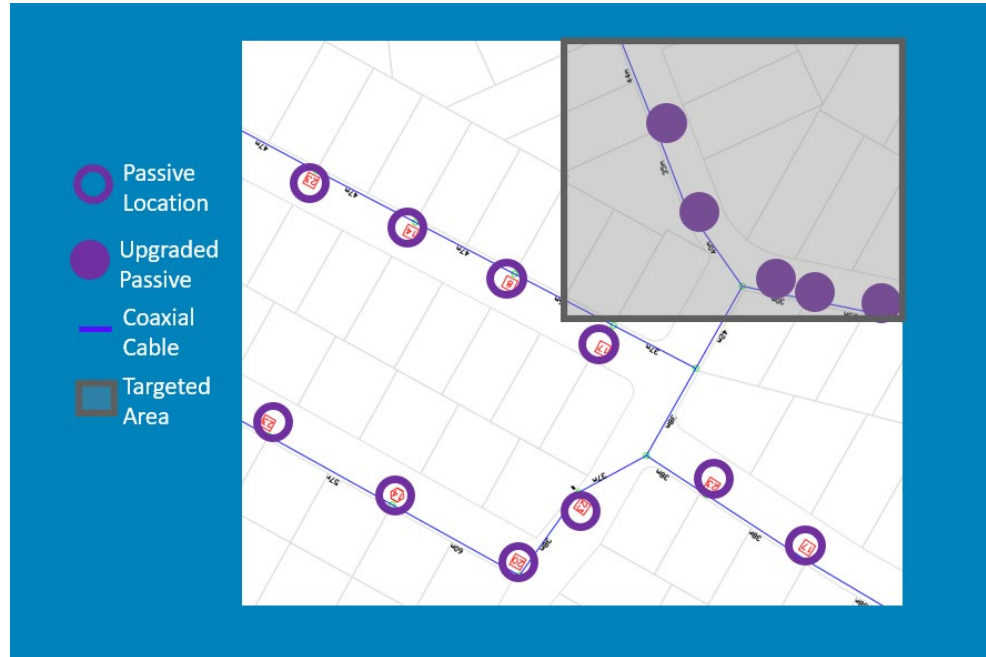

Figure 3 – Blanket Method Illustration

This method is advantageous if the upgrade is complex and requires more than a simple drop-in upgrade. As we will explore further in the paper, upgraded passives may introduce different loss characteristics that will require subsequent changes in the actives portion of the plant.

When using the blanket method, the number of SKUs (Stock Keeping Units) required to maintain the plant doubles. There will be two types of passive devices contained within a system, the existing 1.2 GHz and new 1.8 GHz. Operational teams will be required to stock and maintain equipment for both types of passives. This not only strains local technician resources in terms of truck stock and ensuring the swapping on passives, but it can also exacerbate existing supply chain issues, causing the like-for-like strategy to become unmanageable.

Figure 4 – Blanket Method Truck Stock / SKU

3.2. BAU Method

The second method to consider is the BAU (Business As Usual) Method that we leveraged at Shaw during our mid-split upgrade program. This method is based around making a wholesale switch for the business to a new passive device at a single point in time, across the entire network.

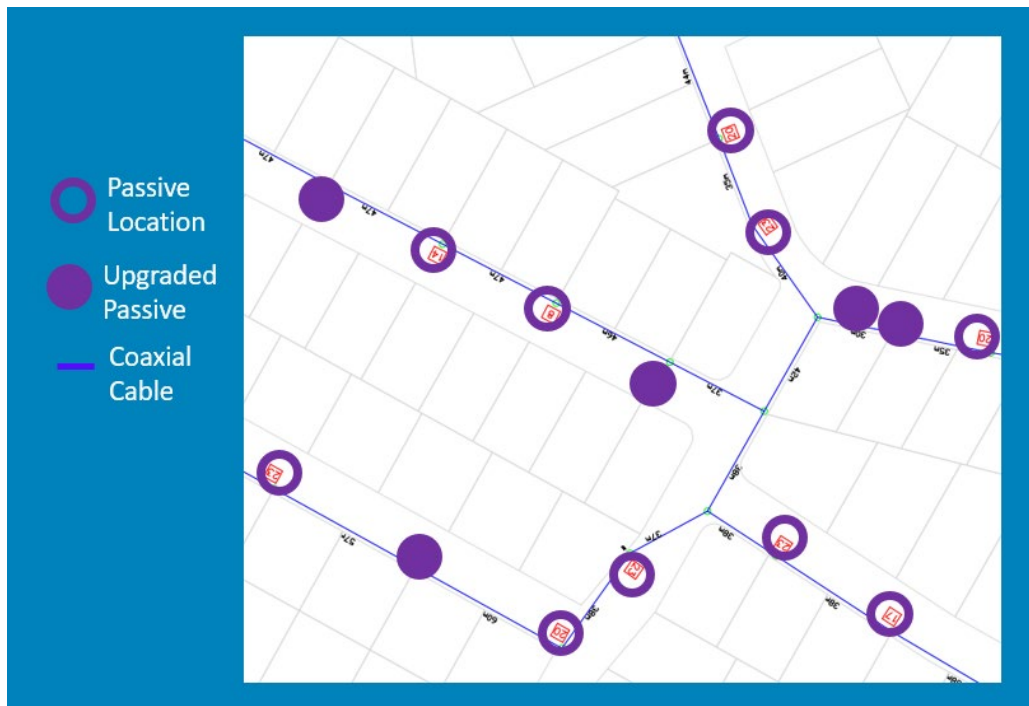

Figure 5 – BAU Method Sample Illustration

This mitigates one of the key operational issues that is seen with the Blanket Method, which is the doubling of the relevant SKUs. This is avoided by doing a straight part-for-part replacement within the inventory system.

Passive	Frequency		Passive	Frequency
Coupler	Legacy	➔	Coupler	1.8 GHz
Power Inserter	Legacy		Power Inserter	1.8 GHz
8 Tap	Legacy		8 Tap	1.8 GHz
12 Tap	Legacy		12 Tap	1.8 GHz

Figure 6 – BAU Method Truck Stock / SKU

The other key operational benefit of this method is that it does not preclude using the Blanket Method when targeting an area ready to offer enhanced service tiers or for an upgrade of actives to complete spectrum expansion.

Figure 7 – BAU Method with Overlay

However, it is important to consider that this method is built upon a drop-in style upgrade, where existing loss characteristics are matched by newly deployed passive devices. Since passives are being replaced on an as-needed basis, they can be dropped into any point in the plant and in any concentration. This creates a scenario in which there is a mix of 1.2 GHz and 1.8 GHz passives in the plant through maintenance and failure replacements. Care and attention will be required to ensure that these are properly documented in the network documentation, or at the very least, that they are easy to physically identify. Additionally, issues may occur if the loss characteristics change because of expanding the spectrum, which would require levels of actives to be reset.

4. Passive-Enabled Spectrum Expansion

When an operator has made the decision to expand their spectrum, there would inevitably be discussions around which equipment to upgrade first—actives or passives. When considering the options in this decision, it becomes clear that the answer is not straightforward—what are the benefits to upgrading the passives when there are no actives to generate the signal, and why upgrade actives without having any passives to pass the signal through?

Figure 8 – Passive Enabled 1.8 GHz Testing

To support the decision-making process, we will argue that there are considerable operational advantages to upgrading passives first that have been, thus far, under explored given that operators have not had a way to characterize or utilize the expanded spectrum.

When we expand spectrum through the use and upgrade of passives, we are able to capture both incoming ingress into the plant, as well as the signals that are already entering the plant on the higher frequencies. This has been noted as we move into the more heavily used LTE frequencies and will only become more notable as the spectrum expands. As operators are becoming increasingly aware, the higher spectral transmissions on the plant can cause egress and be impacted by ingress from smaller physical faults in the cable. It is seemingly no longer the pedestal that has turned into a squirrel nest causing the issue, but an improperly tightened back nut now acting as a slot radiator.

Another often-overlooked benefit is that having a head-start on the passives will minimize downtime and outages as the actives are upgraded in the area due to the larger number of devices in the plant already having been upgraded. This is becoming more and more of a customer experience piece in the work from home era, and with the rollout of more intelligent and power-hungry nodes and amplifiers that may have longer boot times, ensuring that customers' uptime is maximized is becoming increasingly important when making upgrades to the plant.

At the time of this writing, there are massive supply chain issues worldwide that show no sign of relenting. This also feeds into an operator's strategy and is worth including in any evaluation of timing. There has been a shift from an on-demand availability to an as-available environment for network equipment. The impact this has on the strategy for upgrading passives can be felt immediately in lead times for ordering equipment, but also in trying to create and upgrade new plant.

Having a flexible strategy and understanding for implementation of the equipment is a key component of any strategy, especially in the competitive landscape of telecommunications. As operators look to expand their downstream spectrum to reap the benefits of the spectrum available in coaxial cables, there are many options on the path forward, and multiple factors that can impact the decision for which avenue to proceed down first when updating the equipment in the plant to expand services.

5. Conclusion

Every cable operator must continue to upgrade their plant in order to remain competitive in the telecommunications landscape and be able to offer their customers best-in-class services. To do this, a well-considered and evaluated strategy for plant upgrades, and especially for passive upgrades, is vital. There is no longer a single path, or even one simple strategy, when it comes to opportunities to innovate within the telecommunications space, but with that freedom of choice there are often pitfalls, especially as the demands for speed and reliability grow and evolve exponentially. Passives are the foundation on which the rest of the plant is built and allow for our products and services to reach millions of customers around the world every day, and as such, a well-devised strategy can ultimately be the differentiator between competitors.

1. Introduction

Continuous Integration and Continuous Deployment (CI/CD) procedures have been extensively used across software development life cycles specifically around application development. The CI/CD implementation around data engineering tools was challenging within the UI centric tool stack. The delivery requirements were not agile without the need of paired programming and common code base. In most cases, the versioning capabilities of the data tools itself was utilized without utilizing the enterprise CI/CD capabilities.

This paper discusses how data engineers can take advantage of the new flexibility that comes with the deployment of software across different data and integration tools, more quickly and securely. It will provide an overview of CI/CD, with a specific focus on how it is being applied across on-premises, cloud and hybrid data environments.

Over the years, real-time data integration and automation have been highly critical for all organizations to meet their analytic needs and providing better insights and capabilities to customers and business leaders. With the huge amount of data to be collected and processed from different systems across the network, before building analytics models around it, there is a pressing need to adopt DevOps guidelines to deliver quality data outputs.

This paper will describe how Cox Communications leveraged the existing CI/CD tool capabilities and expanded upon the configuration tools to support Agile DevOps delivery for building a hybrid data lake. Data Engineers and analysts could leverage a stable pipeline flow and common set of automation tools for delivering the solutions without much onboarding and transitioning into these CI/CD processes and tools.

2. Data at Scale

The transformation of network devices and the possibility of different data points at higher frequency to derive analytical and business insights have been tremendously growing during the last few years and it will continue to evolve throughout decades to come. When exploring the possibilities of big data and cloud technologies, enterprise teams started collecting data points from all the different devices in and out of network. The understanding of 5v's of Big Data – velocity, veracity, volume, value, and variety, allowed data scientists to derive more value from their data while also allowing organizations to become more customer centric, while being proactive to changes in the network.

With the advancement of analytical capabilities in Cox, all the analytics teams across Cox's Technology and Operations organizations were centralized back in 2017. Analytic initiatives around network and customer service health is solely driven by the data across the network and is focused on four key areas.

1. Deep understanding of data that describes quality and use of service by our customers
2. Ability to predict future service impacts and mitigate or prevent them
3. Machines executing the right actions to take, at scale
4. Continuous learning capabilities to improve over time

Different flavors of data from the edge of the network and across the elements of the network, sampled at different intervals, must be accommodated. Formats must be collected, cleansed and processed for both real time and historical trending. Analytics are required to have more accuracy and lesser development

turnaround time. Hybrid data lake environments coupled with traditional reporting and analytical solutions have resulted in a diverse tool stack for the developers to work with.

The traditional extract, transform, and load (ETL) tools, along with the data warehousing technologies and relational databases, which used to be the primary tool kit for the data engineers, took second place with the new advancement in big data and cloud technologies. Data engineers ended up building and supporting solutions across different technologies and programming languages like the software programming application development. Data engineers are using traditional ETL tools like Informatica, Alteryx for the structural data transformations, along with big data technologies like Apache Spark and using Scala, Python to process unstructured data sets from sources and cloud services for their hybrid solutions.

3. CI/CD Deployment Pipeline

CI/CD are a series of steps that must be performed in order to deliver a new version of software. A pipeline is a process that drives software development through a path of building, testing, and deploying code. The objective is to reduce human error and maintain a steady process to release software through automation. Figure 1 below depicts the continuous integration and continuous deployment pipeline flow here at Cox for a traditional software development application life cycle.

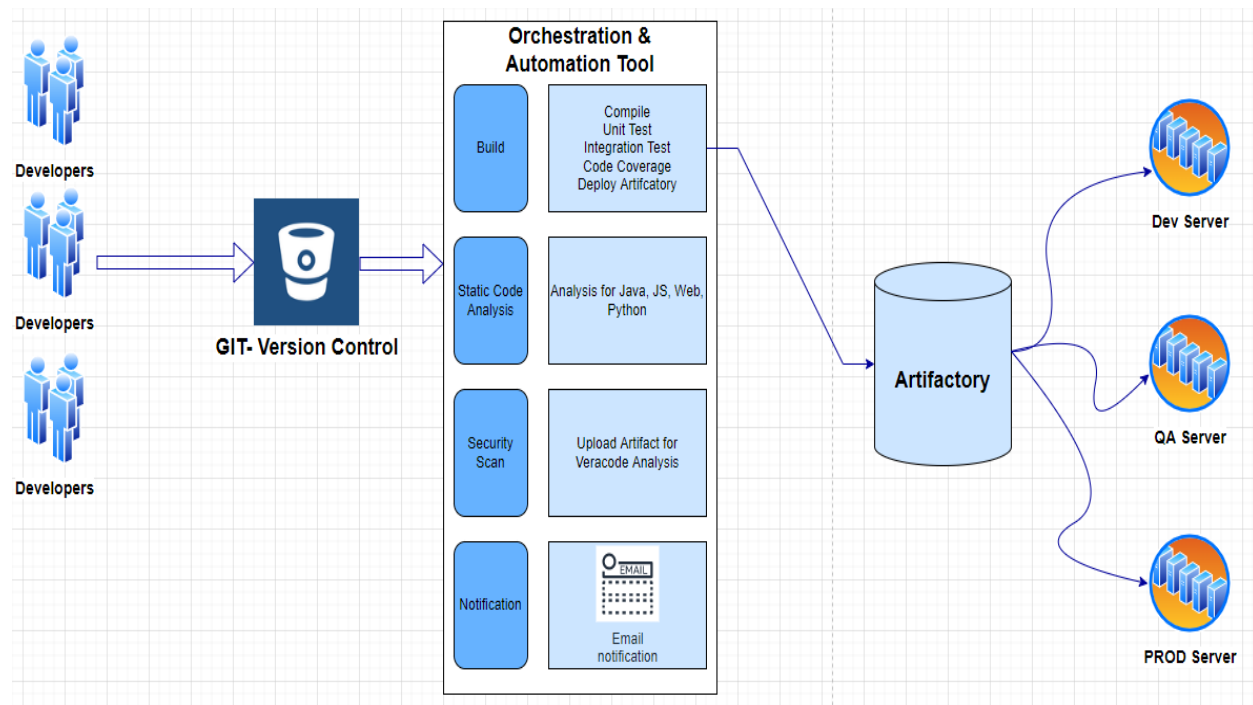

Figure 1 – Deployment Pipeline

In a GitOps-driven deployment process, all activities emanate from the version-controlled code repository. Here in Cox, we drive the deployment process directly within the code repository or version control service BitBucket. Storing the deployment instructions in a central version control repository provides a single source of truth for all deployment activities. Using the repository as a single source of

truth provides reliable change management and auditing capabilities. Version control and access security are also built into the service.

Orchestration tools play the role of managing the deployment process, which can range from a single task – such as running a unit test case against a source code – to a complex deployment process embodying many tasks. When an automation is triggered, it will refer to the playbook in the deployment repository stored within the version control and execute the tasks. Artifactory's build integration to orchestration tool allows our build jobs to deploy artifacts and resolve dependencies to and from Artifactory. Artifactory is a centralized binary management system providing management binary artifacts generated and used by the organization.

4. Hybrid Data Lake and Network Data Ecosystem

Data from different source systems gets loaded into the operational data store either through database (DB) replication or ETL loads built by data engineers over the years. These were built in different tool sets including Informatica, Oracle and loaded into relational databases. With the onset of big data technologies and possibilities of analyzing unstructured data assets, more data points at the least possible frequency started getting streamed (using streaming applications like Apache Kafka, Spark Streaming), pulled from sources on a specified interval (using tools like Apache Sqoop, Spark Batch) and even written into Hadoop Distributed File System (HDFS) for further processing and consumption.

Data engineers started working across multiple tools to build this ecosystem leveraging on-prem ETL processes to relational databases and big data lake for the unstructured data assets for analytical insights. There are different production solutions to meet both real-time and batch reporting needs in place now that are built across different tool stacks that consume data from systems like ticketing, polling platforms and so on. Before the expansion into on-prem big data lake and onto the cloud data lake, we realized the need to have a stable automated deployment process with a common CI/CD tool stack to support most of our needs and deliver in an agile fashion.

Traditional batch loads to meet the enterprise reporting through an enterprise data warehouse (EDW) which have been a stable process for more than a decade with 1000s of daily loads handling data assets from billing, network alarms, construction workflows, ticketing, customer calls, chats, geospatial assets, and many more. At the very beginning of defining the requirements for a more agile delivery and more frequent data needs, the team invested on setting up and configuring an automated CI/CD pipeline, as well for the traditional ETL tool and databases working with the enterprise software configuration management (ESCM) team.

Within the last four years, as Cox Communications started the data cloud journey, most of the on-prem ETL, big data deliveries are managed through CI/CD pipelines that provide more visibility into the source code. The CI/CD pipeline is auditable for security scanning and vulnerabilities and provides the developers the ability to follow a common deployment process for easy handoff for reviews and deployment across all the different tool stacks. End-to-end release cycles starting from the source to the very end at the data lake, are all getting managed through CI/CD pipelines that are configured and managed through individual application and data teams. This makes any changes seamless and controllable, even for an easy rollback in the case of faulty deployments.

For example, the polling data from the modems through a CMTS/CCAP devices goes through all different layers including streaming applications, an on-prem data lake, cloud services for analytics/machine learning models, and the traditional warehouse for enterprise reporting and integration. A change to a device element or the addition of new pollers, would have been a very intensive software

development life cycle (SDLC) process, if the end-to-end architecture, including all data spaces, are not able to support CI/CD processes. With the cloud journey, data is getting processed across multiple cloud accounts based on the department needs for different use cases. The codebases involving streaming applications to ingest raw data using Spark Streaming and landing them into file systems, ETL processing and analytical solutions using Python, PySpark and machine learning models are all stored in an on-prem code repository for orchestration for their respective environments. This provides the ability for development leads and architects across respective organizational units to have a better view of the solutions, and an ability to review and commit to the codebase for production deployments through a single CI/CD pipeline.

Because different servers are involved across the tool stack for ETL, big data processes also pushed the need of automation for the environment life cycle management to include upgrades and server additions. This reduced the need for downtime during the data tool stack upgrades and server additions. This is critical for the proactive service and health analytical solutions that are built on top of these data assets where data unavailability over a time period will have impacts to the model outputs and customer notifications. Figure 2, at a high level, depicts the network data assets and their data processing through a relational database, big data streaming applications, and ETL tools. Enterprise cloud data lake accounts for the hybrid data lake for enterprise consumption, storage and processing serves the downstream consumer accounts for their analytical models and outputs.

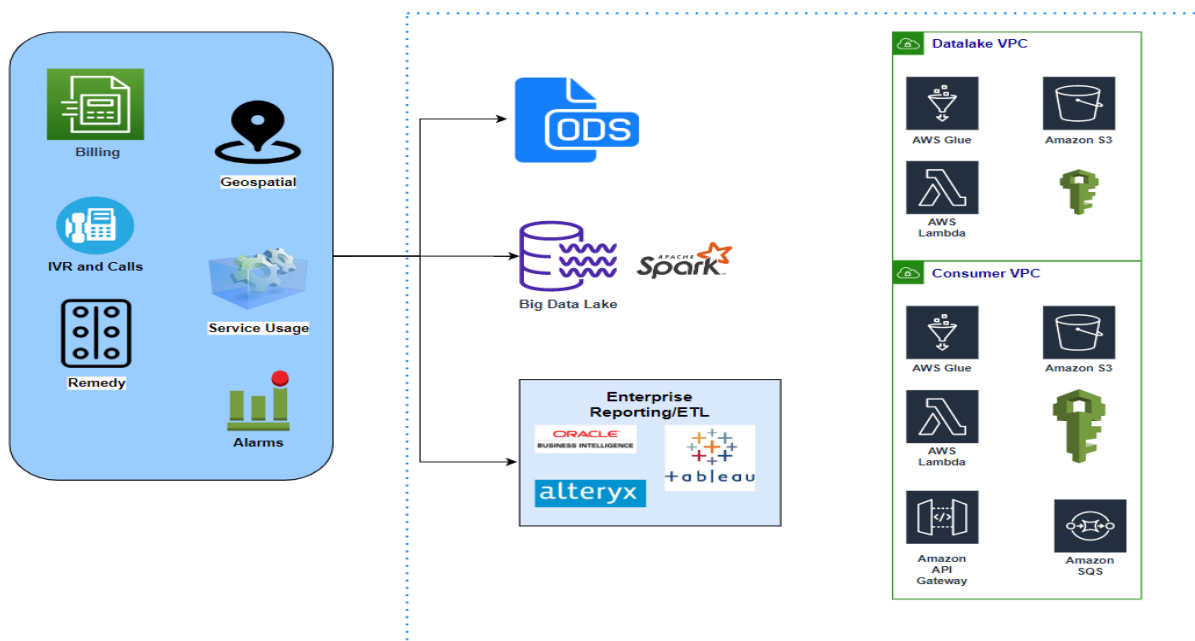

Figure 2 – Network Data Ecosystem

5. Data and Integration CI/CD Lifecycle

At Cox, we have an ECSM team to provide automation services that increase the velocity of development and operations teams across Cox to drive value to the business. DevOps teams across Cox collaborate with the ECSM team to define a deployment pipeline and support the right set of tools for delivering a CI/CD process to help the development teams to deliver the software or infrastructure as a code easily and

securely. Compared to the earlier days of infrastructure automation and traditional application development, the ESCM team plays a pivotal role in identifying, configuring and supporting different automation tools to meet the needs of engineers across data, automation, integration, application development, databases, and infrastructure.

Working with the ESCM team, the first step towards this journey was the identification of a unified platform and pipeline configuration for data engineers that provided minimal overhead for developers and did not impact the end users or customers. Starting with the ETL tool stack, where we had a built-in tool for deployment automations and validations, we tried reusing that stable process orchestrated through BitBucket and Jenkins with the goal of making it easy to use for data engineers new to the programming world and CI/CD tools. CI/CD tools in this case acted as a wrapper process to invoke ETL built in code validations, test scripts, and deployment processes, while also setting up a repository and pipeline flow for unified deployments.

The approach of building an initial prototype and establishing the pipeline configuration was followed during the big data and cloud journey to identify the right set of CI/CD tools and process that is supportable and extensible for different services within these cloud providers. The upfront design and setup time spent with the ESCM team helped the ongoing development teams to reuse the templates, Ansible scripts, and pipeline flows to build their own ETL solutions with minimal changes. User adoption is a key factor for a successful CI/CD model along with the DevOps enablement for agile program delivery. Individual teams will be responsible to maintain the Git projects along with their code base and delivery, while the ECSM team supports the tools and the environments to make this happen for DevOps teams. This allows enterprise teams to reuse the CI/CD tool stack, environments, and to follow standard guidelines along with the enterprise security checks on the codebase and processes.

6. Orchestration Architecture

Enterprise teams at Cox Communications have been using Bitbucket and Jenkins for code source control and automation/orchestration for the CI/CD flow as explained in Figure 3. Ansible is used for automating operations and building templates for repetitive and reusable functions. Figure 3 shows the high-level architecture and tools involved for an AWS Cloud deployment pipeline flow.

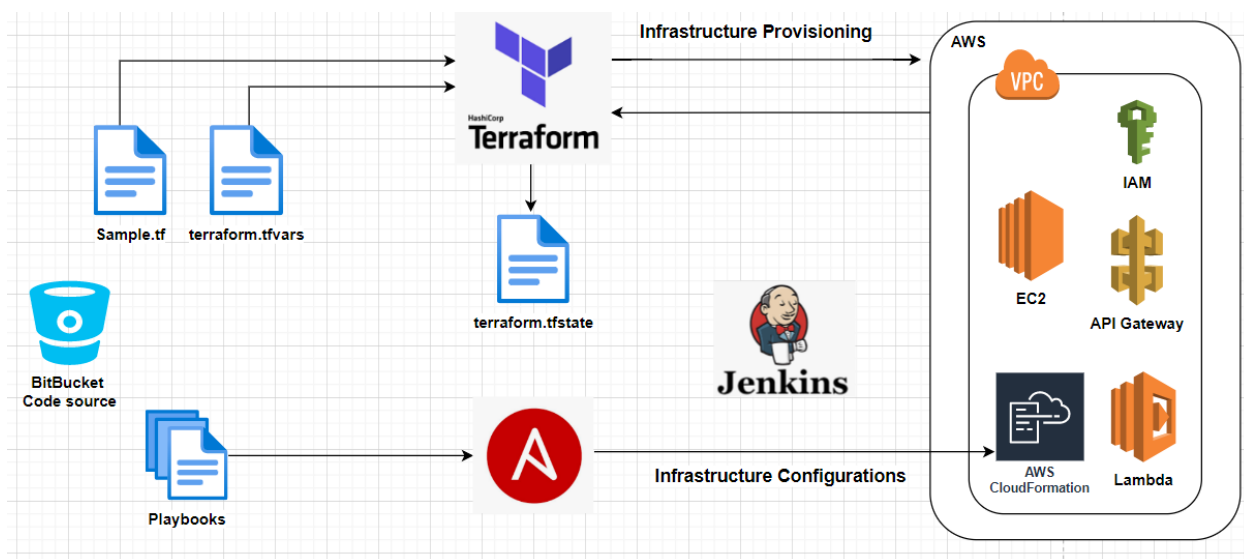

Figure 3 – Reference Architecture

Bitbucket is the source code controller for developers to commit their code. We are following the terraform deployments for infrastructure provisioning in the cloud, including the role provisioning, user accounts. Terraform variable files, modules, and the Ansible playbooks are all stored in the source control tool. Jenkins orchestrates the deployment automation process by invoking the cloud formation templates through Ansible scripts for serverless application deployments such as AWS Glue and AWS Lambda. These serverless processes are heavily used for the integration and ETL processing. Terraform records the state files and compares them against the requested resources while running the plan and deploy the infrastructure as a code to the requested AWS instance.

For the on-prem deployments, we have the built in Informatica power center command shells that manage the deployment through the enterprise supported CI/CD tools Bitbucket and Jenkins. This helps the developers to maintain a common codebase and repository while reusing the deployment pipelines wherever possible. Similarly, the big data applications across different services and tools like Spark Streaming, batch Spark, HBase, Python applications, are all deployed following the above architecture. The exception to this is the on-prem Hadoop file systems that are orchestrated through Ansible automations instead of AWS Terraform and AWS CloudFormation. This provides the developer a simplified and well-established deployment automation pipeline that is configured upfront and can be extended based on the specific use cases.

7. Conclusion

The journey into expanding a culture of Continuous Integration and Continuous Deployment into the Data Integration space has been one that mirrors the actual process of continuously iterating and deploying. Adoption of existing capabilities into the data space, and the partnership with enterprise configuration management teams to extend the capabilities for different software development tools, helped us to build a robust and useful CI/CD process.

People, process and technology are three pillars of a successful delivery model. Rolling out CI/CD into data space was done without jeopardizing the customer experience with frequent releases and lesser overhead on software developers to adopt the process across different tool stacks. Zero down time server upgrades, what would have once been a unique phenomenon, is now a common practice for data platforms with the introduction of standby clusters. Those lessons are now able to be transferred into other sides of engineering, to help drive improvements at a wider scale and without the need of constant manual intervention.

I would like to take the time to thank those who lent their time and expertise into the completion of this paper and presentation – Lisa Pinkey Coleman, Kesha Heard, Greg Garrison and Chandrasekhar Anne.

1. The Case for a 3D Digital Twin

MSO's have two powerful and unique advantages towards delivering Smart City/Community programs – an expansive high speed, low latency network footprint and tremendous experience and expertise in the local markets they serve. However, delivering these expansive projects at scale, including Fiber-to-the-Premise/Home (FTTP/H), fixed wireless access, streetlight modernization, digital kiosks, parking, accessibility, and other intelligent Internet of Things (IoT) deployments presents unique challenges far different from the traditional cable business.

In the traditional business, a “best efforts” approach to data with uneven quality and currency, for example two-dimensional (2D) Geographic Information Systems (GIS) maps that are out of date, in many cases have been “good enough.” In contrast, connected community programs require up-front three-dimensional (3D) information models covering buildings, sites, surface features, existing infrastructure, and ROW (right of way). These models need to be current, hyper-detailed, and comprehensive, and they must offer pinpoint accuracy. As a result, the traditional approach to data gathering with manual field walkouts is time inefficient, costly, and doesn't meet the new requirements for smart community planning, IoT engineering, and project execution.

To effectively address the “Smart City” challenge, a new and innovative approach to capturing field data – infrastructure, assets, and site conditions – is required to support the more precise requirements of fixed and wireless IoT deployments. This includes high resolution 360-degree imagery, dense LiDAR (Light Detection and Ranging) point clouds, and machine learning. Working with Cox2M, a division of Cox Communications, and building on the latest technologies, R&D efforts, and project experience across several relevant use cases, a blueprint for a smart community enablement platform emerged, largely enabled by the power of a detailed and accurate 3D digital twin.

This technical paper will outline the business rationale and specific use cases related to new MSO initiatives in fiber-to-the-home or -premise (FTTH/P), wireless, and private-public partnerships, and then dive into the technical requirements, challenges, and implementation of a 3D digital twin to accelerate and meet the end-to-end deployment needs of leading edge, connected community projects. Key learnings and best practices will be highlighted, along with performance metrics from actual projects – such as cycle time reduction, data quality improvements, and cost savings – that quantify the true benefits and impact of developing and integrating a 3D digital twin for field data automation.

2. Key Components of a Smart Community Planning and Engineering Solution

There are several high level requirements that are unique to smart community IoT planning and engineering (P&E) projects. These include the following key capabilities and attributes:

- 3D model of the real world
- High precision and accuracy
- Immersive online digital environment
- Integration with GIS and design tools
- Timeliness of information

Here is a deeper dive into the five essential components of the digital twin solution for smart community/IoT planning and engineering.

2.1. 3D model of the real world

Any assessment of the existing field conditions, such as infrastructure, relevant assets, surface features, and for that matter everything within the right of way (ROW), has to be presented in a three-dimensional context. This means both imagery and LiDAR are needed in order to produce a digital 3D representation of the true field conditions. The primary reason for this is that optimal placement of IoT-enabled devices and supporting connectivity (fixed and wireless) requires comprehensive and detailed horizontal and vertical references to address factors such as line of sight, clutter, visibility, accessibility, form and fit, and aesthetics. Even something as simple as taking measurements need to be performed in 3D space using x, y and z coordinates. A traditional 2D GIS map falls flat!

2.2. High precision and accuracy

Engineering smart kiosks, lighting, sensors, fixed wireless access (FWA), Wi-Fi coverage, and pre-connected FTTH cables and drops, requires very accurate site information and high precision reference data. GIS maps are typically based on legacy information that has been converted and/or migrated over time with poor positional accuracy, at best 2 to 3 meters but often much worse. Taking measurements, which are dependent upon the precision or relative accuracy of the data, cannot be trusted for engineering tasks. This means that a field survey, often referred to as “boots on the ground” or “field walkout”, is required but this takes a lot of time and expense. The results have worked adequately for traditional cable and telecom engineering for many years, but this approach does not deliver the on the imagery and 3D model requirements, and it does not provide an immersive digital twin (see next section).

2.3. Immersive online digital environment

An extremely important part of the smart community solution is the notion of a “virtual field walkout”. This refers to the ability for project stakeholders to visualize the real world environment from an application on a connected device such as a PC, laptop, tablet, or smart phone – in essence a digital twin. There are many benefits to having this capability, but the primary ones are:

1. Eliminate or reduce time, cost, and risk of “boots on the ground” field work
2. Ensure high quality measurements and calculations based on true 3D data
3. Collaborate and solve problems quickly and confidently
4. Avoid remedial work and mistakes related to poor or missing field information

Figure 1 – High Resolution Imagery & Extracted Assets

A large international engineering firm refers to high resolution street level imagery and LiDAR as “the single source of truth” for planning, high level design (HLD), low level design (LLD), and permitting.

2.4. Integration with GIS and design tools

Planning and engineering work is typically performed using GIS, computer-aided design (CAD) or other geospatially-enabled software tools. Digital field data must be integrated with these tools for productivity, accuracy, and completeness. There are two core requirements for the integration of a 3D geospatial digital twin with GIS and CAD.

2.4.1. Support for 3D data

The GIS or CAD platform being used for smart community/IoT projects must support 3D data management and visualization. Platforms that are used extensively for managing and designing in three dimensions include Esri ArcGIS and ArcGIS Online, and AutoCAD. In addition, the platform must allow high density LiDAR point cloud files and extracted 3D asset/feature vector data layers (points, lines and polygons) to be automatically loaded into the database.

2.4.1. Open API

There are two application programming interface (API) capabilities that are needed for effective integration of imagery/LiDAR and extracted 3D asset and feature data. The first is a 360-degree viewer plugin that works interactively within the system's user interface (UI) so that designers can perform tasks in an immersive 3D workspace. These sorts of plugins are normally set up using Java Script or Practical examples of this include recording measurements and placing proposed design elements in three-dimensional space with x, y and z coordinates. The second API capability that's important to the overall usability of digital field data for design and permitting is live rendering of third party data such as LiDAR, imagery, and vectors in real-time. This would be the approach used for data that is stored on the cloud and made accessible using a standard file format (such as LiDAR .LAZ, or vector DGB or Shapefile), or as an online internet protocol like WMS (web map service) for map tiles or WFS (web feature service) for geospatial data records.

2.5. Timeliness of information

Having the ability to capture field data where and when needed is critical to the overall smart community solution process, sequence of events, and project timeline. Ideally, field data for planning and engineering should be captured within 3-9 months of HLD/LLD and permitting, and no more than 12 months old. Similar to mobilizing field workers to inspect, survey and inventory field information, this means that imagery and LiDAR data capture needs to be mobilized early in the project cycle since it's required as input to planning, engineering and permitting activities. In essence, the field data needed to build a comprehensive 3D digital twin model of the real world must be performed on demand for the target area of interest (AOI).

3. Technical Considerations and Specifications

The foundation of creating a 3D digital twin of the outside plant (OSP) environment is the recording system. There are several options when considering field data capture, such as the method of capture, the type, frequency, resolution, accuracy, and level of effort.

Here is a simple matrix showing the available commercial options for field data capture supporting smart community use cases:

Table 1 – Commercial Data Capture Options

Data Capture Options	Type(s)	Method	Frequency	Resolution and/or Accuracy	Level of Effort*
<i>Fixed Wing Aerial</i>	Ortho & oblique imagery, LiDAR	Low altitude at slow speed, grid pattern flight plan	On a set schedule	30- to 150-megapixel imagery, 50 to 100 points-per-square-meter LiDAR, 0.1 to	Low

				1.0 meter positional accuracy	
<i>Drone</i>	Oblique & 360° imagery, some LiDAR options	Flown with ground-based pilot, requires permit or authorization	On demand	30-megapixel imagery, 500+ points-per-square-meter LiDAR, 0.2 to 0.5 meter positional accuracy	High
<i>Street Level</i>	360° & ortho imagery, LiDAR	Vehicle mounted, follow public and private roads, parking lots, etc.	On demand	30- to 100-megapixel imagery, ~1,000 to 2,000 points-per-square-meter LiDAR, 0.1 meter positional accuracy	Medium
<i>Backpack/hand-held</i>	Conventional & 360° imagery, LiDAR options	Heavy backpack, trolley or hand-held device	On demand	10- to 20-megapixel imagery, 1,000+ points-per-square-meter LiDAR, 0.2 to 1.0 meter positional accuracy	High

* Level of Effort is based on the time and cost per unit of measure, such as square miles or linear miles.

Based on the above criteria along with testing, trials and production projects performed by companies like Cox2M (a division of Cox Communications), Verizon OneFiber and Wireless, Ledcor Technical Services, Byers Engineering, and CalComm Consulting, street level imagery & LiDAR capture is best suited to the specific requirements of IoT and communications planning and engineering projects. The factors that have contributed to this conclusion are imagery/LiDAR resolution and quality, data capture flexibility, speed of capture and post-processing, overall cost, and ease of integration.

3.1. Street level imagery & LiDAR capture

The on-going evolution and recent innovations in vehicle-based street level imaging has enabled the creation of a geospatially accurate 3D digital twin. A great example of this is a recording system comprised of five individual cameras that fire off in sequence to the front, right, up, left, and rear as the vehicle crosses theoretical recording locations, also known as recording points, that are taken 5 meters apart as the vehicle drives and captures the AOI. The source images are merged using a patented process, creating a “GeoCyclorama” – a seamless, parallax-free, spherical, high-resolution, panoramic image taken at street level. At 5-meter (16.4 feet) intervals, the GeoCyclorama” is generated covering the entire road

network for the target AOI. The resulting 100-megapixel resolution imagery, in which each pixel location is identified, provides users and systems with imagery that is both incredibly detailed and accurate.

Figure 2 – Example of Vehicle-Mounted 5-Camera, LiDAR and GPS System

The 100-megapixel resolution provides a full 14,400x7,200 resolution image. There is a 0.025 arc degree separation between pixels which translates to ~4.0mm at 10 meters, and ~6.5mm at 15 meters, between pixels. At 10 meters this is roughly a density of 62,500 pixels per square meter on a vertical plane such as a wall.

The LiDAR scanner is running the entire time so that the imagery and point cloud data capture is aligned and covering the exact same AOI. A high specification global positioning system (GPS) is integrated with the cameras and LiDAR sensor to ensure the best possible position identification and recording.

3.2. Imagery & LiDAR integration and positional accuracy

GeoCycloramas are high-resolution, parallax free images with a built in spatial component providing not only a precise location for each 360-degree image but an x, y & z coordinate for every pixel within the image. The patented capture technology allows for the precise pixel arc separation mentioned previously, which allows the system to accurately tie the imagery and LiDAR together. With the level of integration, the LiDAR point cloud is colorized based on the RGB (red, green, blue) values from the imagery. This is a very important part of the unique and innovative approach – any other process where imagery and LiDAR are collected separately will not deliver the accuracies and immersive capabilities of the GeoCyclorama, even if it's possible to integrate them after the fact (which is extremely uncommon). During this post-processing stage, other positional improvements are applied through steps such as geospatial positioning alignment with a reference datum (control points) or external model, and relative positioning improvement (RPI) that utilize overlapping datasets to improve the data even further.

On average, the absolute positional (x, y & z location) accuracy is +/-10cm at 1 standard deviation. The relative accuracy, for example for taking measurements like pole spans, height of attachments, pavement width, concrete surface areas, is on average +/-2cm at 1 standard deviation.

3.3. Data analytics: asset and feature extraction

Extracting assets and other features from the imagery and LiDAR data is generally called data analytics. Data analytics tools and processes include a combination of machine learning (ML), artificial intelligence (AI), automation, partial automation, and human review and input from skilled analysts and subject matter experts (SMEs). Over time the algorithms improve, and the level automation increases based on

lessons learned on production projects and as feature recognition libraries continue to be further developed.

Data analytics and extractions run through a proprietary and optimized platform that provides a host of automated, semi-automated, and manual tool sets to efficiently detect, extract and deliver a quality asset and feature-rich data analytics product. Over time the teams working on next-generation communications, IoT and smart city projects have built up an extensive library of ML models that can detect common infrastructure, roadway, roadside, architecture, and public works features from the 360-degree imagery and place the geometric representation accurately within the LiDAR point cloud data. The data analytics process has matured to become an entire workflow that includes project tracking, data management, automation, QA/QC, and client delivery to ensure that a quality product is maintained and that consistently meets the service level agreement (SLA) and required specifications.

To show the extent of the collective team's efforts, below are examples of some of the most widely used data analytics extraction assets and features, called data dictionaries:

Table 2 – Asset and Feature Extraction Examples

Pole Details	Overhead	Ground Features	Right of Way
Pole Base & Top	Span	Cabinet	Edge of Pavement
Material	Midspan	Manhole	Back of Curb
Cross Arm	Lowest Vertical Clearance	Handhole	Sign & Structure
Guy Wire POA	Power Vertical Clearance	Vault	Traffic Signal
Guy Wire Anchor	Primary Conductor	Pedestal	Bus Shelter
Equipment POA	Comms Cable	Wall	Sidewalk
Streetlight POA	Streetlight	Fence	ADA Ramp
Power POA		Building	Lane Markings
Comms POA			

4. Conclusion

The teams at Cyclomedia, Cox2M, and the other service providers and engineering firms – not to mention numerous local governments, cities, counties, and municipalities – have firsthand experience that collectively adds up to hundreds of projects and hundreds of thousands of miles of imagery and LiDAR data capture and processing. The use cases that have been successfully delivered include long-haul fiber, FTTH/P, 5G planning, pole inventory and engineering, joint use reconciliation, tax assessment, first floor elevations, sign condition and inventory, accessibility, and highway sign and roadway condition

assessment. Several best practices have emerged and more continue to be developed all the time. The most important findings are summarized as follows:

Remote sensing technologies have advanced so much in the last 3-4 years that imagery and LiDAR solutions have become a viable alternative to manual field data capture, including use cases like pre-engineering walkouts, visual inspections, infrastructure and inventory surveys, and condition assessment.

High quality and precise imagery, LiDAR and data analytics can replace 80-90% of traditional boots on the ground field data capture and accelerate project cycle times by 50% or more. Safety is improved while risk and liability are reduced.

Street level data capture is best suited to smart community, communications, and IoT planning and engineering due to the close proximity to assets, infrastructure and features, high data quality, immersive experience (virtual fielding), speed and ease of capture, and flexibility of the AOI.

Machine learning and automation are continuously able to handle more and more asset and feature extractions over time, but human subject matter experts are essential to training the routines, expanding the capabilities, and ensuring that quality and completeness goals are met.

Street level data is a foundational component of creating a 3D digital twin city model to support smart community, IoT and communications planning, engineering, permitting, and construction.

Cyclomedia and Cox2M are looking at short-term requirements to support additional assets and features along with closer integration with P&E workflows and tools. Longer term, the companies and other partners are looking to automate a greater number of assets and features, streamline the integration to the design and project management systems, and look to incorporate additional data sources into the analytics process. The Cyclomedia and Cox2M leadership teams welcome feedback from other SCTE, CableLabs, and NCTA members, and are open to development collaboration, lab testing and functional pilots to advance the 3D digital twin capabilities for smart community and IoT projects and evolving use cases.

1. Introduction

DAML is intended to include a list of terms that are ever-expanding in *both their breadth and depth*—far too many to list here. This is like looking at a wide-field telescope and a powerful microscope *at the same time*. Very few people can keep up with the changes or make sense of the interpretations between these views.

What this paper is *NOT* is an appeal for everyone to become:

Figure 2: intensely deep programmers on dark screens in dimly lit cubicles,

Figure 3: neuroscientists to optimize all learning, behavior, and processes,

Figure 4: or automation executives that desire very few humans doing all complex work with their single push-button fingers;)

Highly skilled experts and visionaries are essential to create *meaningfully unique* products and services. However, by having a much higher level of awareness and collaboration from the rest of the organization, communicating to the expert's "wavelength" is greatly improved. This enables achieving better results on the most important needs faster, more efficiently and with less resource cost.

1.1. A tale of two CEOs.

The author learned a great deal about the importance of an enterprise wide DAML initiative through two vastly different consulting engagements.

The first was entirely CEO-led at a one-hundred-year-old financial company. It began during a golf game where his competitor suggested he use a particular robotic process automation (RPA) tool and completely plan and implement it with an outside consulting company. Around the same time this CEO's Chairman requested that he implement a specific intelligent document processing (IDP) system used by two sister companies to eliminate manual efforts and errors. Five RPA processes were targeted, but only one was delivered and put into production; one was eliminated far too late in the process because of the high complexity; three others were put on hold when the consultant asked for additional compensation for the second time. The IDP software was eliminated after months of planning and implementation because the cost benefits for the applications considered were extremely poor compared to the sister company's high transaction volume. Sadly, there was another huge effort that targeted AI to transform the call center into

a digital contact center as well. The only people that knew this information in detail was a knowledgeable call center manager who was laid off, a fantastic technical executive that battled valiantly to reduce the weekly management changes, and a two technical contract project managers that were never made full-time employees.

The second CEO was at a software as a service (SaaS) company beginning to utilize DAML in a profound way to improve performance over time once the SW administrators approved the automations. This CEO wanted to completely change the mindset of all his employees by teaching them DAML; the author helped create a strategic organization plan and a potential product roadmap for new applications to be considered in this effort. The results were amazing. Not only did the employees learn these skills but began to suggest new product ideas and help bring them to reality while also looking for ways to use DAML methods in their daily work. This company has continued to evolve, filing several new patents, and being awarded at least two more. All of this helped attract attention from some of the largest multi-national companies in the world.

Much of the HOW information contained below was used from this approach.

1.2. Paper approach.

This paper will first discuss **WHY** DAML is so critical; next **WHAT** to *initially* teach company employees as the DAML bedrock; then finally **HOW** to deploy this strategy using simultaneous top-down and bottom-up approaches.

2. WHY DAML must become your organizational thinking and “vibe”.

In the 2016 motion picture *Hidden Figures*ⁱⁱ, Dorothy Vaughan is a mathematician who worked as a ‘human computer’ for NASA during the 1960s. When NASA installed their first IBM 7090 mainframe computer, Dorothy feared she and her team would soon become redundant, then she correctly predicted NASA’s urgent need for a programming team. Instead of worrying or doing nothing, she taught herself about the computer and the FORTRAN programming language, and then taught it to her team who became NASA’s very first programming team. Vaughan embraced their undeniable future with enthusiasm, helping not only herself but her colleagues, their families, NASA, and eventually society for their contribution.

Figure 5: Hidden Figures' Dorothy Vaughn Learns New Computer Technologies Before It Replaces Her Team

“No doubt about it, data is now a prized business asset, which means organizations of all kinds will want to employ data-literate individuals. In an average business context, data literacy means being able to access appropriate data; work with data confidently (creating/gathering data, keeping it up to date, etc.); extract meaning from data; and communicate those data-based insights to others. It is also important to question the integrity and validity of any data you are working with, rather than blindly following data”ⁱⁱⁱ.

2.1. How the world's leading companies are cultivating a new business culture—Case Study JLL.

JLL is one of the largest owners and operators of commercial real estate worldwide with an astounding 4.6B square feet in property and facilities management. Over the past three years, Paul Chapman, JLL’s global director of business intelligence and technology, has worked to develop a data culture across every aspect of the company. “Our facility managers can see the data for themselves, from showing them how old air conditioning units are and when they should be replaced, to how much each facility is costing per square foot.” Employees at every level of the company have access to this data through a dashboard, helping them to determine the root cause when problems arise and to figure out how to respond.^{iv}

2.2. Motivations for making DAML an enterprise wide initiative.

2.2.1. DAML adoption is already exceedingly high.

Figure 6: DAML Production Deployments Increased from 35% in 2019 to 47% in 2021^v.

Above figure shows high in-use DAML projects, and they are increasing over 15% CAGR.

2.2.2. New DAML knowledge areas are exponentially increasing.

Figure 7: Gartner Hype Cycle for Data Science and ML July 2021

Gartner publishes annually expectations for technologies in specific areas called Hype Cycles where the white and light blue circles depict those knowledge areas advancing the fastest. Organizations implementing these technologies typically must wait for these technologies to advance to at least the 4th

“Slope of Enlightenment” segment for outcomes to change business processes. Beginning a comprehensive DAML program across the entire organization better prepares everyone for the continual change of skillsets, mindsets, and toolsets that these innovative technologies require. One could easily claim these knowledge areas are not simply increasing but *exponentially* increasing.

The time to embrace DAML is *right now*.

2.2.3. Establishing a “data-driven culture” is the biggest contributor to DAML success.

Figure 8: Areas Critical to DAML Success^{vi}

2.2.4. DAML must become EVERYONE’S strategy.

As seen in the figure below, the impacts of enterprise wide DAML initiatives are far reaching.

Figure 9: When an Organization Embraces DAML, Various Team Strategy Components Must Be Implemented^{vii}

DAML skills are also seen as critical in every department of an organization:

Figure 10: Importance of DAML Skills by Department^{viii}

2.3. DAML value for *me* as an employee, and how will it make my job easier?

The initial outcomes of DAML processes starts by *augmenting* human capabilities, reducing mundane, repetitive, and even dangerous tasks to allow a greater concentration on the unique skills that define us as individuals.

These distinctively human talents are the most difficult to automate and therefore will become the most indispensable:

- Effective communication and collaboration through emotional intelligence,
- Empathy, compassion, and authenticity;,,
- Curiosity plus instigation,
- Strategic analysis and analytical thinking,
- Complex, multi-disciplinary judgement, and decision making,
- Adaptability and extensibility,
- Creative thinking leading to real innovation,
- Conflict resolution,
- Cultural intelligence and diversity consciousness,
- Ethical awareness,
- Negotiation and persuasion, and
- Leadership through genuine trust, transparency, inclusivity, and respect.

Can you envision an exemplary, engaged fellow employee NOT wanting to shed monotonous tasks to focus on these critical thinking and empathy skills?

Figure 11: Gartner's Top Data and Analytics Trends for 2022 (Partial)^{ix}

The above figure describes the need to help employees where they work currently and to aid in their efficiency and quantity/quality of work output. This means to augment people with a broad array of contextual data, to build up components optimized on how teams really work, to understand how decisions are made (aka “decision engineering”) to optimize people and process impact, as well as to build a higher level of DAML competency.

Curiosity and desire for continuous learning, growth, and improvement is cited at the one skill everyone must cultivate. Whatever your age, whatever your industry, if you can spark your desire to learn, you will be giving yourself the best chance of a successful, fulfilling life. Especially in a work context, curiosity and continual learning are fundamental to being able (and willing) to embrace change. It ensures your skills stay sharp, that you can keep up with the major transformations taking place, and that you stay relevant. DAML is a major transformation.

2.3.1. YOUR current job may cease to exist.

Figure 12: Funny Because it is True^x

Automation will have a far-reaching impact on the global workforce.

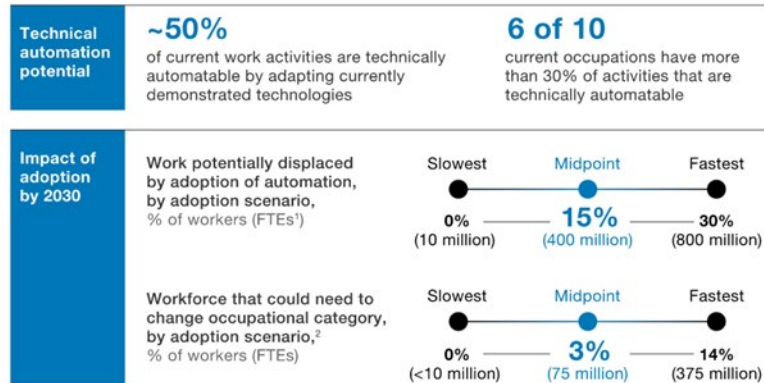

Figure 13: Employment Changes from Automation 2017-2030^{xi}

This same McKinsey study continues “...between 400 million and 800 million individuals could be displaced by automation and need to find new jobs by 2030 around the world...Of the total displaced, 75 million to 375 million may need to ...learn new skills...”. Some respected sources predict over *half of all existing jobs will become obsolete through DAML*—but this can become a source of strength for employees who absorb, employ, and evangelize DAML skills. Every employee must become shrewder in what will disrupt, augment, and improve *every* existing job description, work process, and organizational design.

However, the World Economic Forum predicts that “by 2025, 97 million people will be needed for AI-related jobs, and that doesn't count the numerous other jobs that AI will help produce”. As McKinsey noted, “early, innovation-focused adopters (of AI) are positioning themselves for growth, which tends to stimulate employment.” Moreover, most companies understand that AI's real benefit is not automating people out of jobs but *enhancing their skills, reducing errors, and freeing up employees to do more important tasks*”(italics added)^{xii}.

One reason to not despair: DAML will “*result in the creation of many more (new and unforeseen) jobs.*”^{xiii} Similarly the Institute for the Future predicts that 85% of jobs that will be available in 2030 *have not been invented yet*^{xiv}.

2.4. How can my organization benefit?

The overall benefits of driving an enterprise wide DAML movement are already being embraced by leading corporations across the globe leading to enormous success. The most critical gain from an organizational DAML strategy is to *generate value from information assets* by first improving internal processes, then secondly to increase the value of products and services; both concentrate on efficiency and innovation.

However, the third organizational gain is the wildcard that greatly enhances cultural alignment and cohesion is recruiting and retention. More on this later.

It would be ironic to ignore striking industry statistics that are metricized, collected, and envisioned using DAML processes that themselves indicate the importance of DAML processes:

Figure 14: Impacts of Employee Training Programs

References for Figure 14:

- “Companies that offer”^{xv}
- “A 10% increase”^{xvi}
- “40% of employees”^{xvii}
- “Recent national survey”^{xviii}
- “In a recent”^{xix}
- “According to a study”^{xx}

As stated, the effect of a poor training environment has a profound impact in employee turnover and this impacts recruiting. Employees frequently rank the ability to learn new skills and try different approaches as the key factor in their decision where to work. Intelligent people are also well-connected and talk to others when networking about companies and how employees are treated. The mantra is you tell one person about positive experiences and ten people about the negatives. Therefore, insufficient training impacts recruiting as well as investments in recruiting, hiring, and onboarding a new employee.

Organizational benefits of implementing a comprehensive, DAML-driven, enterprise-wide initiative:

- Connect every aspect of the organization to customers, mission, and vision statements using commonly understood definitions, well-placed metrics, continuous monitoring, and visualization, leading to a reformulation of operating models,
- Use as a valuable tool in cultural change and alignment,
- Create the concept of monetized data; *information* asset values related to actual loaded cost or time value. Also include in values intended/future use, connections to entities/processes/individuals/groups/physical assets, error/believability, security, confidentiality, authenticity, external sales/licensing, update frequency, and expected end of life,

- Improve the prioritization of critical business processes as well as business process efficiencies through elimination of duplicate processes, alignment, optimization, automation, plus continued maintenance, and improvements,
- Combine and accelerate innovation processes to generate new and more meaningful data-driven intellectual property (IP), products, and/or services,
- Focus employees less on tactical execution of repetitive tasks and more on improving the tactical processes. Participating, possibly for the first time, in customer-centric and strategic enhancements,
- Empowers all levels of workers to ask the right questions of data, processes, and machines, build knowledge, make more informed decisions, and better communicate meaning and context to others.

“IDC found that only 36% of their surveyed enterprises succeeded in putting completed (DAML) models into production. Nearly half of the remainder (32%) had not even made it past proof of concept’. By raising the DAML education and experience level of the entire staff, more thoughtful processes will be chosen by the employees that know them best, improved business process flow information will be collected, and more informed visualization and testing will occur leading to higher quantity and especially quality of the resulting information.

2.4.1. How does DAML reduce and eliminate errors?

DAML enables an iterative, experimental approach by personnel closest to customers, opportunities, and obstacles, improving decision speed and *especially quality*, reducing resource waste, and streamlining communications so that all employees can understand and act.

2.4.2. Greater customer insight and retention.

“(DAML) driven companies are twenty-three times more likely to acquire customers than their peers”^{xxi}.

The digital world is built on data and information. Information on user behaviors can be collected and analyzed using DAML methods to understand how people are using and even socially commenting on products and services, enabling customized experiences that better meet their needs, styles, and desires. Using extracted information in context is commonly referred to as hyperpersonalization, and further drives customers to purchase, engage and even evangelize because of experiences tailored only for them.

2.4.3. Retention and recruiting

HR frequently is charged with recruiting and retaining the absolute best, however vague, non-metricized statements are always misleading. It is clear recruiting and retaining competent talent with critical thinking skills—and most especially the most coveted DAML skills—leads to a reduced turnover ratio and therefore a higher profit margin than the competition.

The figure below highlights the key skills required by open roles in several industry segments. Communication, analysis, and collaboration are what every employer needs the most, and these are some of the very skills accentuated by an enterprise wide DAML strategy.

Figure 15: Data Source: Gartner’s TalentNeuron, and represents jobs posted between 4/22/2021 4/22/2022

Most companies pursuing DAML will focus entirely on recruiting a team of highly trained technical experts. However, with the exponential expansion of DAML organizational needs comes a serious shortage of potential employees at this level, forcing many companies to live with extremely high consultant salaries, noticeably shorter tenures, and often very remote or offshore resourcing making direct engagement with the business leaders impossible.

By training *everyone* on DAML, the strain of finding increasingly rare and transient experts to completely lead DAML efforts is reduced—but never eliminated. All employees that become aware of the vocabulary, methods, and potential outcomes of DAML can greatly assist a much smaller and integrated pool of specialists. Employees using their existing business knowledge with their new skills will create a cooperation between them and an atmosphere that exudes excitement both inside and outside the company. When a company understands their value, mission, and customers and becomes emboldened to learn and employ the latest DAML skills to create visible outcomes, recruiting becomes *almost* effortless.

DAML processes are rarely siloed into one small area, but rather benefit from the combination of neighboring departments, subjects, and data sets. By mapping “skill adjacencies,” employees better understand how their skills and job definition connects with their closest working colleges and throughout the company so that their insights can be extended to other areas by both awareness and cross-training.

Use of DAML skills by human resources (HR) *internally* also has great benefits. “(DAML) can influence and improve how human resources departments manage recruitment. Tapping into data can help companies to headhunt the most promising talent by comparing performance metrics. From here, businesses can retain these valuable staff members through the culture of clarity that data-based working environments foster. Essentially, data-driven human resource strategy has significant short- and long-term benefits, creating a productive, motivated staff team who will increase profit margins.”^{xxii}

Figure 16: Every Job Function has Adjacent Skills and Roles. Example Shown for Cloud Engineering Skill Adjacencies

2.4.4. Increased performance through DAML organizational obsession.

DAML drives workforce productivity by increasing efficiencies—whether individually, in work teams, for departments and divisions, or the entire organization. Data selected by the people that best understand the processes and potential outcomes enables more tangible goals by creating a clearer picture of the overall targets, behaviors, and patterns, allowing an agile approach to enhance productivity. It also allows identification of areas for improvement and promotes transparency and accountability.

In a study of over four hundred businesses, it was confirmed that organizations with the most developed analytics capabilities commanded a larger market share, were twice as likely to be in their sector's top 25% for profitability and were five times more likely to make swifter decisions than competitors^{xxiii}. The point being organizations that are not exploiting DAML are certain to lag their competition. Another study confirmed these findings. By analyzing data sets from Fortune 1000 corporations, the impact on profit resulting from DAML was measured. Some notable findings included:

- Companies could increase profit by more than \$2 billion a year by making just 10% of available data usable.
- Return on equity increased by 16% by making data more accessible.
- When advanced reporting was deployed, return on investment increased by 0.7% – which is equal to \$2.87 million in additional revenues.
- Most importantly, a comparably low investment in data analytics was required to produce these significant gains.
- DAML driven companies are 58% more likely to beat revenue goals than those who are not focused on data,

2.4.5. Collaboration and working

in teams.

This is one of those skills that seems obvious for workplace success, so why include it? “Because the nature of collaboration and teamwork will change as teams evolve to include automated processes as well as hybrid workers, fully remote workers, contractors, and other employees from different business units who “float” between projects and teams. With such distributed teams, we need collaborative skills more than ever.”^{xxiv}

Creating a vibrant DAML program will create or enhance the organization’s foundation of cross-disciplinary collaboration and problem solving. More will be mentioned on this later in the HOW section, but employees enjoy brainstorming, goal setting and progressing their own defined initiatives in teams. By composing them of different perspectives and levels instantly adds a diversity element found to be crucial to innovation success, so it is also important for DAML success.

2.5. How can the cable industry benefit?

It is time *the entire cable industry swiftly embraced the implementation of a DAML strategy* to propel it into the future using data-driven initiatives that have been proven by hundreds of leading organizations. DAML is key to not only thrive but exceed the competition and race for the best strategic and forward-looking talent. “Not to decide *is* to decide.”

During a recent virtual conference, SCTE CEO Mark Dzuban made several points in a session labelled “Tackling the 10G Challenge”. 10G is a CableLabs’ series of initiatives to prepare cable operators for symmetric 10Gbit/sec access networks and applications. He described an urgent need to “work with CableLabs to elevate the knowledge base to “bring 10G to life”. He continued to describe “Project Wisdom,” a CableLabs’ training initiative for advanced skills, capabilities, and knowledge through community colleges and universities. “Its goal is to create “unique talents to build 10G” and “AI-driven cable operators” leading to “increased (customer) touchpoints, proactive operations at outages, zero touch for customers, and to connect through all ways (we) communicate”.

Mark closed by saying he would like future job seekers to “think of cable as a career path, especially for automation and AI/ML”^{xxv}. So “(c)able leaders must not only focus on attracting new employees to the industry, but it is imperative to upskill the existing workforce to support the global expansion of connectivity and technological innovation”^{xxvi}.

2.6. Ignoring DAML will doom existing companies.

Failure to embrace this fundamental change will doom an organization’s competitive ability, potentially taking them out of business eventually. “By 2030, AI will lead to an estimated \$15.7 trillion, or 26% increase, in global GDP”^{xxvii}. This increase is greater than both China and India’s current GDP *combined*! Increased productivity accelerated by DAML will contribute to approximately 40% of this increase in GDP growth.

Educating employees to better understand DAML vocabulary, methods, processes, roles, and metrics for both internal and external projects will increase communication, clarity of thought and actions bringing all departments together to speak a universal language that benefits the company.

Figure 17: What You Don't See Can Kill You (and Your Organization)

3. WHAT DAML areas to initially address.

This section gives three initial areas to consider with the goal to model your approach by balancing strategic and tactical priorities of your organization. These are only a few suggestions among thousands, and the tools your organization selects from this DAML toolchest are entirely determined by process selection and prioritization efforts.

Figure 18: Operating Model of a DAML Organization^{xxviii}

3.1. A quick aside on “determinant” vs. “assisted” DAML processes.

DAML is often thought of as determinant, or unsupervised, making complex decisions without any human intervention. Look only to Space Odyssey’s Hal 9000 to see this is naïve; the most critical area to begin with is assisted or *supervised* processes.

Figure 19: Always start with assisted DAML processes

People must still be accountable for the business decisions made, and it is not possible to build everything a human business expert can do well. So, recommendations are output for the human to respond, providing a “feedback mechanism” so that the system can learn from the human response to eventually become *almost* unsupervised; but you can never leave “it” completely alone. The world and organizations are always changing, so system results must always be monitored with key metrics. Documentation must also totally describe the “what and how” of the manual process to enable new employees to take over when manual interaction is required, and automated process for future iterations.

3.2. Focus on data literacy.

“Culture and data literacy are the top two roadblocks for (creating a DAML fueled organization) ... (b)y 2023, data literacy will become an explicit and necessary driver of business value, demonstrated by its formal inclusion in over 80% of data and analytics strategies and change management programs.”^{xxix}

Gartner defines data literacy as the “ability to read, write and communicate data *in context*, including an understanding of data sources and constructs, analytical methods and techniques applied, and the ability to describe the use case, application and resulting value... By 2023, data literacy will become essential in driving business value, demonstrated by its formal inclusion in over 80% of data and analytics strategies and change management programs”.^{xxx}

“Data literacy isn’t a nice-to-have — it must become part of your firm’s DNA.” While most organizations strive to continually enhance decision making for critical tasks, “(t)he problem is not data availability or tools but lack of skills to use the tools and the data to drive business outcomes. Technology executives are creating data literacy programs to bridge this gap. These programs must be comprehensive, companywide efforts with executive support, strategic goals, and established metrics”^{xxxi}.

Tableau rated data skills/data literacy the number one need for Entry Level Skills in three categories: demand, increase in demand, and anticipated importance.

Figure 20: Despite Company Efforts Most Do Not Have Adequate Data Skills^{xxxii}

Goals should include basic data awareness, deeper understanding of insights, how to connect insights to decision-making, continued training of experts, and scaling skills across the organization.

- › Explore the need for data literacy — *Awareness, Comprehension, Expertise, and Scale* — across the entire organization.
- › Understand basic data competencies such as recognizing data and its value to the organization, interpreting data visualizations, data storytelling, data hunting, and insights-driven decision making.
- › Develop a comprehensive data literacy program to increase awareness of data and its value, improve understanding and data decision making, enrich expertise, and scale the program across the entire organization.
- › Identify opportunities for partnerships to expand and enhance data literacy from service providers and data literacy experts.

Figure 21: Forrester Approach to Building a Data Literacy Program^{xxxiii}

Data literacy today suggests the concept of an extended understanding of “Big Data”: literacy that places awareness and critical reflection of big data systems at its center^{xxxiv}. Big data uses extremely large data sets collected from all aspects of a business so that they can be analyzed computationally to reveal patterns, trends, and associations, especially relating to human behavior and interactions.

3.3. “There is No AI without IA (Information Architecture).”^{xxxv}

Figure 22: Most DAML processes fail because of data preparation and access^{xxxvi}

Data collection and preparation is the most time consuming and difficult part of creating meaningful outcomes from DAML. Everyone must begin DAML training on a few key subjects.

3.3.1. *Create data dictionaries that span the organization and align with industry.*

Enterprise culture has been described as “the collective conversations of an enterprise. So, it is impossible to change the behaviors and belief systems of an enterprise without first altering the conversations within it.

“Change your words, change your life.” “Words are containers of power.” Many motivational speakers have used these and similar expressions for good reasons. The way we communicate affects everything. Data literacy harnesses the power of organizational words to provide guidelines for making sure our communications are efficient, constructive, and used to achieve superior results. When companies do not begin with a common and maintained data dictionary (aka glossary), DAML efforts will not achieve optimum outcomes.

Figure 23: “Garbage In, Garbage Out” (GIGO)^{xxxviixxxviii}

3.3.2. *Seeking Common Acronyms*

Just as an organization must have a common vocabulary with identical definitions, they also must agree on acronyms. Common Acronyms used across an entire organization or even industry is not typically explicitly defined. Because they are not common to everyone, they can confuse and alienate unfamiliar audiences. Even well-intentioned writers and speakers may overestimate an audience's familiarity with abbreviations. Abbreviations should not be completely avoided but using them as a default assuming all agree with meaning and context can be problematic.

3.3.3. *Taxono Mies? Taxi please.*

A taxonomy is the discipline of classifying information and are typically created in a hierarchical, parent-child structure. They are extremely well organized by all users of this data and are typically published and maintained by an organization.

The “father of taxonomy” Carl Linnaeus was a Swedish botanist that named, ranked, and classified plants and animals in 1761: Kingdom, Phylum, Class, Order, Family, Genus, Species. Do you remember the helpful mnemonic like “King Philip Came Over For Good Spaghetti”?

Figure 24: Insert Some Humor When Content Appears Boring or Irrelevant

Another quite common taxonomy example that most people are familiar with is the Dewey Decimal System used for information organization, especially in library collections.

001-099	Generalities	PREQUEL TO THE DEWEY DECIMAL SYSTEM WHO AM I?	Encyclopedias, curiosities and wonders, unexplained mysteries
100-199	Philosophy		Books about the self, feelings, dreams, witchcraft
200-299	Religion	WHO MADE ME?	Christianity, Judaism, Buddhism, Hinduism, etc., and Mythology
300-399	Social Science	WHO'S THE GUY IN THE NEXT CAVE?	Customs, cultures, laws, manners, costumes, fairy tales
400-499	Languages	HOW DO I TALK TO THAT GUY?	Dictionaries, parts of speech, sign language, foreign language aids
500-599	Natural Science	LET'S TALK ABOUT THE WORLD WE SEE	Mathematics, earth, astronomy, chemistry, plants, wild animals
600-699	Applied Science	NOW LET'S MAKE STUFF OUT OF WHAT WE SEE	Inventions, robots, transportation, pets, recipe books
700-799	Arts and Recreation	NOW LET'S HAVE SOME FUN	Art, drawing, comics, handicrafts, music, games, sports
800-899	Literature	LET'S TELL OUR CHILDREN HOW WONDERFUL WE ARE	Poetry, plays, classic literature, jokes, riddles
900-999	Geography and History	LET'S TELL OUR FUTURE CHILDREN HOW WONDERFUL WE WERE	Landforms, travel, atlases, exploration, countries
92 and 920	Biography and Collective Biography	FIND OUT ABOUT FAMOUS PEOPLE	Single person: filed by last name of subject Multiple people: by author

Figure 25: Dewey Decimal Library Classification System

Having an organizational taxonomy is critical to begin any DAML project. DAML success only results when the entire organization is speaking the same language—using common definitions and a structured way to hierarchically organize all data and information. Think about it: most organizations continually create their own definitions and information organization, and quite frequently these conflict between groups, departments, divisions, functional areas, and acquired organizations. A company's taxonomy must come together to create a common language in the company and throughout the industry so all can more clearly communicate with each other. This heightened communication is the fruit of a well-versed staff in DAML, increasing productivity and thus contentment among employees.

3.3.4. Aim for INFORMATION CONTEXT.

Organizations must have a thorough and complete understanding and use of common data assets and derived information to maximize their DAML initiative.

When DAML processes connect inventory, data, resources, and people through common data and information communications, not only does the company benefit but the industry benefits as well. If DAML standards are not “set in stone” at the very beginning with pan-organizational definitions of every term, synonym, alternate term, and acronym list, the information *context* will be quickly lost.

It is impossible to create compelling, meaningful DAML outcomes from a misunderstood and fluid data and information foundation.

4. HOW DAML can be understood, embraced, and utilized by all employees.

DAML can be understood through common vocabulary, embraced through clear and simple methods, and utilized by employees who understand the benefits of DAML to themselves, their career, their company, and their industry. The positive DAML outcomes are clear: collaboration, retention, recruiting, mission alignment, external perception, revenues, and the excitement of being part of the future knowing and understand the tools DAML will provide companies in the future.

This section provides an overview of several suggested tactics to get every single person in your organization to understand, adopt, and engage in DAML. By selecting the DAML process priorities based on outcome values, some but not all these methods may make sense.

4.1. Start both “Fast and Furious” and “Slow and Steady”?

Initially the focus is on common DAML-specific vocabulary, basic concepts, methods, and both alignment to the organizational goals and the ability to begin to derive new goals for employees to teach themselves and their teammates. This approach is “Slow and Steady,” involving everyone from the janitor to the board chairperson. This means a tailored agile learning approach for each employee’s personal job responsibility, skill levels, learning style, and pace.

And now for the simultaneous “Fast and Furious” win: creating a one-time, company tiger team. A tiger team is a specialized, cross-functional team brought together to solve or investigate a specific problem or critical issue. People need an example of how to act and a good early success story.

A visible way to display DAML skills is to assemble a “tiger team” to help choose one easy-to-understand, visible-to-all, mundane, repetitive task that if automated would clearly save time and money while reducing errors and risk. This tiger team concept will be explained in more detail later.

4.1.1. Create a grassroot-led effort.

Figure 26: Grass Fed Efforts Produce the Tastiest Results

To succeed in instilling a DAML culture, every senior executive must participate by planning the resource capacity reductions on existing projects so that the entire company can learn DAML at the same time. They must work to identify risks to current projects and determine workarounds, hiring consultants, outsourcing, delaying, combining, and possibly reducing overall number and scope of existing projects., (etc.)

The training itself can take many forms. Bigger, more formal training courses can be used to layout universal guidelines—ensuring everyone is aware of which data is private and which is public, and how to handle it. Small, interactive group training can be an effective way to teach workers how to gain a better understanding of the data they work with every day.

4.1.2. Dub DAML development director.

Adding a new executive function for Chief Data Officer (CDO) really sets an enterprise DAML strategy on fire. The CDO generally oversees a range of data-related functions that may include data management, ensuring data quality, and creating data strategy. They may also be responsible for data analytics and business intelligence — the process of drawing valuable insights from data.

Whatever title is chosen, the CEO/President must personally introduce this person and then work with that leader *directly* on all DAML strategy areas to demonstrate the importance of this initiative.. By beginning from executive request and hands-on leadership, the initiative launches from the crucial *financial value of DAML*, then less so on data quality metrics (accuracy, completeness, scale, and usage), and then even far less measures of the key information and data assets impact of on business processes, such as KPIs.

The CDO should *not* report to the CIO but instead the top business executive (CEO, COO, CFO); it is the only way to demonstrate the value of DAML in the context of the organization's business. CIOs have far too much on their day-to-day workloads to either prognosticate/create the overall organizational future (the CTO's role) or to establish a vibrant DAML center of excellence effort. The marketplace mirrors this: in Gartner's 2018 CDO survey, CDO reports to top business executives increased from 45 to 48% YOY, while those reporting to the CIO declined from 23 to 22% for this same period.

Chief Data Officers (CDOs) or the highest lever executive charged with teaching and utilizing the entire organization should intelligently coordinate the creation of competencies across the enterprise, ensure the efficacy and consistency of distributed practices through metrics and scorecards, and build enterprise capabilities that underlie future success.

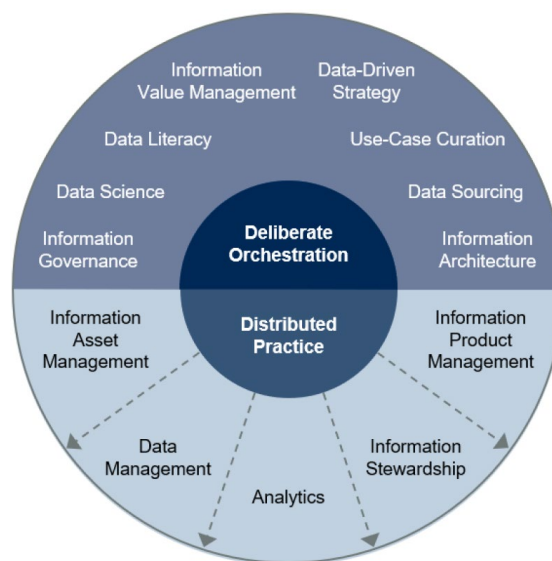

Figure 27: Essential CDO Actions to Create DAML Success Across an Enterprise^{xxxix}

Divide all DAML technical staff into groups that either facilitate enterprise-wide or are assigned to one to three groups of cross-functional staff. These group technical leaders should propose potential collaboration opportunities between members of different teams, and then assist as needed. They also should discuss external organizations that could either lead or supplement the training as well as provide expertise in the DAML developments, but they must be *incredibly careful* about consultant or chosen toolset lock-ins.

4.1. Methods to infuse data driven competencies.

Building a data-driven enterprise is not just about encouraging the use of data in decision making. Data and analytics leaders must lead development of the appropriate competencies and align work to be consistent with their enterprise's ambitions for generating information value.^{xl}

4.1.1. Publicize DAML program and add participation into job evaluation criteria.

Senior management needs to begin continuous messaging to employees about the urgency for ALL employees to know DAML, and why it will benefit them individually in their current work and career plans, as well as their work teams, departments, the entire organization, and even the industry.

Employees should be encouraged to share their ideas. This messaging effort should support employee conversations that are collaborative, assisting both internal and external DAML opportunities with their inside knowledge, especially in their own jobs and on every company level. Management also must connect DAML to what the organization's business is all about, and new direction the organization is heading through their mission and vision statements; these may need to be revisited to accentuate this push. Wherever possible they should use specific examples of planned and currently released product/service features to frame all DAML explanations of new benefits.

To cement this into the company culture, all job descriptions should be updated to reflect expectations for DAML training, competency levels, participation in ideas and methods for products/services, and how these new skills will be used by them personally. This should begin by management first evaluating their own roles to continuously seek the highest ROI applications and then to prominent and visible in designing, testing, and continuously maintaining their applications.

4.1.2. "Tiger Team" taming.

The term "tiger team" originates from the military but was made famous by NASA who deployed a tiger team during the endangered 1970 Apollo 13 mission^{xli}.

Here we begin with top-down approach using a *one-time* tiger team composed of top cross-functional staff to help employees understand by visible example how eliminating a routine task using DAML will allow a focus on higher, more strategic functions of their jobs. To create a tiger team approach, choose an important and well-known business process with established metrics, and then automate this process through a DAML demonstration project that greatly improves the metrics. This shows all employees what they are expected to achieve.

This suggested approach should directly impact one or more people who drudgingly slug through this repeatable task. With this in mind, at least one of these employees needs to help clearly communicate the mundane nature of these job tasks and how they personally will change their approach to their role with the extra emancipated time. They become a DAML "poster child," altering their future by learning new skills that will keep them important in their company role into the future.

Carefully choose staff that take part in this tiger team employees known to work hard, are cross trained to think through various roles/perspectives, can communicate to diverse groups very well, and are not perceived to be favored by executives. This is a one-time shot and must derive successful results and excitement.

Figure 28: Choose Your Tigers Carefully or One Might Dominate

4.1.3. “DAML Academy”?

Creating a DAML Academy (also known as a Center of Excellence) can become the heartbeat of the DMAL strategy. By establishing this as a central organizational theme, all aspects of the company begin to “spoke” around it forcing all processes and procedures to be seen considering DAML opportunities. This DAML Academy should address naming conventions, standardized teaching methods/materials, describe development phases, enable internal DAML strategy refinement, and publicly “show case” the company’s new strategy and positive outcomes.

Figure 29: Make Strange Uniforms and the DAML Salute an Academy Requirement

4.1.4. Form “DAML Translators” to bridge technology and business realms.

“DAML Translators” (or champions) ensure business needs are met and adoption of DAML strategies is smooth. Translators are there to expand(s) the typically siloed IT technical role to become a problem-solving collaborator with an enterprise perspective concerning data and analytics. They enable the formation of communities of practice and DAML competency development.

The best fit will be employees who know every aspect of the department and are known by all key staff members. These employees will excel in their understanding of DAML and will be capable of leading or moderating departmental DAML initiatives. Where qualified employees are lacking, find certifications that can transform them then add that to their job evaluation criteria. Executives may also want to

partner with department leaders to provide clear insight from on the ground as to how DAML can assist and benefit each department and employee directly.

These also could be DAML technical professionals that have excellent empathy, emotional intelligence, and communications skills with a good knowledge of the department and possibly paired with a departmental expert that is lacking DAML skills but will benefit from the paired interaction.

4.1.5. Develop communications and training to inform organization and external stakeholders.

The goal of company communication concerning DAML is to explain the extreme urgency of getting every employee not just *thinking about* but intensely *engaged* in the company DAML strategy.

Figure 30: Best to Outsource for this Communications Approach

Choose one key people management leader in each team so they help communicate training importance, expectations, responsibilities etc. That person will be responsible for creating and participating in a team that will design processes, contacts, roles, responsibilities, project updates, and performance metrics.

Company employees need to hear success stories of top companies and especially their competition to better comprehend the importance for their organization. Employees who envision their current job in an entirely unique way will see that applying data skills in their daily work will eliminate boring and routine actions, giving way to higher levels of engagement and greater company contribution that will insure their own personal growth as well as their future success in the company.

4.1.6. A little DAB'll do ya!

Figure 31: DAML! What the Heck is This Guy Doing?

An external DAML Advisory Board (DAB) can provide profound insight that can save extraordinary savings of time and company expense. Organizations commonly benefit from advisory boards with a combination of business, innovation, and technology capabilities. Here, external professionals are assembled that have DAML experience with the specific business processes of the organization. Meet with DAML technical staff and senior execs to determine initial goals, the best approach to achieve these goals and when, etc. Areas such as reduce operational cost 20% in 3 years can then be exploded into the many sub areas and what each one would take to contribute to this entire org goal.

4.2. Brown bag training.

Begin ongoing sessions for the entire staff led by DAML *teaching* pros with/without professional meeting facilitation or hire an organization to lead this training. Organize series of learning events for each organization and/or team, make it fun and interactive, gauge understanding. Focus on the basics of DAML with definitions and use examples. Describe how staff once free from mundane tasks can contribute at a higher level. Goal is to build in-house capabilities without hiring (as many) business savvy external DAML resources.

Figure 32: Critically Observing People Managers “Change the Face” of Brown Bag Sessions

The author helped plan and facilitate a company-wide brown bag learning and development program at a data center product company. All employees were assigned tables to distribute functional responsibilities, and managers were intentionally kept out. Over the course of several months the knowledge on innovation processes (remarkably like DAML processes) increased allowing the teams to conceive product ideas related to the company's areas of highest competency. These ideas were refined into business proposals, voted on, prioritized, and presented to senior management. Several concepts were then presented to a newly formed corporate advisory board and with their input at least 3 new products emerged that captured customer and industry analyst attention. These combined with the current market leadership led to a 9-figure acquisition.

4.2.1. Find mundane and repetitive tasks and prioritize.

Break into groups of 6-8 on round tables. Larger companies may want to have color-coded badges for each department and/or division. Those that are people managers separate and meet in different rooms from the staff and use data available and stated goals to determine the highest operational cost components. In each case have only one "color" at each table. Goal for each table is to determine 3-5 job activities that are important and could be automated, and then prioritize all or at least the top two.

Figure 33: Frequent, Repetitive, and Error-Prone Processes are Where Initial Automation Excels.^{xlii}

Gather all ideas from each table and discuss as an entire group, then senior management take the top 5-7 ideas and add data on operational costs, direct and indirect benefits, etc. to prioritize by value.

4.2.2. Create a competition.

Can either use hand-selected cross-functional teams to fill in new tables or the same table groupings. Assign each table one process and have them create flow charts to determine normal and variations with all connected processes, systems, and people. Use available information to gauge ROI for choosing and automating this solution and allow them to determine the best business processes where automation can give an immediate benefit.

4.2.3. Present chosen automation processes to DAB.

Opportunity for select team member(s) from each competition table to communicate select information to external stakeholders to increase their understanding of how the organization is evolving. Also, this method forces the speakers to hone their listening and speaking skills to an audience level they may not have addressed before. DAB selects top three processes then senior execs give associated table participants public recognition and some reasonable monetary award (Amazon gift card, extra day of PTO, etc.). Ensure that employees and other stakeholders are working toward common goals, strengthen operations.

4.3. Constantly sharpen the hard and soft skills of technical personnel.

Begin continuous training for your DAML experts, particularly on data science tools and soft skills to enhance collaboration with their fusion teams. Allow unlimited certifications mean something to their peers, but also require proof of competency. Begin weekly seminars led by each DAML technical staff member on his/her focus area, ideas, and extremely focused discussions on challenges they are facing.

4.3.1. Incentivize technical team participation at local DAML groups and events.

Ask each DAML technical staff to begin attending all local relevant technical meetings and consider this part of their job and not “on their time and dime.” Propose and reward speaking at an event on how DAML is changing their organization, and/or taking a visible role in one or more DAML organization.

Figure 34: Try Hard to Actively Network with Meeting Attendees

4.3.2. HOST a DAML event.

Attract like-minded professionals and change the external perception of your organization by hosting a DAML event in the coolest company location. Use this to seed the community for job recruiting, mentors, and other events for the staff to attend. Propose hosting technical group events at the company facility for learning, collaboration and to help get the word out about hiring top talent and changing existing hiring practices.

4.3.3. Crossbow training?

Figure 35: STOP!!! Cross Training NOT Crossbow Training!

Cross training is the practice of training an employee to be able to do the work that another employee does, in addition to their primary job role. Incorporate cross-training initiatives—allow employees to experience the information, processes, methods, and day-in-the-life of 3-5 different departments/divisions, then gather lessons learned feedback.

Cross-Training and significant collaboration lead to increased empathy and awareness that enhance communications leading to meaningfully unique DAML products and services. This improved cooperation between organizational teams also enhances thoughtfully linking their knowledge and datasets to bridge disconnected knowledge and information silos, accelerate cross-training, and improve workforce cohesion.

4.4. Optimizing the learning experience with training and certification programs.

Figure 36: SCTE's Unique Focus on Cable Workforce Development Will Be Key.^{xliii}

DAML requires the addition of new skills, and SCTE will continue to serve the cable industry through existing and new agile, individually tailored training opportunities. SCTE's "Workforce 2027" initiative is an industry outreach to attract the future cable workforce and is aligned with CableLabs' 10G messaging. It includes components of DAML and is focused on enhancing cable employees' knowledge and capabilities in all key areas to learn in the individual's best means paired with question analytics (using DAML methods) to measure competency and help each individual grasp every crucial subject area.

Figure 37: Yes, shameless self-promotion here.

Coordinated with this effort is the "CORTEX[®] VirtuLearn" wholistic learning platform where "learners are getting a clear and concise overview of course content to prepare their minds for training with LightningMods[™] in as little as 10 minutes...eBooks provide in-depth content presented at a pace that

suits learners and provides them with knowledge of how and why...and...correlating games improve knowledge absorption and retention”.^{xliv}

4.4.1. Use DAML to optimize DAML training.

Create an organizational dashboard to track DAML individual progress. Information must include courses that individual employees are enrolled in and answer the following questions:

- What series of courses has been proposed?
- How far within the series of courses at a given point in time?
- How far within a specific course at a given point in time?
- Have they completed the course within the prescribed time or stalled in progress?
- Were there skipped modules along the way
- How long does it take to complete each course’s test?
- How many attempts did it take to pass a test?
- What was performance on the final course test and how it compared to the initial test?
- What was performance on the series of courses final test and how it compared to the initial test?
- Which questions were missed and what was the subject matter?
- Which competencies were mastered?
- Which competencies require additional coursework?

4.4.1.1. Focusing “Fusion Teams” to create breakeven net energy.

Figure 38: Fusion Teams Must Achieve 100 million Kelvin to Become a Self-Sustaining Reaction

Fusion Teams are “a multidisciplinary team that blends technology or analytics and business domain expertise and shares accountability for business and technology outcomes”^{xlv}. This *ongoing* approach, in contrast with the one-time Tiger Team, bridges technology and business areas to reduce failure and improve the value of the DAML project outcomes.

Figure 39: Average value DAML brings to the company based on the organizational model

Fusion Teams overcome the silo effect and finger-pointing between centralized teams, and are typically composed of DAML experts, technical, and business staff working together on a commonly defined, analyzed, and managed problem resolution towards a measurable goal.

One eventual outcome of continuous DAML training and pursuing fusion team projects in every department and division is for every single level of a company to have a ‘data champion,’ a well-known resource to go to for questions related to the area of interest. This more capable expertise inside each work group further catalyzes idea selections for automated processes.

4.5. DAML big picture ideas.

4.5.1. Showcase individual contributors or teams that are exceeding expectations.

Spotlight individuals who are passionate about using data to solve challenges in their role

Simply feature a prominent employee and how they approached a problem or opportunity to create a positive and measurable outcome. Positive peer pressure pushes others to be in that temporary spotlight.

Business leaders need to ensure that data is being used to inform employees’ decisions at every level of the company. An effective way to do this is to routinely spotlight individuals who are passionate about using data to solve challenges in their role. This can be only internal but consider publishing this in your customer newsletter or online current news. This not only celebrates people using data to achieve meaningful outcomes but creates “positive peer pressure” to actively push their peers to do the same.

Figure 40: Gift cards blur tax reporting requirements;)

4.5.2. Publicize DAML effort to all customers, shareholders, on website, and in press releases.

Instrument marketing, sales, and product management for external messaging to improve marketing and brand identity. Alter mission and vision statements on how DAML is now part of the organization mindset. Assist marketing, product management, HR, partnerships, etc. to communicate team's intense focus on continually sharpening their DAML skills. For outreach, do not overestimate the sophistication and literacy of the company's market, may need to provide resources, assistance, and training so they better understand how DAML will automatically optimize resolution of their most common issues.

Figure 41: YES, It's Real! Think We Just Made This Ourselves 🏆

4.5.3. Alter all hiring descriptions to focus on measurable DAML skills and accomplishments.

“According to a recent survey conducted by leading analytics platform, Tableau, half of all knowledge workers in the UK wouldn't want to work for a business that shows no sign of using data to inform decisions”xlvi.

Equip HR for external messaging to improve recruitment of higher-level candidates and ways to measure job evaluations specifically for DAML accomplishments.

4.5.4. DAML Program integrates with organizational change management.

Transforming an enterprise towards broad DAML adoption will require culture change impacting structure, workflows, and ways of working. This is not simply another department. This means to create a buzz by every employee about DAML, how their company leverages data effectively, and how they are

using it in their daily routines allowing them to step up in responsibility. This excitement will translate into a more engaging and questioning culture and necessarily will be felt by customers, analysts, press, and potential employees.

It will also reformulate operating models by enabling an iterative and experimental approach by those closest to the customers, opportunities, and obstacles to improve efficiencies and accelerate revenues.

4.5.5. Tie DAML program into innovation initiatives.

Many organizations have a vibrant innovation initiative in place, and DAML can add to this—or kick start it. Employees that use DAML to experiment with data will uncover new insights and opportunities that can lead to new intellectual property (IP), operational or best practices, products, and/or services.

5. Conclusion.

The crescendo of DAML has been building for decades. It has become a pivotal business strategy giving meaningful outcomes from optimizing, interconnecting, and advancing every occupational process and dataset. The goal of digital transformation is automating every reasonable, critical, and/or error-prone process using technologies like DAML. Ignoring DAML for an industry, organization, or personally is using an umbrella for an avalanche.

There are far too many DAML areas to focus on here, but only your organization can decide the tool based on the challenge to overcome. Three key, underlying areas are described to make sure they are not skipped.

By what means DAML is implemented is nearly exhaustively outlined to give your organization a toolbox of methods to begin, continue, and add to what will become your most important asset.

1. Introduction

The domain name service (DNS) is one of the most critical internet services. It is often referred to as “the phonebook of the Internet”, meaning that the DNS facilitates a human-readable fully qualified domain name (FQDN) to be translated to a network IP address, which in turn allows networked devices to communicate to one other and provide content or needed services to allow applications to work as expected. The DNS was first introduced in 1983 by Paul Mockapetris and is one of the original Internet Standards per the IETF since 1986 (https://en.wikipedia.org/wiki/Domain_Name_System).

Since the advent of the DNS, it has been inherently insecure because DNS packets are transmitted in clear text either via the User Datagram Protocol (UDP) or the Transmission Control Protocol (TCP). There have been numerous initiatives to secure the DNS, notably DNS security extensions (DNSSEC), which encourage authoritative DNS operators to add extensions and caching DNS operators to perform validations. While this enhances security for the user, it doesn't solve the clear text request and response problems.

More recently, encrypted DNS protocols have been implemented across the Internet, including but not limited to, DNS over HTTPS (DoH), DNS over TLS (DoT), DNSCrypt, and in the near future DNS over QUIC (DoQ). Comcast is one of the first major ISPs to provide DoH and DoT to their customers and has also become a trusted recursive resolver with Mozilla’s browser Firefox.

2. DNS at Comcast

Comcast’s DNS infrastructure currently handles approximately 1.3 trillion queries per day at peak (fig. 1), with a portion of that traffic being encrypted. Decryption is accomplished using a network appliance front end to handle the DoH and DoT translations, which in turn hand off DNS queries to the backend DNS servers. Comcast also implemented DNSSEC validation at the caching layer and DNSSEC signing on most of their zones in 2011, with a commitment to make the DNS infrastructure more secure for their customers. (<https://corporate.comcast.com/comcast-voices/dnssec>)

Figure 1 – Recent 30-Day Graph of Comcast DNS Queries

3. First Steps into Encrypted DNS

In 2017, Mozilla was looking to design a new encrypted DNS protocol to help protect their users' privacy by limiting the exposure to the cleartext DNS packets. A request for comments draft (RFC) was submitted to the Internet Engineering Task Force (IETF), to outline the requirements and goals of DoH. RFC 8484 was published in October of 2018. This RFC helped drive some of the first DoH translators to take a TLS handshake, decrypt the packet, send the DNS query, get a response, re-encrypt, and send back to the client. (Hoffman & McManus)

In 2019, Mozilla partnered with Cloudflare to turn this feature on as a default for all Firefox users. The feature, which was turned on for all US-based customers in 2020, sends encrypted DNS traffic to Cloudflare's implementation of the protocol. Comcast engineers kept a close eye on what was being proposed and started looking into how to implement this protocol without a complete redesign of the whole DNS infrastructure.

Initially, Comcast's goal was to gain a comprehensive understanding of the protocol and how it works before the next steps of designing a solution that could go into production. Comcast hosts "lab weeks" twice a year for their engineers and in 2019 there was a proposal to create a DoH translator and to test it on the DNS infrastructure (fig. 2). This gave the engineers an opportunity to understand how the protocol works, latency measurements, and if it would affect any other services that Comcast offers to their customers.

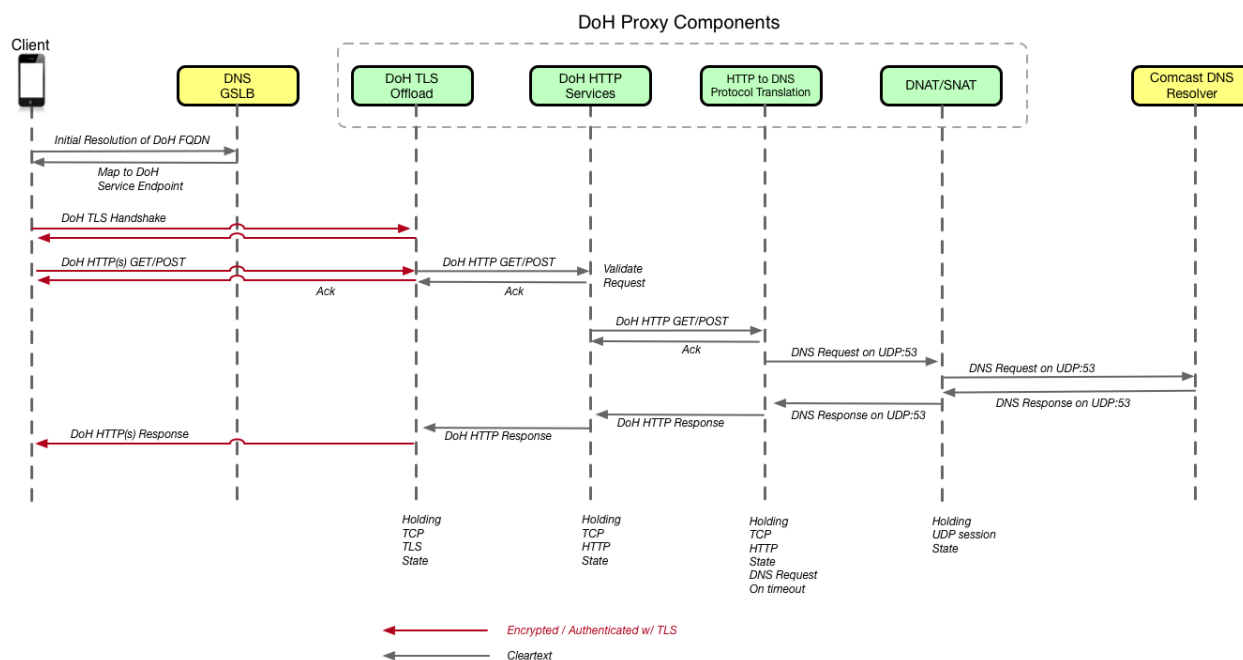

Figure 2 – DoH Proxy Components

DoH traffic utilizes Port 443, the same port that HTTPS uses. DNS traffic is hidden within packets on this port; therefore, a translator is needed to translate from HTTPS to UDP and vice versa. After the lab week in 2019, there was a push to utilize the learnings from the lab week project to build a solution that would work for Comcast. Since the DNS protocol uses mainly UDP and some TCP, the engineers did not want

to install a translator on the current DNS servers, due to unknown and hard-to-test performance capabilities on the current systems. The current server hardware was scoped out for a UDP-centric DNS server application, and the compute required for a TCP application with encryption at scale is drastically different. Therefore, a solution that efficiently reuses current infrastructure was pursued. During some of the initial conversations it was suggested to utilize a network appliance that can handle TLS offloading already, to front-end the DNS servers, and to have a translator on that appliance handle the TLS offloading, encryption/decryption, and forward to the current DNS infrastructure already in place.

4. Path from the Lab into Production

The team determined that using network appliances to perform the encryption and decryption was the most efficient way to introduce a solution to Comcast's infrastructure quickly. The engineering teams engaged with network appliance vendors and internal teams familiar with network appliances operation to develop a workable solution. The opening conversations were around the new DoH protocol and sharing RFC 8484 with the vendors. There was a need to have a network appliance handle the HTTPS connections, store the TLS certificate for the DoH FQDN, decrypt the DoH packet, translate the DoH packet to a DNS packet, forward that packet to backend DNS servers, receive that response, encrypt the packet, and then respond back to the client (Fig. 3).

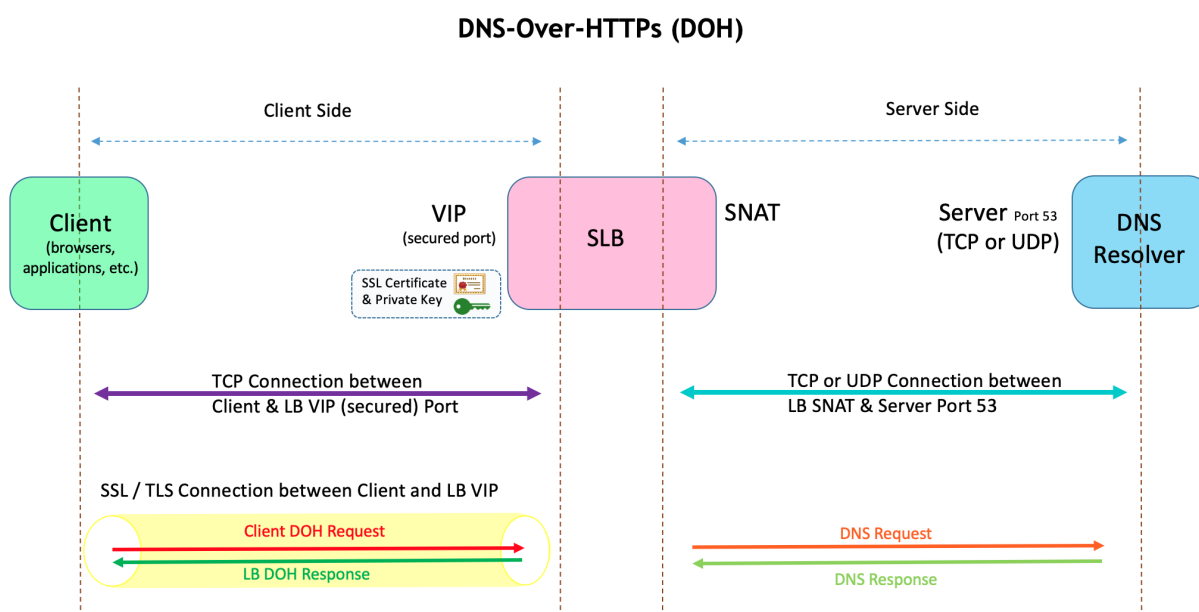

Figure 3 – DoH Using a Network Appliance

Each of the network appliance vendors were able to provide their versions of the specialized software that included the DoH translator and gave Comcast's engineers a chance to test and determine what would work from both a performance and financial perspective. Discussions landed on a specific device that could handle the query load and was relatively cost effective. During this early phase, there was discussion within EDDI and other DNS operator forums on how to stress test this new protocol. The toolsets for DoH operators to test the functionality, latency, capacity, and other unknown scenarios, were very limited in the early stages of testing. One of the toolsets that helped was an open-sourced tool called DoX which can be found at <https://github.com/wttw/dox>. This tool allowed testing against the DoH endpoint set up and comparisons with other known DoH endpoints. A few other tools were used

internally at Comcast to benchmark DoH end-points such as wrk and wrk2. The tools offer parameters that can be tuned to measure important metrics such as requests per second, connections per second, and performance provided by a DoH end-point at different levels of concurrent connection load. After there was comfortability with the network appliances and DoH functionality, there was an opt-in public beta test of the Comcast DoH service in October of 2019. This allowed other DNS operators to test the endpoint <https://doh.xfinity.com/dns-query>, give feedback, and help identify some of the issues that were not found in initial testing. The path to production involved knowing what the architecture would look like and how to provide the best service for customers.

5. Encrypted DNS at Comcast

Launching an encrypted DNS architecture posed a few technical challenges, particularly around ensuring high availability and localizing DNS responses for a given area where DNS is already being served to customers. Currently the way clients are directed to doh.xfinity.com is to either have the FQDN and IP address hard coded into the client or to utilize DNS to get a response. Utilizing geo load-balancing, the DNS lookups to doh.xfinity.com are shaped by where the DNS query originates. The DoH endpoint, doh.xfinity.com, utilizes a canonical name (CNAME) record that is directed to a geo network appliance, to help shape traffic to the correct DoH IP address for a region. Client lookup will go as follows, assuming that the customer is using Comcast's DNS servers provided by the dynamic host configuration protocol (DHCP):

1. Customer's client (browser, application, DNS forwarder..) will do an initial look up for doh.xfinity.com utilizing Comcast's DNS servers.
2. Based on the Comcast DNS resolver that queried for the CNAME endpoint, doh2.gslb2.xfinity.com, the network appliance will give a response for the corresponding caching DNS region's virtual IP (VIP) address.
3. The client will then connect to the encrypted DNS network appliance using the VIP and all subsequent DNS queries are now encrypted, with the VIP acting as the "client" doing queries for that customer.

The last step obfuscates the customers' source IP addresses to Comcast's DNS servers and give an extra layer of privacy. In Q2 2020 Comcast offered encrypted DNS to their customers. The queries per day for DoH currently sits around 90 billion at peak. (fig. 4). There are currently 12 points of presence on Comcast's network that handle the encrypted DNS functions, with 3 more points of presences slated to be deployed in 2022.

Figure 4 – Comcast DoH Queries Per Day

6. Comcast's Commitment to Privacy

During the initial path towards encrypted DNS services, Comcast worked closely with engineers from Mozilla, to find out how Comcast's DoH implementation could be offered to Firefox customers. Mozilla's trusted recursive resolver (TRR) policy had to be followed by any DNS operator to be considered as a DoH endpoint within Mozilla's Firefox browser. (Mozilla) Some of the requirements prompted Comcast to release a privacy statement just for DNS (Xfinity), along with updates to the broader privacy policy for the internet services. (Xfinity, 2021) Comcast has brought support and privacy commitments to Mozilla's TRR program, becoming the first major ISP to be part of that program and advocating for the privacy concerns of their customers (Mozilla, 2020) Along with becoming part of Mozilla's TRR program, work was done in conjunction with Google engineers to help provide Comcast's DoH endpoint to users of the Chrome browser. Furthering the exposure of the commitment to privacy utilizing encrypted DNS. Comcast also contributes to the Encrypted DNS Deployment Initiative (EDDI) (<https://www.encrypted-dns.org/>), a forum for DNS operators to collaborate on their findings of deploying encrypted DNS protocols on their respective DNS infrastructures, while helping shape some of the best practices for encrypted DNS deployments.

7. Encrypted DNS in the future

At Comcast, engineers are constantly looking at ways to improve on solutions in terms of scalability, cost-efficiency, and performance. One such work is harnessing the power of data processing units (DPUs) or SmartNICs to provide DNS encryption. Comcast has built a software solution that utilizes hardware TLS offload components provided by DPUs to efficiently translate between DoH and traditional UDP DNS. The rationale for exploring this method for solving the encrypted DNS problem is illustrated in the following diagram.

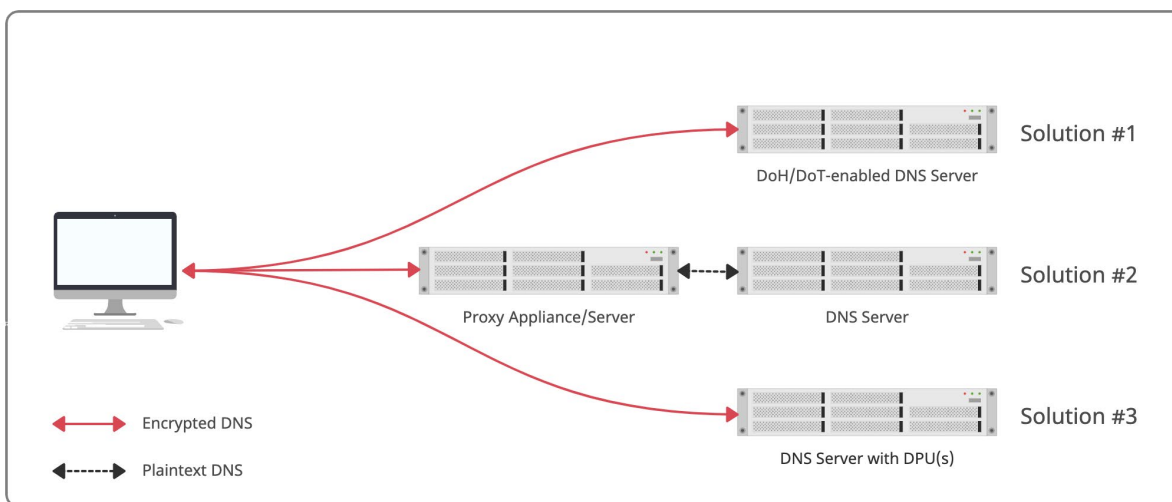

Figure 5 – Encrypted DNS Architecture Possibilities

Solution #1 describes enabling DoH and DoT features on the current DNS server application running on present hardware. As mentioned earlier, current server specifications do not account for DoH/DoT application requirements. In this model, scaling for capacity means adding more servers which results in increased power, space, and licensing costs.

Solution #2 scaling involves increasing the number of expensive hardware proxy appliances in the network.

Solution #3 offers a solution developed at Comcast using open-source components. The components are vendor DPU agnostic and can easily integrate with different DPU vendor offerings. The DPUs are a lot more cost-efficient compared to proxy appliances. Scaling capacity in this model means replacing DPUs with next generation DPUs or adding more DPUs per server. This method provides opportunities to deploy new services at the edge and gives Comcast the ability to cater to the evolving landscape of encrypted DNS standards.

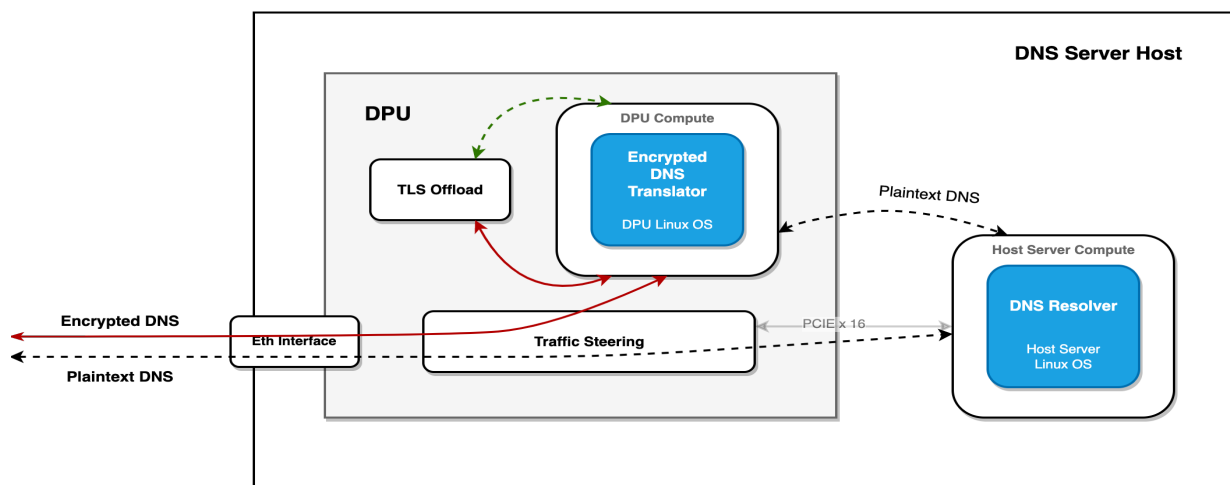

Figure 6 – Encrypted DNS Using DPUs Block Diagram

This solution is being actively benchmarked and tested and is a potential method to add encrypted DNS capacity across the Comcast footprint.

8. Conclusion

As mentioned previously, encrypted DNS continues to evolve, and internet providers have moving targets to hit as new standards are proposed and adopted by the industry. DNS over QUIC (DoQ) is currently a proposed standard for encrypting DNS using QUIC as the underlying protocol. QUIC is designed to reduce protocol induced delays with features such as mitigation of head of line blocking, zero round trip time session resumption (0-RTT) and advanced packet loss and congestion control mechanisms. Additionally, the next version of the HTTP protocol, HTTP/3, is also designed to run on QUIC as the underlying protocol. Comcast is closely monitoring these developments and is working on integrating QUIC into its encrypted DNS capabilities.

Abbreviations

DNS	domain name service
DHCP	Dynamic Host Configuration Protocol
DoH	DNS over https
DoT	DNS over TLS
DoQ	DNS over QUIC
DPU	data processing unit
FQDN	fully qualified domain name
HTTP(S)	Hypertext Transfer Protocol (secure)
QUIC	quick UDP internet connection
UDP	User Datagram Protocol
TCP	Transmission Control Protocol
FQDN	fully qualified domain name
TLS	transport layer security
VIP	virtual IP

1. Introduction

5G will deliver significant societal value as it provides critical infrastructure, mission critical applications, smart manufacturing, connected car, and other use cases. As a result, our risk tolerance must decrease due to the increased impact from a cyberattack on a 5G network. Radio Access Networks (RAN) is evolving to Open RAN, including Cloud RAN and O-RAN, characterized by a disaggregated, virtualized, cloud-native, automated, and intelligent network. Open RAN brings many security benefits, including vendor diversity, but it also introduces security risks that must be managed to ensure Open RAN deployments have a strong security posture.

Cloud security risks are not exclusive to Open RAN, but they must be considered during a risk analysis to ensure secure Open RAN deployments. Cloud deployments of Open RAN can offer many security advantages inherent from third-party cloud-based services while also expanding the RAN attack surface due to increased internal threats. Open RAN must be built upon a zero trust architecture (ZTA) to mitigate risks from internal and external threats. This is a new paradigm for securing RAN, where traditional on-premise networks have focused primarily on protection from external threats.

The O-RAN architecture, from the O-RAN Alliance, expands the attack surface by specifying new functions and interfaces built on the 3GPP standardized architecture. The Lower Layer Split (LLS 7-2x) with the Open Fronthaul (OFH) interface, as well as RAN Intelligent Controllers (RICs), with xApps and rApps, and the Open Cloud (O-Cloud) must all be secured to protect O-RAN's network functions, interfaces, and data. The Service Management and Orchestration (SMO) can enhance the Open RAN security posture, but it must also be securely designed and implemented to prevent internal and external threat actors from gaining access and control.

The goal of this paper is to present the security risks and recommend security controls to establish a strong security posture for Open RAN deployments. Section 2 of the paper provides a baseline discussion of evolving Open RAN architectures, including O-RAN from the O-RAN Alliance. Section 3 introduces the Open RAN security posture, presenting the security tradeoffs of Open RAN and expanded attack surface of the O-RAN architecture. Section 4 discusses additional security considerations for a strong Open RAN security posture with focus on ZTA and cloud security to support deployment of 5G critical infrastructure for protection against external and internal threats. Section 5 provides a detailed technical analysis of the security risks across the O-RAN architecture and recommends security controls to mitigate those risks. Recommended security controls are provided with the goal to strive towards a ZTA that protects against internal and external threats, ensuring Open RAN deployments will be secure.

2. RAN Architectures

The 5G network is built from Radio Access Network (RAN) and Core (5GC). RAN uses radio frequencies to provide wireless connectivity to devices for delivery of applications and consists of antennas, radios, baseband (RAN compute), and RAN software enabling high data rates for innovative mobile use cases. Antennas radiate the electrical signals into radio waves and the radio converts digital information into signals that can be transmitted wirelessly while ensuring the transmitted signals are in the assigned frequency bands at the configured power levels. The baseband provides signal processing functions for efficient wireless communication and secure use of spectrum to deliver extremely high data processing speeds.

Traditionally, baseband functionality has been complex software providing intelligence to assign data bits to available frequency and time slots and prioritizing users on a millisecond (or sub-millisecond) basis, running on proprietary hardware deployed at cell sites. With the evolution to virtualization and containerization of network functions, baseband functionality can be implemented in software to operate on Commercial Off the Shelf (COTS) server hardware at edge sites, or central sites, co-located with 5GC components. This means that RAN and 5GC software may be geographically co-located, deployed on the same infrastructure, and managed as a single solution. As a result, the security of 5G RAN has evolved to be as critical and sensitive as security of the 5GC.

Open RAN, including Cloud RAN, such as [1], and O-RAN from the O-RAN Alliance [2], is a general term for open radio access network architectures defined by open and interoperable interfaces, virtualization, cloudification, and intelligence enabled through AI/ML. Open RAN solutions use the 3GPP-specified air interface that provides security features such as signaling confidentiality and integrity protection, user plane confidentiality and integrity protection, and the Subscription Concealed Identifier (SUCI) for subscriber privacy [3].

Cloud RAN is based upon the Third-Generation Partnership Project (3GPP) Release 15 (R15) Higher Layer Split (HLS) having the RAN Compute disaggregated into a Central Unit (CU) and Distributed Unit (DU). The CU and DU use the enhanced Common Public Radio Interface (eCPRI) fronthaul interface between them, as shown in Figure 1. Cloud RAN provides the advantages of open, standards-based cloud-native network functions managed by a SMO, without requiring a LLS.

The O-RAN architecture introduces a LLS disaggregating the RAN's O-DU and O-RU with the Open Fronthaul interface between them, as shown in Figure 1. The O-RAN Alliance's Open Fronthaul interface specifies a Control, User, Synchronization Plane (CUS-Plane) and Management Plane (M-Plane) running over eCPRI. The primary goal of the disaggregation to the O-DU and O-RU is to further increase vendor diversity in the RAN.

The O-RAN architecture also introduces the Near-Real-Time RAN Intelligent Controller (Near-RT RIC) and SMO, with an internal Non-RT RIC, for automation, orchestration, and optimization of RAN functions and performance. The Near-RT RIC and Non-RT RIC are specified to support RAN applications, known as xApps and rApps, respectively, with the goal to enhance RAN innovation and optimization through an ecosystem of purpose-built applications from RIC platform vendors and third-parties. O-RAN specifications also provide an O-Cloud for infrastructure upon which the O-RAN network functions run as applications.

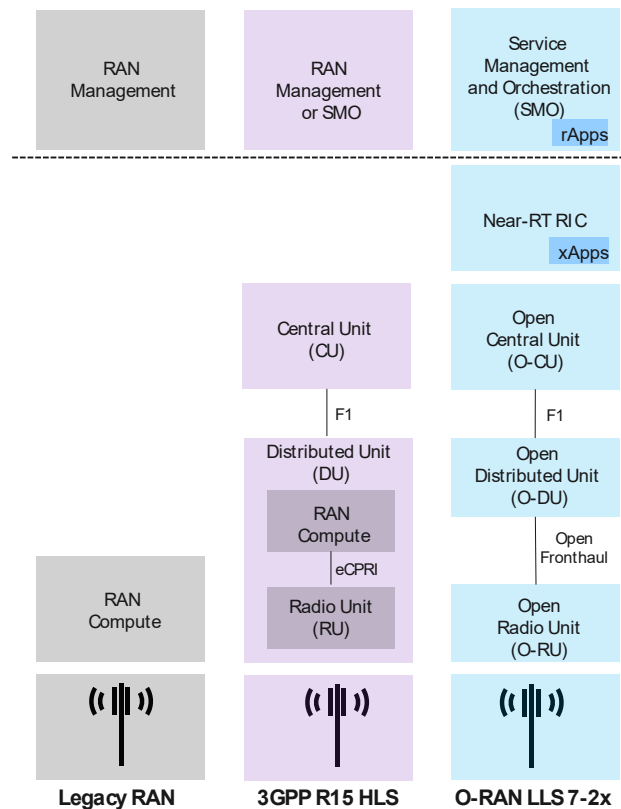

Figure 1 - RAN Splits

3. Open RAN Security Posture

Open RAN solutions and architectures, including Cloud RAN and O-RAN, share common security advantages and disadvantages. This section discusses the security tradeoffs for Open RAN and examines the expanded attack surface specific to the O-RAN architecture.

3.1. Open RAN Security Tradeoffs

A security posture of a telecommunications network is the security status of a network, information, and systems based on security controls *in place* to manage the defense and react to situational changes [4]. Open RAN, including Cloud RAN and O-RAN, provides enhanced RAN security including use of open-source software enabling transparency and common control; open interfaces ensuring transparency and use of standard, interoperable, and secure protocols; disaggregation enabling supply chain security through vendor diversity; and use of AI/ML enabling visibility and intelligence to achieve greater security [5]. However, Open RAN solutions also tradeoff introduction of security risks, such as open-source software vulnerabilities exploited by malicious threat actors, new interfaces with weak security specifications, and architectural modifications that expand the RAN attack surface. These security tradeoffs are summarized in Figure 2. Open RAN security risks were first analyzed in [6] and the O-RAN Alliance Working Group 11 (WG11) (formerly Security Focus Group – SFG) has been evolving O-RAN’s security specifications to support a strong O-RAN security posture.

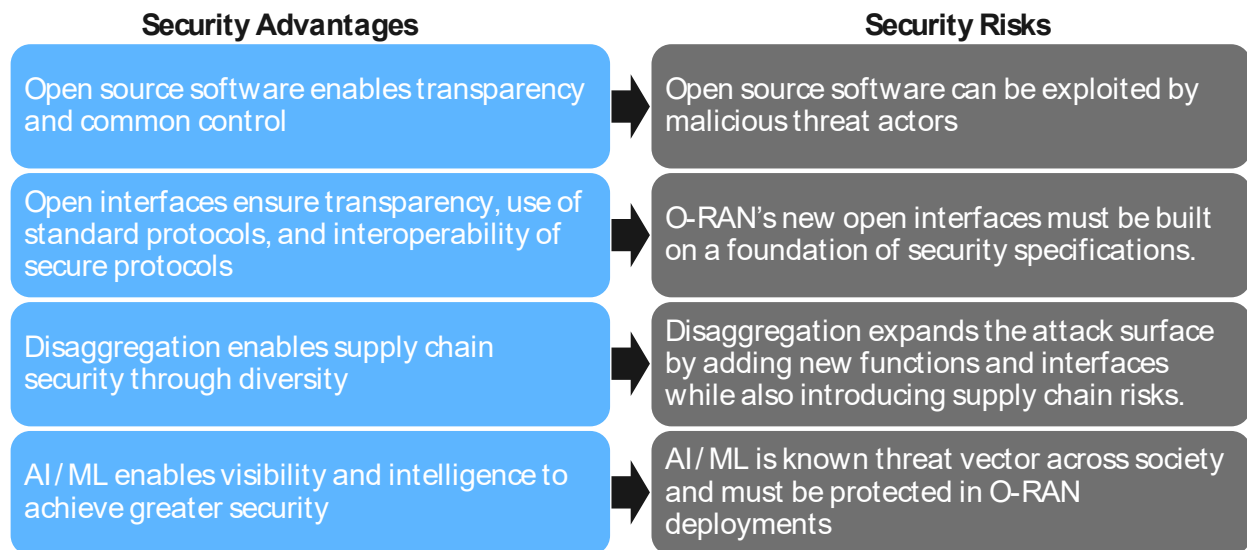

Figure 2 - Open RAN Security Advantages and Risks

3.2. O-RAN Attack Surface

O-RAN introduces architectural changes through disaggregation, opening the ecosystem for increased vendor diversity. The architectural changes that define O-RAN are the LLS 7-2x, OFH interface, RICs, and RAN applications known as rApps and xApps. However, O-RAN's new network functions and interfaces expand the O-RAN attack surface [7], [8], [9]. A strong O-RAN security posture must implement security controls at each layer of the architecture to protect the network functions, interfaces, and data from external and internal threats, as shown in Figure 3. The O-RAN Alliance's WG11 has performed a detailed threat analysis of O-RAN [10] and continues to evolve O-RAN's security specifications to meet the security baseline expected by network operators and their users. The specification effort considers a Zero Trust Architecture (ZTA) in accordance with US NIST SP 800-207 [11] to provide protection from external and internal threats.

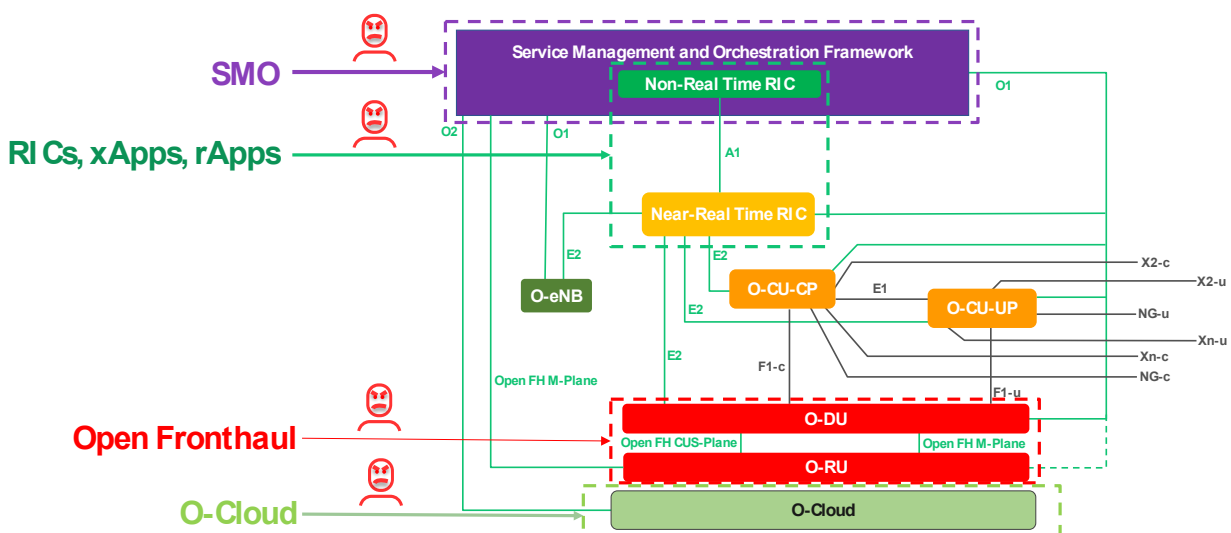

Figure 3 - O-RAN Expanded Attack Surface [adapted from 12]

4. Additional Security Considerations

Additional security considerations should be made to achieve a strong Open RAN security posture built upon a ZTA for cloud deployments. This section discusses ZTA and cloud security to support deployment of Open RAN critical infrastructure that provides defenses against internal and external threats.

4.1. Zero Trust Architecture

5G is the first generation of mobile technology designed for cloud deployments of RAN and Core. Open RAN enables cloud migration of the RAN to leverage its benefits of rapid elasticity, on-demand self-service, broad network access, and multi-tenancy. However, cloud deployments introduce an expanded threat surface due to the increased risk of internal threats, shifting the security paradigm to building a ZTA from the traditional perimeter-based security focused on protecting against external threats. In a ZTA, this is no longer sufficient because we must design for a perimeter-less network [13] that assumes the adversary is already inside the network [14]. This is a new paradigm for RAN security, as RAN has been traditionally secured at the perimeter because it has run on operator hardware in an operator managed network in an operator facility assuming internal trust. 3GPP releases 15 and 16 specify 5G with security features that align well with the NIST seven tenets of a ZTA. Some examples are provided in Table 1 below with additional examples provided in [15].

Table 1 – Alignment of 3GPP 5G Standards to NIST ZTA Tenets (Examples)

#	ZTA Tenet	5G Feature
1	All data sources and computing services are considered resources	The end-to-end 5G network, including UEs, RAN, Transport, Core, Applications, and Services are assets and data sources
2	All communication is secured regardless of network location	Subscriber identity privacy using SUCI . TLS provides confidentiality and integrity protection across the SBI .
3	Access to individual resources is granted on a per-session basis	UE access is granted using 5G-AKA, EAP-AKA', and EAP-TLS. Authentication and authorization between NFs over SBI in the 5GC is provided with certificate-based mutual authentication using TLS
4	Access to resources is determined by dynamic policy	The PCF feeds the AMF with access and mobility policies that affect UE authorization to access 5G network resources
5	The operator monitors and measures the integrity and security posture of all owned and associated assets	NWDAF incorporates standard interfaces from the SBA to collect data and evaluate systems in terms of compliance with security policy rules
6	All resource authentication and authorization are dynamic and strictly enforced before access is allowed	Mutual authentication enables the device to authenticate the network using the AUTH (Authentication Token) returned by the network
7	The operator collects information about the current state of assets, network infrastructure and communications and uses it to improve its security posture	The MNO should have a mature supply chain risk management to ensure NFs are compliant with GSMA NESAS.

NOTE: See acronym list for acronyms used in Table 1.

While Open RAN provides opportunity to deliver an ecosystem of innovative vendors and products, mobile network operators (MNOs) are accountable to evaluate the security posture of its deployment. A threat analysis identifies potential threats, vulnerabilities, and exploits while a risk analysis determines the likelihood and impact of attacks compromising confidentiality, corrupting integrity, or degrading availability. A ZTA approach may increase risk likelihood scores due to consideration of external and

internal threats, while implementation of security controls can decrease risk impact scores. The O-RAN Alliance WG 11 is evolving O-RAN's security specifications to align with industry best practices and meet the security baseline established by 3GPP for 5G, while pursuing a ZTA [16].

4.2. Security Controls for 5G Cloud Deployments

As 5G networks are critical infrastructure, it is important to properly secure cloud deployments to protect against external threat actors at the perimeter and internal threat actors exploiting zero-days, performing lateral movement for reconnaissance, and conducting advanced persistent threats (APTs). With the evolution of 5G to public cloud and hybrid cloud deployments, the 5G attack surface expands due to running on third-party infrastructure in a multi-tenant environment managed by another third-party. The cloud introduces increased internal threats from lateral movement, reconnaissance, and advanced persistent threats (APTs) from nation-state, criminal, and internal threat actors. Open RAN and 5G Core have increased risk of internal threats in the cloud due to increased dependency on cloud service providers, lack of defined security roles across stakeholders, resource sharing with other tenants, greater risk of security misconfiguration, and increased use of open-source software [17].

A risk-based approach must be taken to select the proper security controls for Open RAN deployments to mitigate internal and external threats in the cloud, or O-Cloud. Each layer of the cloud stack must be secured to reduce risk from potential vulnerabilities being exploited by internal or external threat actors. 5G cloud deployments should pursue a ZTA to align with US DHS Cybersecurity and Infrastructure Security Agency (CISA) guidance with the following capabilities [18]:

- prevent and detect lateral movement
- secure isolation of network resources
- data protection
- ensure integrity of cloud infrastructure

Common vulnerabilities, such as misconfigurations, weak authentication and use of open-source software with known vulnerabilities, can be prevented using industry best security practices. Well-known attacks in the cloud, including container escape, host escape, shared resource exhaustion, remote code execution, information disclosure between tenants, distributed denial of service (DDoS), and advanced persistent threats (APT) must be mitigated for Open RAN deployments [19]. Security controls must be provided at each layer of the cloud stack, as shown in Figure 4, to protect data, containers, container runtime engines and orchestration, operating systems, and infrastructure including servers, networks, and storage.

Recommended controls include micro-segmentation, tenant isolation and container isolation, mutual transport layer security (mTLS) 1.2, or 1.3, and X.509 certificates, Identity and Access Management (IAM), Multi-Factor Authentication (MFA), and role-based access controls (RBAC) for user access. To help ensure a secure and trusted runtime environment, Open RAN deployments should operate on a hardware root of trust using hardware security modules (HSM), a purpose-built appliance compliant with 3GPP security standards for hardware-based storage and lifecycle management of cryptographic keys. 5G critical infrastructure deployed in the cloud must have continuous monitoring, logging, and alerting with periodic vulnerability assessments and configuration validation to protect against evolving threats. Security controls for Open RAN deployments in the cloud are discussed further in [20].

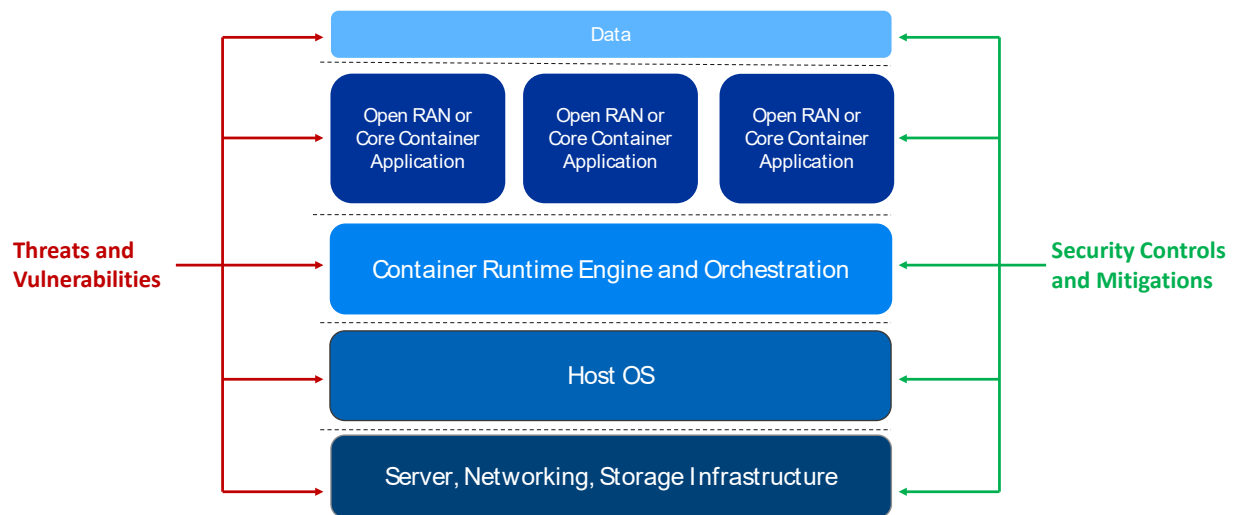

Figure 4 – Multi-Layer Security for 5G Cloud Deployments

5. Securing the O-RAN Architecture

A strong O-RAN security posture provides security controls for protection from external and internal threats introduced by O-RAN's expanded attack surface due to the architectural changes with new network functions, interfaces, and data. This section provides analysis of the threats, risks, and controls for O-RAN's OFH, RICs and applications, SMO, and O-Cloud.

5.1. Open Fronthaul

Fronthaul carries data between the 5G radio and RAN compute nodes using eCPRI, an industry consortium interface specification that utilizes an ethernet for packet forwarding [21]. The design of eCPRI is highly resource efficient and provides the flexibility for different deployment scenarios and functional splits, while enabling use of standard secure IP-based protocols, such as mTLS 1.2, on the fronthaul. The choice of ethernet in eCPRI enables the packet-based fronthaul, COTS, and Open RAN.

O-RAN's OFH interface, using LLS 7-2x, provides O-RAN Alliance specified Control, User, and Synchronization Plane (CUS-Plane) [22] and Management Plane (M-Plane) [23] over eCPRI to provide message exchange between the O-DU and O-RU for coordination. The C-Plane runs over eCPRI to provide message exchange between the O-DU and O-RU for scheduling and beamforming, numerology, and spectrum sharing control. The U-Plane runs over eCPRI to provide uplink and downlink frequency domain IQ data samples. The S-Plane provides timing and synchronization of the O-DUs and O-RUs using Synchronous Ethernet and IEEE 1588 Precision Time Protocol (PTP) [24]. The M-Plane manages and initializes the connection between the O-RU and O-DU. The OFH should have security controls implemented to protect against external and internal threats, consistent with a ZTA. M-Plane and CUS-Plane security are discussed in the sections below.

5.1.1. M-Plane Security

The O-RAN M-Plane specification has mandatory requirement for vendors to support two methods of authentication [25]:

1. O-RU supports Secure Shell version 2 (SSHv2) with password-based authentication of the O-DU and the O-DU supports SSHv2 with simple public key based authentication of the O-RU.
2. The O-RU and O-DU support mutual authentication with TLS 1.2, or higher, and X.509 certificates.

While it is mandatory for the O-RU and O-DU vendors to support both methods of authentication, the operator has the option which to use in production. Password-based authentication is considered weak security for critical infrastructure [26] due to the efficiency in which an attacker can perform a brute force attack upon gaining access to the interface, which can be exploited for lateral movement to northbound functions of the O-RAN architecture to execute broader network attacks. Best security practice, consistent with 3GPP security standards, is for operators to use mTLS with X.509 certificates for 5G deployments [27], including O-RAN deployments for which “it is recommended that operators use NETCONF/TLS and FTPES in production networks” on the M-Plane [28]. This tradeoff for M-Plane security is shown in Figure 5 below.

SSHv2 with Password-based Authentication

- Weak Security
- Does not meet industry best practice
- Violates USG guidance

mTLS with Certificate-based Authentication

- Strong Security
- Meets industry best practice
- Aligns with USG Guidance

**Both are mandatory for vendors to implement
and optional for operators to use**

Figure 3 - OFH M-Plane Security

The M-Plane has two optional deployment models, Hybrid and Hierarchical, as shown in Figure 6, which influences the operator’s approach to certificate management. In the Hybrid model, the O-RU and O-DU have direct IP connectivity to Public Key Infrastructure (PKI) and management systems. The O-RU and O-DU are considered separately managed entities by the SMO platform and enroll their unique operator-signed certificates in a Certificate Authority/Registration Authority (CA/RA) server using Certificate Management Protocol version 2 (CMPv2). PKI provides full lifecycle management of certificates for the O-DU and O-RU and the unique O-RU and O-DU enrolled operator-signed certificates are used to establish the secure mTLS session between O-RU and O-DU.

In the Hierarchical model, the O-DU has direct IP connectivity to PKI and management systems, enrolls its unique operator-signed certificate in the CMPv2 capable CA/RA server, and is considered a managed entity by the SMO platform. The O-RU does not have direct IP connectivity to PKI and management systems and is not considered a managed entity. During start-up installation the O-RU optionally downloads configuration from O-DU, which includes the trust anchor (root certificate) for the O-DU

operator-signed certificate used by O-RU to authenticate the O-DU. The configuration may also include identity of a CMPv2 capable CA/RA server reachable through the O-DU, if supported in the production deployment, for certificate enrollment. The O-RU establishes mTLS sessions with the O-DU by using either an enrolled operator-signed certificate in the CA/RA server reachable through the O-DU or its factory installed vendor-signed certificate when the CA/RA server is not reachable through the O-DU, as shown in Figure 6 below. The O-DU installs the O-RU vendor-signed root certificate used for authenticating the O-RU in the Hierarchical model deployment scenario that the O-DU does not provide the O-RU connectivity to a CMPv2 capable CA/RA.

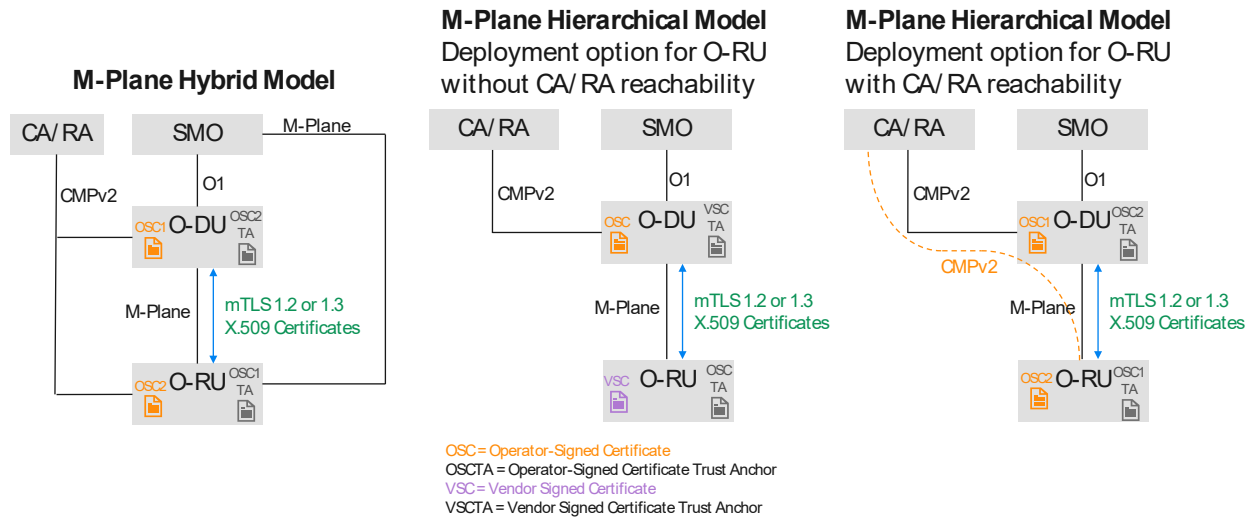

Figure 4 - Certificates in the Optional M-Plane Models

5.1.2. CUS-Plane Security

The OFH interface C/U/S-Plane has control and synchronization messaging that is unauthenticated and in the clear, enabling the man-in-the-middle (MitM) attack vectors shown in Figure 7 and as follows:

- C-Plane - Intercept messages to learn subscriber and network information.
- C-Plane - Message spoofing to inject false information to influence network parameter settings.
- S-Plane - Impersonation of PTP Master Clock or Grand Master, which can be exploited to degrade U-Plane performance and availability.

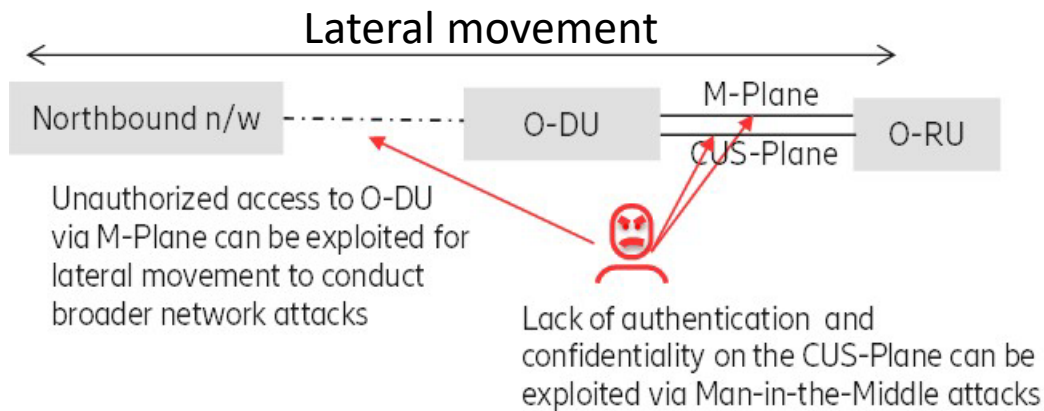

Figure 5 - O-RAN Open Fronthaul Attack Vectors

Security controls for confidentiality and integrity of messages on the CUS-Plane have been limited due to latency requirements on the CUS-Plane [29]. Further study is needed to identify potential security solutions. IEEE 802.1X-2020 Port-based Network Access Control 0 can be configured to provide protection of OFH interfaces at the physical layer for secure network access in point-to-point LAN segments within the Open Fronthaul network [31].

5.2. RICs and RAN Applications

Open RAN architecture describes two new RIC frameworks, Non-RT-RIC and Near-RT-RIC, for hosting automation applications known as xApps and rApps, respectively, as shown in Figure 8. The xApps and rApps enhance RAN innovation and optimization through an ecosystem of purpose-built applications from RIC platform vendors and third-parties. The Near-RT RIC and xApps provide automation and management of use cases with a suggested control loop of 10 msec to 1 second, while the Non-RT RIC and rApps provide automation and management of use cases with a suggested control loop of one second or more. The Non-RT RIC uses its rApps to decide RAN policy that it pushes to the Near-RT RIC, and its xApps, across the O-RAN Alliance specified A1 interface. The R1 interface between the SMO, Non-RT RIC, and rApps enables any rApp, as a Service Producer or Service Consumer, to work with any SMO and other rApps to enable insights from one rApp to serve as input to another, forming more complex decision-making capabilities.

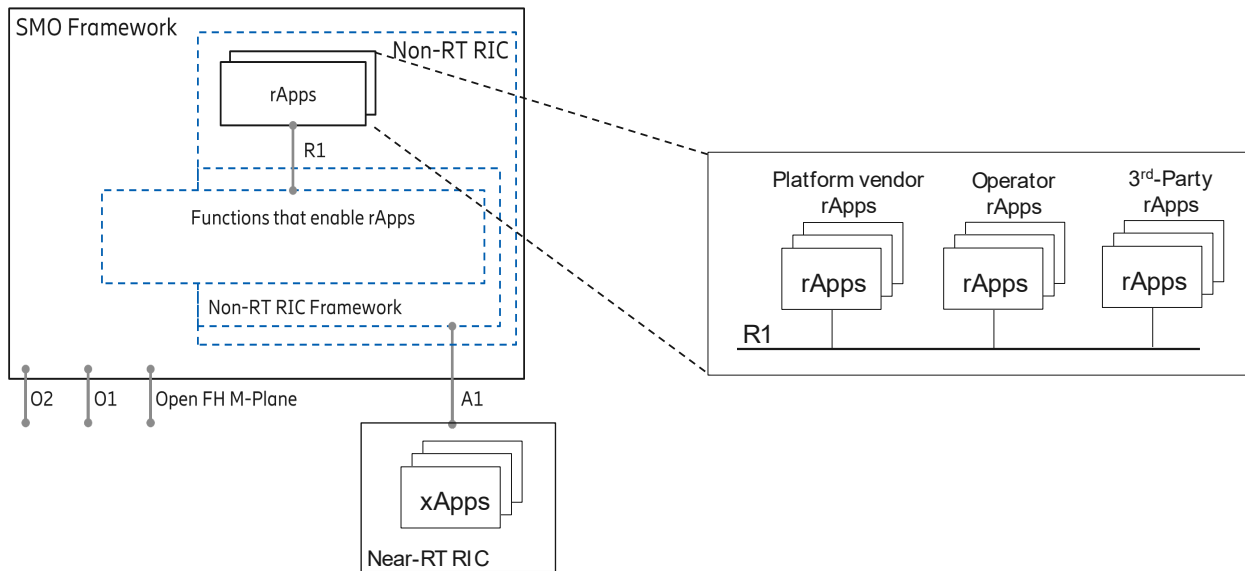

Figure 6 - Open RAN RICs and RAN Applications [adapted from 32]

A primary driver to have xApps and rApps is to broaden O-RAN innovation through smaller best of breed vendors to offer microservices leveraging AI/ML technology for use cases such as spectral efficiency, handover management, network optimization, and network healing. The specification of the A1 and R1 interfaces enables third-party xApps and rApps to efficiently integrate into an Open RAN deployment. However, considerations must be made for architectural and supply chain security risks to the RAN introduced by the RICs and their xApps/rApps. The risks and appropriate security controls are as follow:

- Risk: RICs may decide RAN parameter settings that have direct or indirect conflicts with local gNB decisions, which can degrade performance or availability. The risk of parameter conflicts increases as the number of third-party xApps vendors increases.
 - Solution: The Near-RT RIC supports a conflict mitigation function.
- Risk: Conflicts between rApps from multiple vendors could unintentionally or maliciously push conflicting RAN policies and parameter settings to degrade performance or availability. The risk of parameter conflicts increases as the number of third-party rApps vendors increases.
 - Solution: The Non-RT RIC supports a conflict mitigation function.
- Risk: Use of unsigned, untrusted, or improperly secured third-party xApps or rApps can introduce risks to deployments.
 - Solution: xApps and rApps are digitally signed, penetration tested, and vulnerability scanned prior to delivery. xApps and rApps are securely on-boarded and monitored for anomalous behavior in production. xApps and rApps must support logging and export of logs to the SMO.
- Risk: Malicious Near-RT RIC or Non-RT RIC can attempt to gain access across the A1 interface
 - Solution: The A1 interface supports mutual authentication using mTLS with X.509 certificates.

Figure 7 - Mutual authentication on the A1 interface

- Risk: Malicious rApps can attempt to gain access to other rApps through the Non-RT RIC Framework
 - Solution: The R1 interface supports mutual authentication using mTLS with X.509 certificates.

Figure 8 - Mutual authentication on the R1 interface

- Risk: xApps or rApps could be exploited by internal or external threat actors to gain access to private personal information or sensitive business information.
 - Solution: Near-RT RIC, Non-RT RIC, Non-RT RIC Framework, and rApps support authorization using OAuth 2.0. xApps and rApps provide confidentiality protection for sensitive data at rest. Data in motion across the A1 and R1 interfaces has confidentiality and integrity protection using TLS 1.2, or 1.3.

5.3. Service Management and Orchestration

The SMO is an intelligent automation platform for Open RAN, including Cloud RAN and O-RAN, radio resources that applies automation at scale to simplify the complexity of networks, improve network performance, enhance customer experience, and minimize RAN operational costs. The SMO, as a component of the operational support system (OSS), enables automation and increases the abstraction offered to users by managing Open RAN as a service and intents. The O-RAN Alliance defines technical specifications and interfaces related to the O-RAN's SMO Framework.

The SMO, through its Non-RT RIC, provides policy-based guidance and enrichment information to the Near-RT RIC. The Non-RT RIC is an automation platform that uses rApps to deliver higher layer automation policies, orchestrating the Near-RT RIC and RAN nodes. The rApps provide RAN optimization, with the potential to extend to other RAN functions such as capacity planning or security. The rApps are used in conjunction with AI and ML models, leveraging data sets from other functions in the Open RAN and external sources. A secure, standardized R1 interface enables any rApp to work with other rApps, providing the flexibility to group rApps for more complex use cases and decisions.

The visibility and intelligence of the SMO, such as [33], make it an ideal platform to enhance the security posture of Open RAN cloud deployments, aligning with a ZTA. The SMO's logging capabilities coupled with its AI/ML can provide the awareness, threat intelligence, and automated responses needed for a secure Open RAN. The SMO's intelligence and its support for rApps, as shown in Figure 8, enable an ecosystem of purpose-built security functions providing faster and deeper threat detection, helping to ensure secure Open RAN public and hybrid cloud deployments. As the SMO has network-wide visibility from internal and external data sources, its rApps can be purpose-built to provide RAN-protecting security functions, such as Open RAN anomaly detection, O-Cloud threat detection and response, security configuration validation, and security compliance monitoring [34]. The SMO also provides the flexibility to build-in rApps with Security Information and Event Management (SIEM) and Security Orchestration Automation and Response (SOAR) functionality, plus the ability to integrate with external SOAR or SIEM in the security operations center (SOC).

However, securing the SMO is critical because a vulnerability in the SMO could be exploited to serve as an entry point for attacks against Open RAN and lateral movement across Open RAN interfaces and functions. While the SMO can enhance the O-RAN security posture, the SMO must have built-in security controls implemented with a zero trust mindset, assuming the adversary is already inside the network. It is critical that the SMO implements proper controls to ensure secure access with authentication and authorization of external and internal resources. The SMO must also provide security controls for confidentiality, integrity, and availability protection of SMO functions, interfaces, and data from internal and external threats.

5.4. O-Cloud

While cloud threats and cloud security controls are not exclusive to Open RAN deployments, critical infrastructure deployed in the cloud requires a higher level of due diligence and design with built-in security. O-RAN's O-Cloud inherits the threats and vulnerabilities inherent in the cloud where RAN will run on third-party hardware in a multi-tenant environment managed by a third-party. Recent real-world security events, including Solarwinds, Kaseya, Log4Shell, have demonstrated the potential risks of operating Open RAN as critical infrastructure in the cloud due to external and internal threats, including APTs which could exploit Open RAN vulnerabilities for lateral movement and reconnaissance.

O-Cloud is the cloud computing platform specified by the O-RAN Alliance to host O-RAN network functions, including Near-RT RIC, O-CU, and O-DU. The O-Cloud is a collection of physical infrastructure nodes supporting software components, such as operating system, container runtime, and management and orchestration functions. The O2 interface between the SMO and the O-Cloud provides platform resources and workload management of the cloud infrastructure for support of O-RAN network functions, including discover and administrate, create and delete, dynamic scaling, and Fault, Configuration, Accounting, Performance, and Security (FCAPS).

A risk-based analysis, considering a ZTA to protect against internal and external threats, should be performed to secure the O-Cloud and the O2 interface used to manage it. The O-RAN Alliance WG11, O-RAN Security, has identified O-Cloud threats across the five following threat categories [35]:

- Compromise of virtual network function or cloud-native function images and embedded secrets
- Weak orchestrator configurations, access controls and isolation that can be exploited
- Misuse of a virtual machine or container to attack another virtual machine/container, hypervisor/container engine, or other hosts via shared resources such as memory, network, or storage
- Spoofing and eavesdropping on network traffic to access all O-RAN data processed in the workload

- Compromise to supporting network services

These threat categories are consistent with the Cloud Security Alliance (CSA) identification of the current eleven most important threats to cloud deployments as of 2022 [36], including:

1. Insufficient Identity, Credential, Access and Key Management, Privileged Accounts
2. Insecure Interfaces and APIs
4. Lack of Cloud Security Architecture and Strategy
6. Unsecure Third-Party Resources
9. Misconfiguration and Exploitation of Serverless and Container Workloads
11. Cloud Storage Data Exfiltration

The O-RAN Alliance WG11, O-RAN Security, has a current work item to ensure the O-Cloud and the O2 interface will be securely specified to protect against internal and external threats.

6. Conclusion

5G migration to the cloud provides great opportunity to transition the RAN from proprietary hardware to open software while increasing vendor diversity. While Open RAN, including Cloud RAN and O-RAN, provides security advantages, it also expands the RAN attack surface introducing new security risks requiring a shift in security paradigms from a perimeter-based approach to a ZTA that protects against internal and external threats. The O-RAN Alliance's WG11 continues to evolve the security posture of O-RAN's Open Fronthaul interface, RICs, SMO, and O-Cloud to align with a ZTA. Existing security protocols, including mTLS 1.2 with X.509 certificates, CMPv2, and OAuth 2.0, are valuable tools to protect against external and internal threats. The SMO, along with security rApps, can further enhance the security posture of Open RAN deployments. A secure Open RAN can help fulfill the promise of 5G use cases and ensure secure deployment of 5G critical infrastructure in the cloud.

1. Introduction

Sophisticated ML models function more or less as black-boxes. A neural network may easily classify a photo of an animal as a cat or dog, but is silent about *why* it made that decision. A recent development is *Explainable AI* (XAI), also called *Interpretable AI*. Dubbed as an enabler for ‘third-wave of AI’, it helps open up the black-box model [1][2]. XAI has found niche applications in many industries. For example, in credit-risk analysis it is common practice to use machine learning models. If a loan application is denied then XAI can further reveal the reasons why it was deemed risky. Another scenario is in product recommendations. XAI could bring to light the contributing factors as to why a certain product was recommended to a specific customer.

In spite of its prowess, XAI applications in cable industry have been lacking thus far. In this paper, we present a timely application that reflects broad global interest in ways to share customer data in a privacy-compliant way.

An emerging solution is the Data Clean Room (DCR) concept [3]. Its goal is to provide a safe place for partnering companies to bring respective data for analysis in a secure manner. Guidelines are established to restrict any sensitive queries to protect the customer identity. However, sensitive querying may occur unintentionally due to micro-targeting. This is ascribed to how the queries are constructed (e.g. too many conditions in the SQL filter). Since the queries have originated from credible sources, blocking them entirely is not desirable. A pragmatic solution would be to assess and relax the query sensitivity which would lead to efficient database querying. This can be achieved with XAI enabled machine learning. Additionally, the query sensitivity scores can be used to fine-tune the privacy mechanisms. This is illustrated with reference to leading privacy technologies.

[Please Note: Charter has a longstanding commitment to protecting the privacy and security of its customers. For example, Charter provides customers with detailed information about its privacy practices, explicitly allows customers to opt out or change sharing preferences at any time, and restricts the collection of information (when enabled by the customer) to what is necessary to provide and optimize service. Learn more at Spectrum.com/Privacy.]

2. Explainable AI – Brief Overview

Explainable artificial intelligence (XAI) attempts to answer the ‘why?’ question about machine learning models. *Explainability* has gained much attention recently as its potential for trustworthy AI is recognized. A common algorithmic technique is to slightly change (perturb) a single feature at a time and measure the impact on the model prediction.

2.1. How it works

To illustrate how XAI works, consider the widely available Titanic dataset listing the survival rate of passengers. XAI analysis results are shown in Figure 1 (see reference [4]). The passenger survival rate is high on the right half of the diagram (positive values) and vice versa.

The XAI (SHAP) analysis reveals the survivors were either mostly female or paid higher fares or belonged to young age group. The ‘embarked destination’ seems to have little impact on survival rate.

Figure 1 - XAI Example - Titanic survival analysis

2.2. XAI algorithms

The well-known XAI algorithms are:

- Local Interpretable Model-agnostic Explanations (LIME)
- Shapley Additive explanations (SHAP)
- Partial Dependence Plot (PDP)

LIME and SHAP are called surrogate models because they attempt to approximate the predictions of the underlying black-box model. The algorithms tweak the input slightly and test the changes in prediction. If there is appreciable change in the predicted value, then that input variable is considered to have a higher impact on the model prediction. Other techniques include gradient-based saliency maps for image analysis. LIME generates a new dataset by randomly turning the data points (pixels/words) on or off. Hence it is a local approximation to the black-box ML model. The surrogate models are model agnostic since they treat the ML model as a black box.

SHAP has origins in game theory. Corresponding to a game, each feature is considered a ‘player’ and the prediction is the prize money. In a game, Shapley values determine how to assign payouts to players in proportion to their contributions to the prize money. In machine learning it is the contribution by each feature to the final model prediction. SHAP algorithm determines the average marginal contribution of a feature to the model prediction.

PDP provides a graphical representation of how each feature affects the prediction in a machine learning model. Each feature value is changed in ascending order and the corresponding change in the prediction is plotted. A partial plot depicts the dependency of the target response over the range of input features. One limitation is that PDP assumes no correlation between input variables, an assumption which is not always realistic.

3. Data Clean Room

Recent privacy regulations and app tracking transparency frameworks reflect a growing trend requiring explicit user consent for tracking. Some major companies are also ending the support of third-party cookies and identifiers, making it harder to run effective campaigns or measure attribution. The challenge for businesses is how to share consumer data for analytics without compromising consumer privacy.

An emerging solution is the Data Clean Room (DCR) model. Its goal is to provide a safe place for partnering companies to bring respective data for confidential analytics. Security and privacy-protection measures are applied, such as data anonymization, obfuscation and differential privacy. All data stays within the data clean room and is not shared with outsiders (Figure 2). Guidelines are established to restrict any sensitive queries to protect the identity of customers in the database [6]. One drawback, however, is that when a query is blocked the analyst (querier) has to reconfigure the filters in the query string and resubmit until the blocking is removed. Since the queries have originated from credible sources, blocking them entirely is not desirable.

Figure 2 - Data Clean Room concept

Another application scenario is programmatic ad-buying, in which the ad-spaces are bid in real-time on ‘ad exchanges’, (*cf.* stock exchanges in finance). The highest bidder wins the auction and places the ad alongside the main content. For more effective targeting, a matching audience need to be identified and is done via querying the publisher database. Multiple advertiser proxies are involved in this process and all such entities may query a publisher database to build profiles. Similar to DCR, a common practice is to block any queries that are deemed sensitive.

Secure multi-party computation (MPC) is a cryptographic technique that secures the privacy of data even in collaborative computing. Some DCRs advocate the use of MPC. Confidential Computing is a related paradigm to protect the data ‘in use’ (compared to data at-rest and data in-transit). Additionally, it may also involve the siloed enclaves with memory partitions and containerized abstractions.

4. Query Validation

Validating a database query prior to execution is done for several reasons:

1. To correct the syntax of a query
2. To prevent hacking attacks targeting security vulnerabilities (e.g. SQL injection)
3. To thwart privacy attacks designed to divulge sensitive data

The third item is the focus of this analysis. While the stored data remain anonymous, sensitive queries could divulge personal data and could pose a privacy risk. As such, a common practice is to block any queries that are perceived as sensitive. This practice however reduces the *utility value* of the database. Also, it disrupts certain business models where a multitude of queries are generated from credible sources.

One such scenario is DCR, where each party query the partner databases to build user profiles. Note that the querier in this scenario is not an adversary but a partnering company. As such, sensitive querying may occur unintentionally due to micro-targeting. This is ascribed to how the queries are constructed, such as having too many conditions in the defined filter. Simply blocking or invalidating such queries is costly and inefficient. It also increases traffic to the database due to repeated attempts of failed queries.

Accordingly, there is a need for an enhanced query validation method to:

1. Notify the querier why a query was deemed sensitive and suggest improvements
2. Determine the conditions to be relaxed for a failed query to be executed successfully
3. Assess the query sensitivity and use it to enhance privacy protection mechanisms

To accomplish this, it is necessary to first identify the factors which contributed to blocking the query from execution. In general, the purpose of a query is to retrieve data records that fulfill a specified criteria. It becomes a *sensitive query* if the query string is constructed in such a way that it could divulge privacy-sensitive data. For example, if a query returns only a handful of matching records, releasing such data may be a privacy risk for the affected individuals or the cohort. Also, in this scenario injecting statistical noise to mask the query response could skew the results. A more appropriate solution would be to devise a way to *relax* the query criteria to enable (unblock) query execution. This applies to other types of querying scenarios such as in graph databases.

In the ensuing sections, a machine learning-based solution is outlined for identifying sensitive queries. Explainable AI techniques are then used to obtain the reasons why the query was deemed sensitive. A distributed workflow is presented for relaxing the query criteria and deriving a quantified query sensitivity, which is then used as input for privacy settings.

4.1. Query Relaxation Example

Relaxing the search criteria constraints will unblock a sensitive query. For example, assume that in the first pass XAI indicated three possible reasons for the blockage.

Blocked by: Ethnic code = Danish, Age group = 50 – 55, Income bracket = 100k – 110k

These conditions are then relaxed iteratively and the query is run recursively. Table 1 shows the contributing factors for blockage at each pass.

Table 1 - Query relaxation Iteration

Query Iteration	ML Outcome	XAI Outcome (Reasons for blocking)
First Pass	query blocked	Ethnicity, Age, Income
Second Pass	query blocked	Ethnicity, Age,
Third Pass	query blocked	Age
Fourth Pass	query validated!	

For example, the age group can be expanded gradually by ± 5 years.

Figure 3 - Query filter relaxation example

Similarly, the ethnic code can be relaxed as in following steps:

- 1st try – Ethnic Code = Danish
- 2nd try – Ethnic Code = Danish + Swedish
- 3rd try – Ethnic Code = all Scandinavian countries
- 4th try – Ethnic Code = all Nordic countries
- 5th try – Ethnic Code = Nordic + Baltic countries

The above steps are continued till the blockage is cleared, or until the max depth is reached (as defined in the rules engine and database schema). By relaxing the conditions, a valid query can be achieved. This is vital to the querier as it avoids the trial and error method of submitting multiple queries and getting a “Your query was blocked” error message. Instead, the ML-XAI based solution provides a more productive response: “Your query was deemed sensitive and blocked. The following conditions may need to be relaxed...” Additionally, (if sanctioned by the contract), the query is run with relaxed conditions on the main database. The results (with noise injected), are supplied back to the querier.

5. Machine Learning Module

ML engines are generally trained on the data gathered externally, such as in transfer learning. In the present case, the training data resides in the main database itself. While database-integrated ML engines already exist (e.g. Amazon Aurora and Google BigQuery), the usage described below is different: In addition to query retrieval, its sensitivity is also analyzed. For this task, a collection of queries over a wide range of conditions is amassed and run on the main customer database. The outputs are then classified and graded according to sensitivity. This action is based on Rules Engine settings, additionally supported by human expert analysis. Database and privacy experts review the queries and classify those based on the perceived sensitivity. The outcome is a gradation based on the level of sensitivity. The neural ML engine is trained (weights adjustment), with the classified queries from the query database. Once trained, the ML engine is able to classify whether a fresh query is sensitive or not.

5.1. Machine Learning Model Training Steps

1. Raw queries are collected from multiple sources.
2. Query database is formed with ‘unclassified’ queries.
3. Queries are run on the main database (which contains user data records).
4. The query outputs are analyzed for sensitivity per rules engine settings.
5. Queries are then classified (graded), according to sensitivity.
6. The sensitive queries are submitted to the XAI module. Reasons for blocking are derived.
7. The ‘unclassified’ queries are updated with sensitivity data.
8. The ‘classified’ queries are used to train the ML engine.

The classified* query strings form the inputs for training the ML engine. Additionally, XAI layer provides the explanation why certain queries were considered sensitive. The latter is used for further analysis and refinement of the model. (*the term *classified* here means, ‘assigned to different classes’.)

Figure 4 illustrates functioning of the ML Engine for the case of a supervised neural network. The categories (fields) in the database form the input layer. The output layer contains the predicted sensitivity of the query. It could be a binary y/n type or a graded value as shown for more granular assessment.

Figure 4 - ML classification of graded query sensitivity

Referring to Table 2, queries form the leftmost column (usually thousands or millions of entries/rows). The next set of columns refer to the types of records in the database, typically ranging from hundreds to several thousand columns. Each row indicates a data record. Column heads are the fields in the database searched by the query. The Sensitivity columns on the right are derived during the training phase as described above. The ‘Y’s in the column indicate blocked queries that were perceived as privacy compromised. The middle column is a more granular representation of sensitivity. Instead of a binary (Y/N) outcome, the sensitivity is represented as a graded score based on the severity of privacy risk. The last column indicates the assessment from XAI for sensitive/blocked queries.

Table 2 - Sensitivity Analysis - Example

Queries	Types of Records in the Database					Sensitivity score (binary)	Sensitivity score (graded) 1- 5	Sensitivity analysis (XAI)
	Income (X1)	Age (X2)	Zip (X3)	Race (X4)	etc. etc.			
Query 1	100-110k	50 - 55	12345	Danish		Y	4	Reason
Query 2								
etc.								
etc.								

5.2. Constrained Optimization

In a typical database, there could be hundreds or even thousands of columns each representing a feature. Without the XAI analysis, it is not easy to pinpoint which feature contributed more for the query sensitivity. Formulating it as a multivariate discrete optimization problem:

If the input variables are denoted by X_i and the target variable (query sensitivity) as ‘y’.

$$X_1 \cap X_2 \cap X_3 \cap \dots X_n < y$$

The constraints for each variable: $a_1 < X_1 < b_1$, $a_2 < X_2 < b_2$, ... $a_n < X_n < b_n$

Then to relax the conditions, each X_i is incremented by $\pm \Delta X_i$.

$$(X_1 + \Delta X_1) \cap (X_2 + \Delta X_2) \cap \dots \cap (X_n + \Delta X_n) \geq y$$

The set of minimum ΔX_i values which meet the constraints would be the optimal result.

Figure 5 - Incremental query relaxation

For example, consider the simplified case of 2 variables.

Age constraint (X_1) $50 < \text{Age-group} < 55$

Income constraint (X_2): $100k < \text{Income-bracket} < 110k$

Assume the sensitivity boundary is ‘ $y=10$ ’. That is, any compound query that returns less than 10 records would be blocked as sensitive.

$$\text{Age-group} \cap \text{Income-bracket} < 10$$

As the field ranges are extended/relaxed, at one point the query will return 10 or more results. i.e. the query is no longer sensitive. It is necessary to find the lowest increments for each variable to meet that criterion. For example, simply expanding the Age-group broadly to 30-70 years might return a large number of records but would be irrelevant. While it may preserve the privacy (query no longer sensitive), the query result will have no utility value to a marketer who is targeting 50-55 age group.

Finding which variable(s) and by how much (ΔX) “minimally” to tweak each is an optimization problem. It gets complicated when dozens or hundreds of variables are involved.

5.3. Model specific considerations

The ML module is based on common classification algorithms such as neural and statistical models. During the training phase, queries with known outcomes (sensitive/not-sensitive) are used to update the weights in the ML engine. (Weights of each link determine the impact of a category). Once trained, the ML engine can classify whether a fresh query is sensitive or not. If the data is volatile, then frequent training would be needed. Statistical ensemble methods such random forests and XGBoost are also options. For more than two outcomes, multinomial logistic regression is another paradigm.

6. Solution Architecture

Process Steps:

1. The Query Controller submits the initial query to the (trained) ML engine.
2. If the query is deemed sensitive, it is run through the XAI module.
3. XAI supplies the reasons for blocking. The querier may be notified.
4. Sensitivity conditions in the string are relaxed per rules engine iteratively.
5. Query is submitted to ML engine recursively until it passes the sensitivity test.
6. The validated query is run on the main database.
7. Query response is assessed for privacy risks and noise injected.

6.1. Workflow

The workflow for the query validation solution are presented below.

Figure 6 - Enhanced query validation workflow

6.2. Functional components

Figure 7 describes the functional components of the distributed solution. The ML engine, XAI module and the rules engine work in conjunction to define, detect and quantify the query sensitivity. While functionally separate, the ML Engine and XAI are integrated components. XAI can be considered a functionality on top of the machine learning layer and is used recursively with the ML Engine. Once XAI is invoked, it parses the input query and supplies the reasoning for the ML classification.

Figure 7 - Solution components

Main Database (Customer Data) – A standard database, such as RDBMS or NoSQL type, either central or distributed. Queries are run on the database and the outputs are classified for sensitivity, then used to train the ML engine.

Query Supply Module – To populate the ‘Queries database’, queries are supplied in several ways.

- Historical data (a collection of previously run queries)
- Queries obtained from an external entity for training purposes. (Transfer learning is a well-known machine learning training paradigm, in which external data is used first to train an ML engine. Then local data is used to fine-tune the algorithm.)
- Boosting and resampling is a standard ML technique to generate data. Also, the use of a sub-module that auto-creates new queries by modifying the existing queries in the database. Suppose that an existing query has the qualifiers: area code, age group, income bracket, vehicle driven and hobby. Then it is possible to auto-change one qualifier at a time and test how the sensitivity changes. The query is run against the actual data in the main database to classify it as sensitive or not.

Queries Database – The queries database is populated by the Query Supply Module, mentioned above. These queries are used for training the machine learning engine.

Rules Engine – Rules are constructed to define instructions, thresholds etc.

Examples:

- A query is considered sensitive if the query response contains less than five records.
- A query is considered sensitive if a combination of certain categories are present in the query string.
- A query is considered sensitive if similar (coordinated) queries originated from the same source.

Query Controller (QC) – QC module interacts with others systems to automate process flows as well as perform decision making based on the Rules Engine settings. It consists of three subsystems described below.

Query Runner subsystem – Queries (retrieved from the ‘Queries database’) need to be run on the Main database to train the ML engine. First, each query result is classified as sensitive or not. This can be done based on the settings of the rules engine or with expert input, as it is done offline. During normal operation (after the ML engine is trained), Query Runner’s function is to run queries submitted by external entities (queriers).

Query Analyzer subsystem – Analyzing the query for sensitivity based on Rules Engine settings.

Query Modifier subsystem – A software construct with automated processing capability. Assume a query was deemed sensitive and the specific reason for blocking was supplied by XAI module. The Query Modifier will relax the constraint(s) (based on Rules Engine settings) and run the query iteratively until it passes the ‘sensitivity test’.

7. Application to Privacy Mechanisms

‘Differential Privacy’ (DP) is a statistical technique for protecting individual privacy during database querying. When a query is run on a database, DP adds a carefully chosen amount of noise/perturbation is added selectively to the result masking the user identity. For example if the query is to find those who subscribed to a certain TV channel, then some of the user responses (yes/no) are flipped randomly. This gives rise to a new concept called ‘*plausible deniability*’. So by looking at the data, it is not possible to establish if that data is truly associated with a person or randomly generated. The flip side of adding noise is the need to strike a balance between *utility* and *privacy*. One cannot be enhanced without compromising the other.

Algorithmic basis: Given two neighboring datasets D and D' differing by one data record, the randomized function K provides ϵ -differential privacy when the following probability condition (denoted by ‘Pr’) is satisfied for all $S \subseteq \text{Range}(K)$.

$$Pr[K(D) \in S] \leq \exp(\epsilon) \times Pr[K(D') \in S]$$

ϵ (epsilon) denotes the privacy loss. For small values, $\exp(\epsilon) \sim 1 + \epsilon$. Note that *differing by one data record* implies that it would not make a difference whether one individual’s data are included in the dataset or not. The query result would still be within the statistical error margin. The definition of sensitivity in DP is tied to this formalism.

Small ϵ (more noise) – better privacy but low utility

Large ϵ (less noise) – low privacy but high utility

Figure 8 shows the query validator functionality (in schematic form) as input to the DP privacy module. Statistical/random noise is added to the outgoing query response. The role of DP controller is to coordinate the epsilon values across a distributed implementation of differential privacy. Such a solution is warranted in the case of targeted advertising, to account for viewership and billing considerations. See reference [5] for implementation details.

Figure 8 - Query validator and privacy module

7.1. Query sensitivity score and Privacy

The leading privacy technologies contain parameter settings to control the level of protection. Examples are the (ϵ) epsilon value in differential privacy, 'k' and 'l' values in k-anonymity and l-diversity, respectively. Calibrating these parameters is a trial and error process. In this regard, the graded *query sensitivity score* described above can be used in tuning the privacy parameters as shown below.

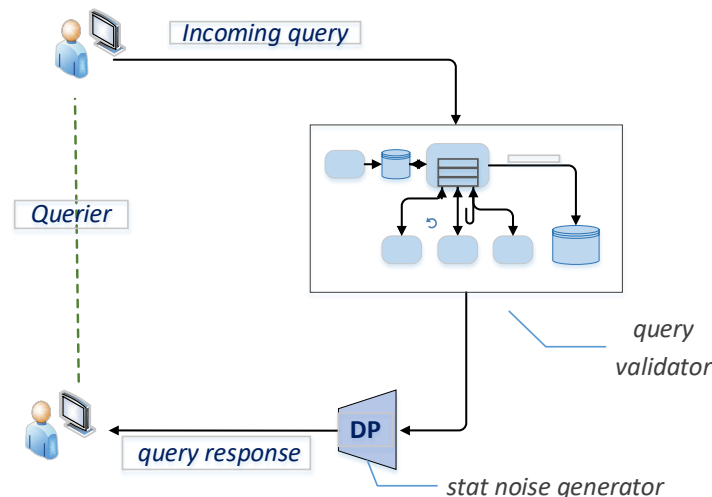

Figure 9 - Query sensitivity input to privacy module

In addition to structured databases, the solution described may also apply to search engines. Instead of a terse message (‘no results to display’), the user would appreciate receiving some form of approximate results. This can be achieved with ML based query relaxation.

8. Conclusion

A timely application of Explainable AI to the cable industry was presented, driven by recent privacy regulations. XAI-enabled machine learning leads to more efficient database querying in specific applications. The quantified query sensitivity scores can be used to enhance privacy mechanisms.

1. Introduction

Over the past decade, Cable operators and communication service providers have been striving towards Distributed Access Architecture (DAA)^[1], which disaggregates Converged Cable Access Platform (CCAP) systems for cable network scaling, operation simplification and cost reduction, as well as resource and space savings at the HFC headend or hub location. DAA deployment also provides a platform for cable operators to continually integrate virtualization elements into their networks for service velocity.

The Flexible MAC Architecture (FMA) specification^[2] released by CableLabs in 2020 is the latest undertaking for DAA evolution. FMA compartmentalizes DAA management plane, control plane, and data plane functions with APIs for vendor product interoperability. It accommodates DAA Remote PHY (R-PHY) and Remote MAC PHY (R-MACPHY) system architectures for flexible DAA solution variants. FMA access technologies include xPON and 4G/5G wireless for evolving last-mile access architectures. The FMA specification further calls out software defined networking (SDN) and network function virtualization (NFV) for future implementation with DAA.

Today, FMA is undergoing vendor product implementation and multi-vendor interoperability demonstrations. But what will FMA NFV look like end to end? How will the FMA NFV be implemented? Will FMA be further optimized for a cable operator's service agility and cost reductions? These questions are all open for exploration and development.

This paper proposes FMA cloudification to advance FMA along its evolutionary path. Many communication service providers (CSP) in the telecommunication industry have recognized Cloud as a mechanism for lowering operator's total cost of ownership (TCO) and gaining operations efficiency. Some CSPs have started migrating their network infrastructures as well as IT workloads to Cloud. Challenges in supporting virtualized network functions (VNFs) in Cloud are often around real-time constraints, high availability, and operation automation. This is particularly true for DOCSIS like products.^[3] Our approach to FMA cloudification is to properly map FMA functions across cloud region, cloud edge, and on-premise environments based on their latency tolerance characteristics and access network technology requirements. Specifically, we allocate FMA control plane functions such as MAC Manager and management plane functions such as Operations Support System (OSS) in the cloud region and control functions of auxiliary cores at the cloud edge, leaving latency-sensitive Remote MAC Devices as well as last-mile access networks AS IS in the field. With this MFA cloud architecture, CSPs can focus their capital and resources on the last-mile technology and deployment into a particular geographic area while simplifying network provisioning and management processes with the cloud.

In the following, we briefly review the FMA architecture in Section 2. Section 3 details our approach to FMA cloudification by introducing a Cloud Continuum model and positioning FMA functions along the cloud continuum based on timing analysis and FMA architecture. In section 4, we describe how the cloud FMA can be realized through a cloud infrastructure and address FMA high availability and deployment automation using cloud-native services. We further demonstrate the FMA cloudification with cloud-native services for an FMA use case – streaming telemetry in Section 5. We conclude the paper in section 6.

2. Flexible MAC architecture overview

The FMA concept began after a number of discussions among technical staff from Cox Communications and the AT&T Foundry as they worked on what became known as “CORD” (Central Office Reimagined as a Data center). FMA was originally called “HERD” (Head-End Reimagined as a Data center), but as it transformed from an architecture for simply managing remote MACPHY devices to an agile service delivery platform that included its original intent of Remote MACPHY Device (RMD) interoperability, the decision to rebrand it was made.

FMA was designed from the beginning with the idea of all components being able to work in a physical and virtual environment. The legacy back-end software, MAC manager, SDN and DOCSIS controllers, and auxiliary cores, would be designed to be placed at the point in the compute network that was consistent with the architectural demands of each individual operator. The interfaces between FMA components were standardized which would allow for the decomposition of functions and their strategic placement in the operator network or public cloud as desired.

The core objectives of the FMA working group are as follows:

1. Define interfaces between a management entity and DOCSIS MAC network element such that the management entity from Vendor A may be interoperable with a DOCSIS MAC network element from Vendor B.
2. Define a DOCSIS MAC network element that contains all necessary DOCSIS MAC layer functions such that a CCAP core network element is not needed for data plane forwarding of customer data traffic.
3. Define a DOCSIS MAC network element for both physical network functions (PNFs) and virtual network functions (VNFs) used for data plane forwarding.
4. Define an architecture such that typical CCAP functions such as management plane, L2/L3 control plane, and DOCSIS control plane may be separate from the DOCSIS MAC network element.
5. Define an open standard interface between operator BSS, OSS, NMS, and orchestration with the management entity or entities which may include management plane, L2/L3 control plane, and DOCSIS control plane used to operate the DOCSIS MAC network element.
6. Leverage previous cable industry specifications as appropriate as well as consider the transition to next generation approaches used in the areas of software defined networking (SDN), network function virtualization (NFV), VNFs, and PNFs, new protocols, new data models, and new telemetry methods as desired by the R-MACPHY MSO steering committee and working group.

Towards the objectives, the FMA working group developed and published the first FMA System Specification in 2020 and since has made two revisions.^[2] A detailed view along with the connections between the FMA components can be seen in Figure 1 below.

The FMA architecture will evolve in three phases.

Phase 1 – Support key components necessary to bring RMDs into existing operator networks without causing disruption to legacy EMS and NMS platforms

Phase 2 – Allow for continued use of Remote PHY devices in the FMA network management paradigm

The diagram illustrates a network architecture centered around a **Converged Interconnect Network**. On the left, a vertical stack of components includes:

- ERM Video Mgmt**
- OOB Video System**
- RF Systems**
- COPS / PCMM**
- Operator (CU)**
- IPDR Collector**
- TOD Server**
- SYSLOG Server**
- SNMP Server**
- DHCP Server**
- File Server**
- NETCONF/Yang Models** (dashed box)
- New Telemetry Data** (dashed box)
- Operator (RESTCONF)** (dashed box)
- Overlay/Underlay Controller** (dashed box)

These components interact with the central network via interfaces labeled **NETCONF,GCP,... New Interface**, **GCP/RCP**, and **R-DEPI/R-UEPI**.

The central **Converged Interconnect Network** connects several key nodes:

- RMD Manager**: Contains a **Management Plane** and an **RPD Management Agent**.
- Auxiliary Video/OOB Core(s)**: Contains an **RPD Management** agent and two planes: **Control Plane Video/OOB** and **Data Plane Video/OOB**.
- Remote MACPHY Device (RMD)**: Contains a **Management Agent**, an **RPD Management Agent**, and three planes: **Control Plane L2/L3**, **Data Plane L2/L3**, **Control Plane (DOCSIS)**, **Data Plane DOCSIS MAC**, and **Data Plane DOCSIS PHY**.
- Remote MAC Core (RMC)**: Contains a **Management Agent**, an **RPD Management** agent, and three planes: **Control Plane L2/L3**, **Data Plane L2/L3**, **Control Plane (DOCSIS)**, **Data Plane DOCSIS MAC**, and **Data Plane DOCSIS PHY**.
- Remote PHY Device (RPD)**: Contains an **RPD Management Agent** and two planes: **Data Plane DOCSIS PHY** and **Data Plane Video/OOB PHY**.

Arrows indicate the flow of management and data traffic between these components through the central network.

Figure 2 shows the FMA Phase 1 reference architecture with components and their functions and interfaces. For details, refer to the FMA System Specification^[2].

This paper introduces how to take Cloud advantages for business agility, operation efficiency, modern application services, and cost savings by running the components of the Flexible MAC Architecture in a cloud environment. The paper focuses on the FMA Phase 1 reference architecture for cloudification.

3. Approach to FMA cloudification

The FMA cloudification builds on a cloud infrastructure model, called Cloud Continuum. Typical cloud workloads such as web applications are centered around Cloud Region which consists of multiple inter-connected data centers. The Cloud Continuum extends the cloud region to cloud edge for time-sensitive network functions and applications. It enables multi-access edge computing (MEC) for network operators' business growth. The Cloud Continuum is further out to the far edge with cloud services like IoT for managing physical devices in the field.

Figure 3 shows the Cloud Continuum model with Cloud Regions, Cloud Edge, and Cloud Far Edge. They are inter-connected and have the same “look and feel” for cloud infrastructure services such as networking, compute, storage, CLI commands, and deployment automation.

Figure 3 – Cloud Continuum: Region, Edge, and Far Edge

With the Cloud Continuum model, FMA is overlayed across the cloud region, cloud edge, and cloud far edge in on-premises environments. This is accomplished through analyzing the real time characteristics and operation locality of FMA systems^[2] and accordingly allocating FMA functions along the Cloud Continuum and remote MAC network elements (MAC-NEs). Table 1 summarizes the analysis with respect to the degree of latency tolerance per major FMA functions, where High means the latency requirement is greater than 50ms roughly, Medium is in-between 20ms - 50ms, Low in-between 5ms - 20ms, and Ultra Low is less than 5ms. It also shows the operation locality of an FMA system or function, i.e., Backoffice, Headend, Hub, or MAC-NE.

Given the timing constraints and operation locality, the FMA functions are now allocated across cloud region, cloud edge, access network, and MAC-NEs. Figure 4 illustrates the FMA System Architecture^[2], where the upper portion shows the management and control plane functions allocated in Data Center, Headend, Hub, and Optical Node and the lower portion depicts the data plane.

The FMA System Architecture can be cloudified in a cloud architecture pattern shown in Figure 5. The FMA functional allocation and architecture cloudification scheme is as follows.

Table 1 – Analysis of FMA Function Timing Characteristics and Operation Locality

FMA System	FMA Functionality	Plane	Latency Tolerance*	Operation Locality
MSO Backoffice	OSS - IPDR Collector, Syslog Server, SNMP Manager, DHCP Server, File Server, AAA, PNM Server, Telemetry	Management	Medium - High	Backoffice
	PacketCable management - PCMM Policy Server, PacketCable CMS, PacketCable PKS	Management	High	Backoffice
	Auxiliary Core Management - OOB Video Mgmt, OOB RF Sys Mgmt, ERM Video Mgmt	Management	High	Backoffice
MAC Manager	Manage MAC-NE through FMA protocols	Management	High	Backoffice or Headend
PacketCable Aggregator	Scale PacketCable Multimedia Backoffice element to RMDs	Management	High	Backoffice or Headend
OOB Core	Manage and control legacy set-top boxes (STBs) as RMDs in substitution of SCTE 55-1 and SCTE 55-2 OOB Cores	Management Control	Medium Low	Headend or Hub
NDx Core	Support Narrowband Digital Forward (NDF) and Narrowband Digital Return (NDR) capabilities	Control Data	Low Low	Headend or Hub
Video Core	Provide video EQAM processing functions, except video PHY and QAM-related processing in RMD	Control Data	Low Low	Headend
PTP System	Clock synchronization across RMDs	Control	Low	Headend
MAC-NE (RMD)	DOCSIS MAC and the upper layer protocols, QAM, digital to/from analog conversion for RF/Ethernet or PON transmission	Management Control Data	High Low Ultra low	Hub or Node

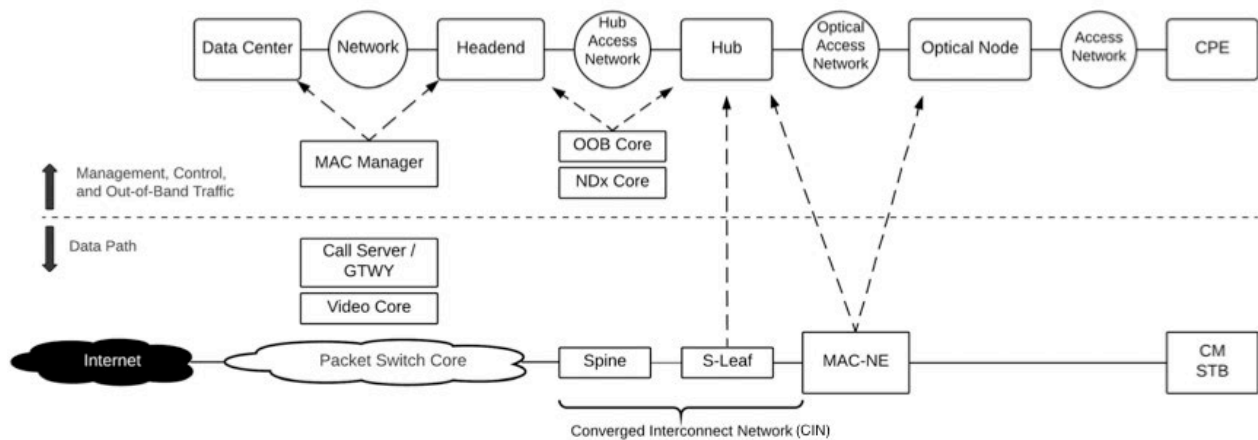

Figure 4 – FMA System Architecture

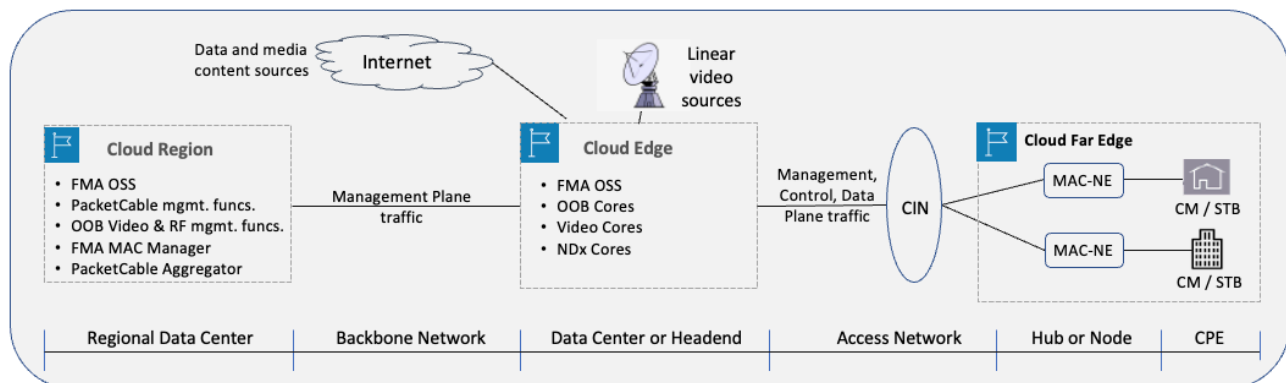

Figure 5 – FMA Cloudification Architecture Pattern

FMA Management Plane consists of FMA OSS functions, MAC Manager, PacketCable Aggregator, PacketCable management functions, and OOB Video & RF management functions. They are High in latency tolerance. Mirroring Multi-System Operator (MSO) Backoffice at regional data centers, MAC Manager, PacketCable Aggregator, most of OSS functions, and PacketCable management functions are placed in the cloud region. The OSS functions such as streaming telemetry that deal with a large amount of data can be allocated at the cloud edge to localize data processing, filtering, and analytics. MAC Manager and PacketCable Aggregator can run at the cloud edge as well because of the operation locality.

FMA Control Plane involves auxiliary Cores, OOB Core, NDX Core, and Video Core, under the FMA Phase 1 Reference Architecture shown in Figure 2. Since they are Low in latency tolerance, they run at the cloud edge. The FMA control plane functional entity resides in MAC-NE for processing L2/L3 control plane traffic. For example, the MAC-NE DOCSIS Control Plane functional entity processes control plane traffic from the PacketCable Aggregator. Hence, the FMA control plane functional entity in MAC-NE is allocated at the cloud far edge.

FMA Data Plane is comprised of data plane functions of MAC-NE (Remote MACPHY Device) as well as NDx Core and Video Core systems. As physical device, MAC-NE performs RF conversion with Ultra Low data process latency outside of cable plant. In addition, MAC-NE may run IoT functions for Proactive Network Maintenance (PNM). Hence, MAC-NE is at the cloud far edge. NDx Core and Video Core data plane functions are Low in latency tolerance and thus placed at the cloud edge.

FMA Networks are comprised of Packet Switched Network Core and Converged Interconnect Network (CIN). The Network Core is for communications between FMA data centers and headend systems as well as Internet traffic. CIN consists of Spine switches and Secure Leaf switches (S-Leaf), connecting MAC-NE (RMD) instances in a hierarchical structure. In the cloud environment, the infrastructure backbone network and SD-WAN in-between the cloud region and cloud edge replace the FMA Network Core, thus relieving FMA operators from the core network management. CIN remains as it is in the field for network technology as well as vendor deployment flexibility.

FMA MAC-NE (RMD) and CPE are vendor and customer choices. Cloud IoT can be added to RMD and CPE for MSO to provide advanced services such as device control, fault diagnostics, or preventive network maintenance which the FMA System Specification^[2] describes.

In summary, the FMA cloudification builds on the cloud continuum infrastructure with FMA functions allocated in the cloud region, cloud edge, and cloud far edge according to their timing characteristics and operation needs.

4. Cloud infrastructure and services for FMA cloudification

This section describes how the FMA cloudification can be realized in cloud. It uses Amazon Web Services (AWS) as an example of a cloud infrastructure. Please note that similar architectures can be built with other cloud providers.

4.1. Cloud edge services and selection

The cloud continuum is comprised of different types of cloud edge technology. AWS provides three types of cloud edge services: Outposts, Wavelength, and Local Zones as shown in Figure 6. Though all provide cloud compute, storage, and networking services for real-time, short-latency or high-throughput virtualized network functions (VNFs) and applications, they are architected for different use cases. MSOs or cable operators need to examine and select a right type of cloud edge technology and services for FMA cloudification.

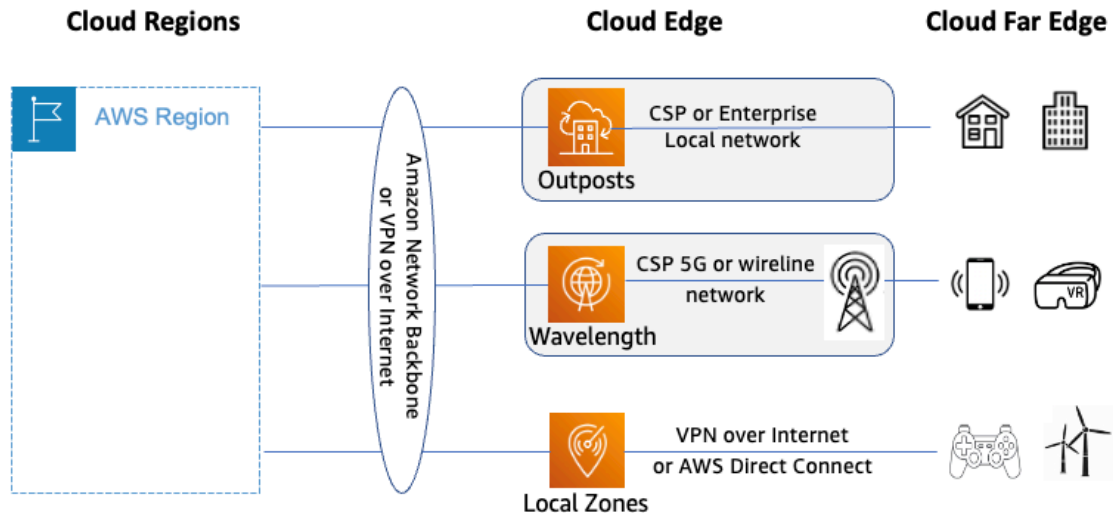

Figure 6 – Types of Cloud Edge Services

Table 2 summarizes the characteristics and use cases of these three types of cloud edge services. Although both AWS Outposts and Wavelength are embedded in CSP networks, the former is dedicated to an operator or enterprise, thus called “private edge cloud,” whereas the latter is shared by different enterprises, organizations, or users, called “public edge cloud.” That is, the Outposts is for private use and the Wavelength is for public. AWS Local Zones is fully managed by AWS with end-user connectivity through CSP wireline or wireless services or enterprise’s direct connection. Hence, the private edge cloud service (Outposts) is suitable for FMA in MSO or cable operator networks. MSO deploys and manages FMA systems and functions in the cloud.

Table 2 – Comparisons of Cloud Edge Services

Type of Cloud Edge Service	Cloud Edge Architecture & Deployment location	Use Case	Type of CSP	Management Responsibility
Outposts	On-premises networks or in CSP networks	<ul style="list-style-type: none"> Private Multi-Access Computing (e.g., smart factory, healthcare operations, real-time ML and analytics) Private Mobile Network MSO network 	<ul style="list-style-type: none"> Telecom operators MSOs 	<ul style="list-style-type: none"> Cloud infra. & cloud services: AWS Local network: CSP or on-premises operator
Wavelength	In CSP networks, especially 5G mobile networks	<ul style="list-style-type: none"> Public Multi-Access Computing (e.g., intelligent vehicles, real-time retails) 	<ul style="list-style-type: none"> Mobile network operators 	<ul style="list-style-type: none"> Cloud infra. & cloud services: AWS Local network: CSP
Local Zones	In AWS infrastructure	Public Multi-Access Computing (e.g., real-time gaming, interactive live video streams)	N/A	<ul style="list-style-type: none"> Cloud infra. & cloud services: AWS Local Zones connectivity: CSP or enterprise

4.2. FMA cloud architecture

Figure 7 depicts an FMA cloud architecture with AWS Region and Outposts-based cloud edge integrated with CIN and MAC-NEs at the far edge.

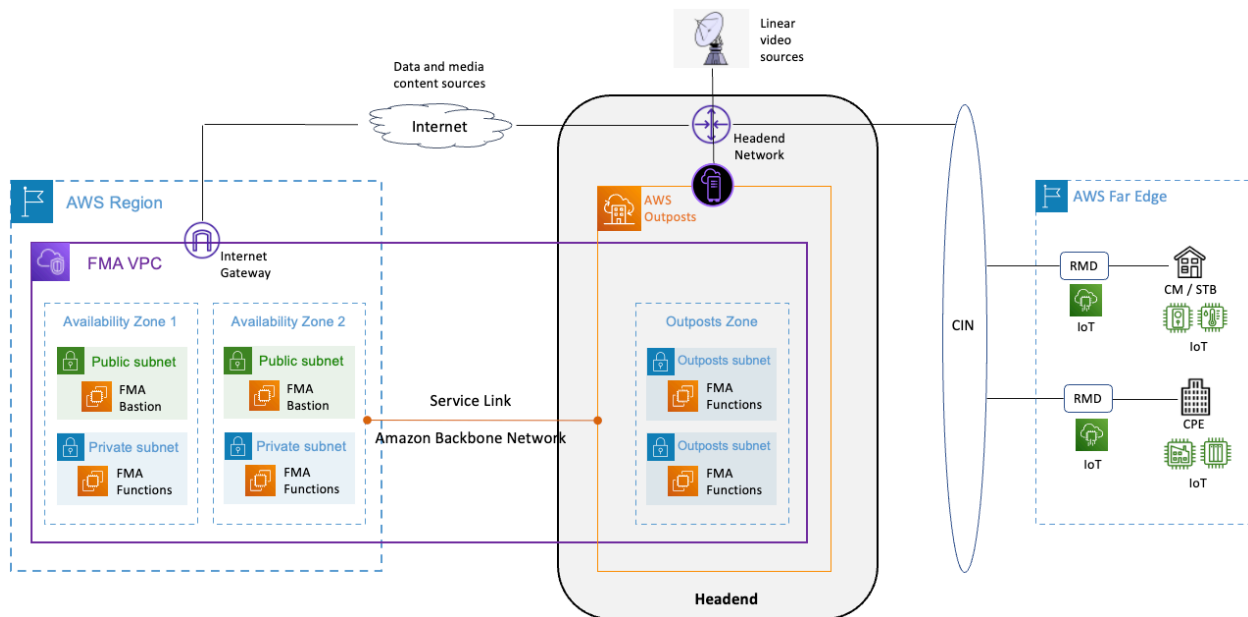

Figure 7 – FMA on AWS Cloud

The FMA cloud portion is comprised of four building blocks:

- *AWS Region* – is a physical location, which is comprised of multiple Availability Zones for high availability and high scalability. Each Availability Zone has multiple datacenters housed in physically separated facilities with redundant power, networking, and connectivity. A region hosts the high latency-tolerance FMA management plane functions such as OSS and PacketCable management.

- *AWS Edge Outposts* – are cloud edge platforms in three form factors, 42-RU, 2-RU, and 1-RU. The platforms provide cloud-native services such as Elastic Cloud Computing Service (EC2) for virtual machines and Elastic Kubernetes Service (EKS) for containers. The Outposts run FMA functions that are low latency tolerance (e.g., auxiliary Cores), require intense local data processing and analytics (e.g., OSS telemetry), or need to be operated at headend (e.g., MAC Manager and PacketCable Aggregator).
- *AWS Virtual Private Cloud (VPC)* – closely resembles a traditional network in a data center, with the benefits of using the scalable cloud infrastructure. For the FMA cloudification, a VPC is extended from a region to one or more edge locations where headend resides. Interconnecting the region and the edge is an AWS Service Link over the Amazon backbone network.
- *AWS Cloud Edge Network* – provides L2 and L3 connectivity with the headend network. It serves FMA traffic between AWS Outposts and three places: CIN for RMD, Internet for data, voice, and media content, and local equipment for linear video.
- *AWS Cloud Far Edge* – provides AWS IoT services on RMD and CPE with device connectivity over CIN to the cloud edge and cloud region. Since the subject of applications such as IoT is out of the FMA scope, the cloud far edge is not discussed below.

This FMA cloud architecture serves the traditional MSO Backoffice, headend, and their Packet Switch Network Core as a whole and leaves to MSO operators the flexibility and choice for CIN connectivity and the last-mile access network technologies (e.g., DOCSIS Remote PHY, DOCSIS Remote-MACPHY, EPON, GPON). The managed AWS infrastructure services (e.g., VPC, Outposts, EC2, and EKS) enable MSO operators to focus on the FMA functionality for technology innovation and business growth.

4.3. High Availability

High Availability (HA) is essential in cable services. Along the cloud continuum, HA can be achieved for FMA systems and functions using cloud infrastructure services. Figure 8 illustrates multiple HA solution patterns in the cloud region and at the edge with AWS as an example.

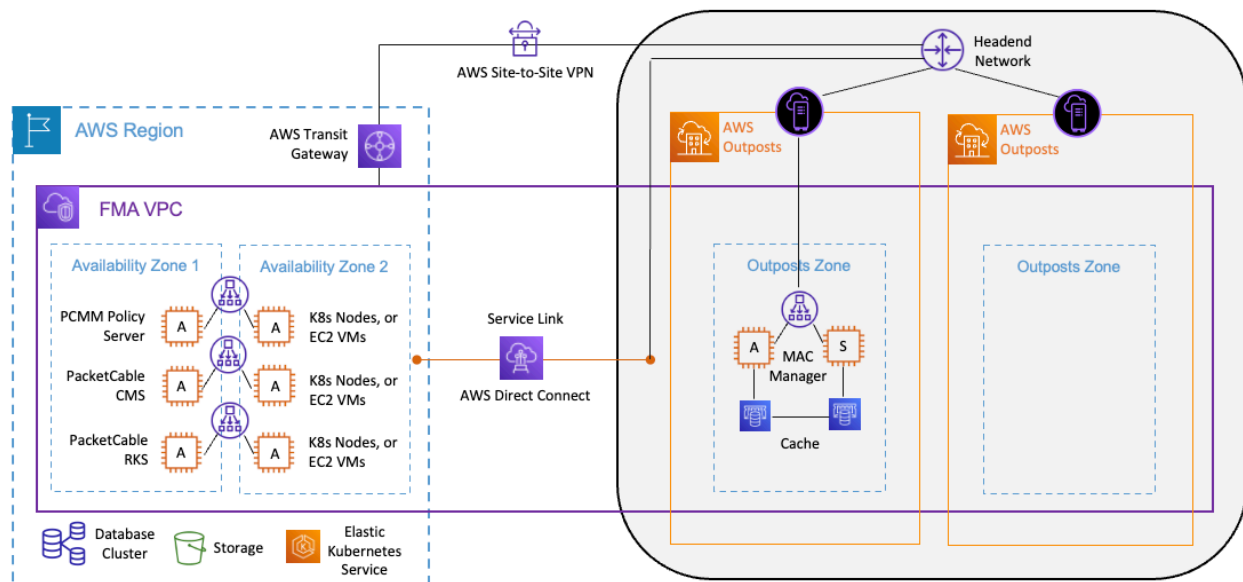

Figure 8 – HA Solution Patterns

Active-Active server HA solution pattern is based on a cloud service mechanism which runs two or more Kubernetes (K8s) nodes with containers in a K8s cluster, or two or more Virtual Machines (VM) instances, across two or more Availability Zones (AZ). The containers or VM instances, are load-balanced through Load Balancers. It is illustrated with FMA PacketCable management functions running in the Active-Active mode in the AWS Region in Figure 5. Failure of an entire Availability Zone, a VM instance, a K8s node, or physical server hosting the VM instance or K8s node will lead to re-routing the traffic to the active resources. Combined with the AWS Auto Scaling service, the Active-Active HA solution delivers the required resource capacity by automatically replenishing lost resources (VM instances or K8s nodes) after the failover.

Active-Standby server HA solution pattern uses two sets of resources (VM instances or K8s nodes) in two AZs in an AWS region or on an Outposts platform, with one set in the Active mode and the other Standby. When the Active fails, the Standby takes over. To simplify the Active-Standby HA solution, the application running on the VM instances or K8s nodes should be stateless with its state data stored in a cache or storage. Figure 5 illustrates the Active-Standby HA model in an AWS Outposts at the edge hosting MAC Manager. For higher availability, two Outposts platforms can be used and the applications are configured for failover over local network paths.

Network HA is supported for the Service Link between the cloud region and the edge with an encrypted set of VPN connections through AWS Direct Connect-based private or/and public connectivity or/and Internet-based public connectivity. In addition, the FMA may add a redundant out-of-band AWS Site-to-Site VPN link over Internet or AWS Direct Connect in-between the cloud region and the edge.

Database, cache, storage, and file system HA are provided as cloud-native services managed by AWS. For example, Amazon Relational Database Service (Amazon RDS) supports High Availability with one standby or two read standbys. AWS ElastiCache provides Redis replication groups within an AZ or across multiple AZs with automatic failover. Amazon Simple Storage Service (S3), an object storage, provides HA and durability through across-AZ replication; S3 can be enabled for cross-region replication as well. Amazon FSx and Amazon EFS file systems can also be deployed across multi-AZs for HA. The FMA cloudification will benefit from these and many other cloud-native database, cache, and storage services.

4.4. Operation automation

The FMA cloudification can utilize cloud services to ease FMA system deployment, provisioning, upgrade, and event monitoring and handling through automation, thus reducing MSO OpEx and in turn TCO. Figure 9 illustrates a procedure for FMA cloud operation automation. It represents an FMA cloud life cycle with AWS services as example.

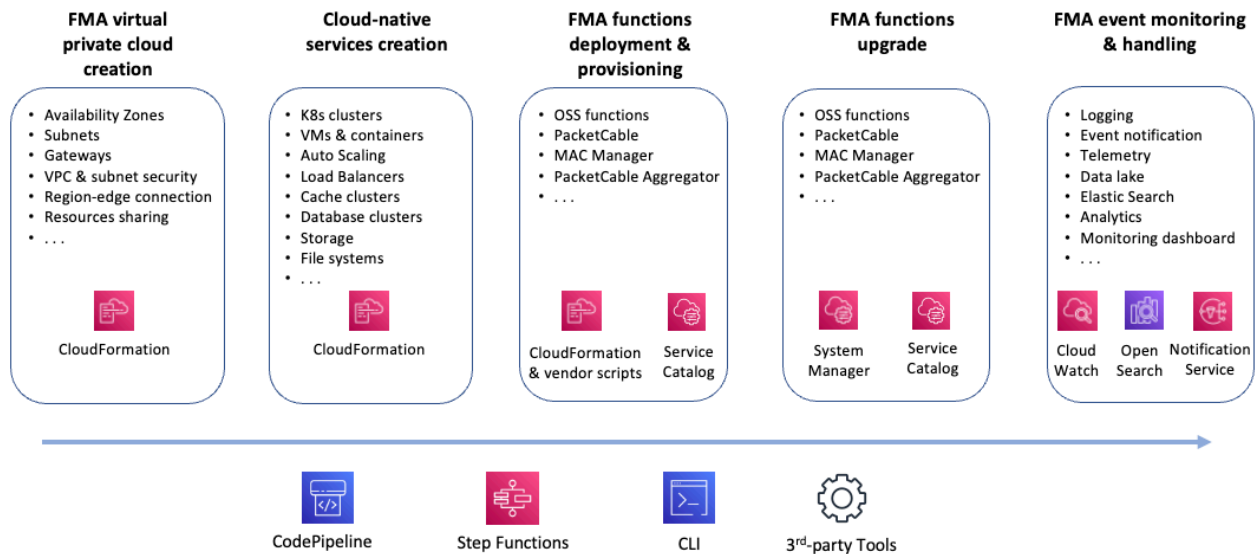

Figure 9 – FMA Cloud Operation Automation

- *FMA AWS VPC creation* – sets the network and security environment for the cloud continuum automatically by AWS CloudFormation templates.
- *AWS cloud-native services creation* – establishes AWS services used by the FMA cloud automatically by AWS CloudFormation templates.
- *FMA functions deployment and provisioning* – are performed in combination of AWS CloudFormation, container services, 3rd-party tools, or scripts with vendor container or VM images. AWS Service Catalog is used to manage products deployed in AWS.
- *FMA functions upgrade* – is part of product life cycle in the FMA cloud. Among different tools, AWS System Manager is a cloud-native service for product update. AWS Service Catalog is used to track the product upgrade.
- *FMA event monitoring & handling* – can be supported by AWS cloud-native services such as AWS CloudWatch, OpenSearch, Analytics, and Simple Notification Service (SNS). These services can implement or integrate some of FMA OSS functions.

The FMA cloud deployment, provision, and upgrade procedures can be driven by AWS CodePipeline and Step Functions with other 3rd-party operation automation tools.

The above content uses AWS cloud infrastructure and services as an FMA cloudification example. Similar solutions can be built with other cloud providers.

5. Cloud FMA use case exercise

The previous sections establish a cloud FMA reference architecture with solution building blocks and provide methods for FMA high availability and deployment automation in the cloud. This section demonstrates how an FMA function – Streaming Telemetry can be implemented across MAC-NE and CIN on premises and MAC Manager and Network Support Services (NSS). It uses AWS cloud infrastructure and services as an implementation example. Similar implementation can be built with other cloud providers.

The streaming telemetry is a PUSH-based mechanism to transport monitored network status data from network elements to external data collectors. Instead of the traditional data PULL model, FMA as well as CCAP utilize the PUSH model to stream data to backoffice applications in near real time^{[4][5]}. Figure 10 shows the MAC-NE dial-out streaming telemetry sequence diagram in the FMA OSS Interface Specification^[4].

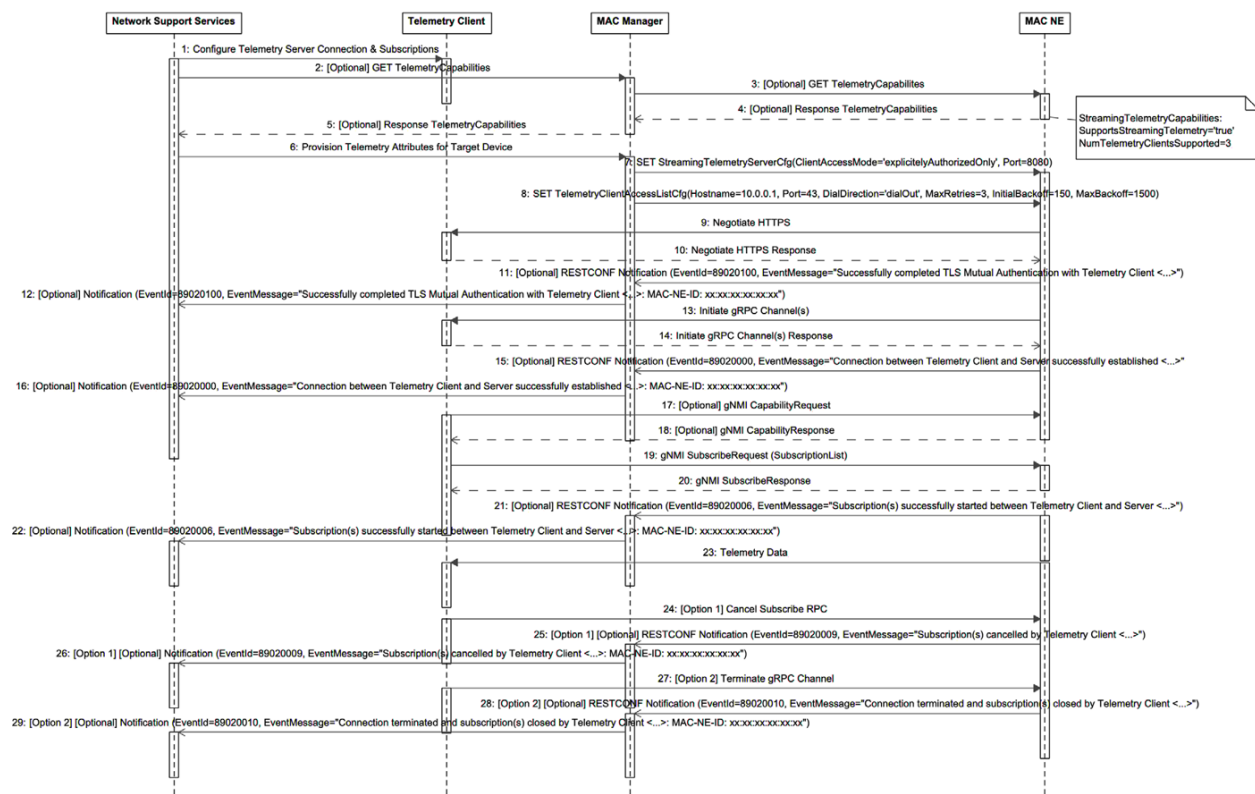

Figure 10 – MAC-NE Dial-out Streaming Telemetry Sequence Diagram^[4]

Figure 11 depicts the streaming telemetry cloudification with cloud-native services on AWS as an example. An AWS Region hosts a Cable operator's backoffice, where the NSS, MAC Manager, and Telemetry Clients are deployed in the FMA VPC subnets. These FMA components can run as VMs on Amazon Elastic Compute Cloud (EC2) or as containers on EC2 orchestrated by either Amazon Elastic Container Service (ECS) or Amazon Elastic Kubernetes Service (EKS). According to the dial-out streaming telemetry protocol, the components communicate with each other through the subnet traffic routing within the VPC. The telemetry

servers in MAC-NEs are connected to the telemetry clients and NSS in the backoffice in the cloud region via Amazon Direct Connect over AWS network backbone. AWS Site-to-Site VPN over Internet is a backup link for connection high availability. Note that the telemetry clients can be implemented at the cloud edge as well if preprocessing, filtering, or analysis of telemetry data should take place locally first.

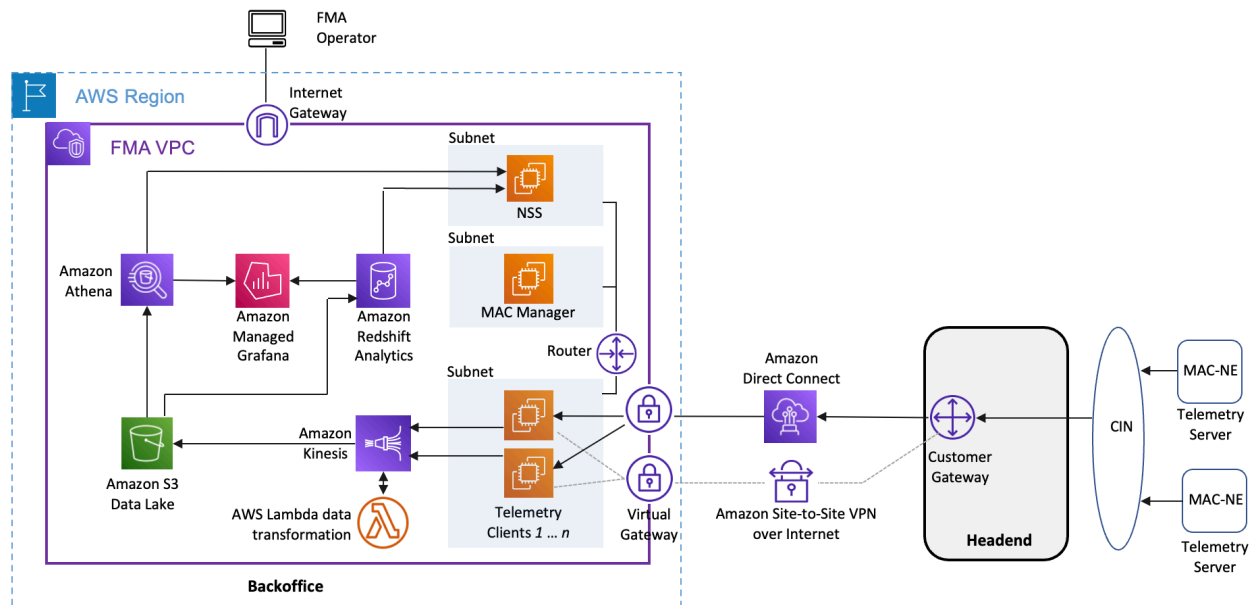

Figure 11 – Streaming Telemetry in Cloud FMA

In addition to the streaming telemetry implementation, the cloud provides several salient services for advanced OSS operations as illustrated in Figure 11.

- *Data lake* – is nowadays a common service provided by cloud service providers to store, process, and secure large amounts of structured and unstructured data. For example, AWS Simple Cloud Storage (S3) is a durable and scalable data storage to host a variety of OSS data for recording, troubleshooting, and predictive equipment maintenance. The telemetry clients further stream the received data to S3 using Amazon Kinesis Data Firehose service.
- *Analytics* – is used by advanced OSS operations for network event correlation, root cause analysis, and outage prevention. Many types of analytics services are provided by cloud service providers. As an example, Amazon Redshift is a fully-managed data warehouse service that can analyze petabytes of telemetry and other OSS data efficiently. Coupled with Amazon Machine Learning service, Amazon Redshift ML makes it easy for data analysts to create, train, and apply machine learning models.
- *Dashboard* – is an essential function of network observability. Grafana is a widely used open-source observability tool. For instance, with Amazon Managed Grafana in the cloud, cable operators can analyze and visualize telemetry and OSS metrics, logs, and traces and configure alerts for OSS event notifications. The Grafana service uses Amazon Athena as data source to access the telemetry and other OSS data stored in the data lake S3.

Note that there are other methods or cloud services for implementing the Streaming Telemetry function for cable operator's data networks, e.g., [6], which are not out of the scope of this paper.

6. Conclusions

The telecom industry has started its journey from network function virtualization to cloudification in order to lower the total cost of ownership, increase operation efficiency, leverage modern application services, and achieve business agility. FMA cloudification is the next undertaking by communication service providers and multi-access operators to further modernize the Distributed Access Architecture.

This paper shows that the FMA can be cloudified along the cloud continuum across the cloud region, edge, and far edge with FMA systems and functions allocated based on their timing characteristics and operation locality. At the same time, the FMA cloudification enables the operators to retain the flexibility of access network technology choices and operations.

It is shown through the cloud infrastructure and services that the private edge cloud is more suitable for cable operator's latency-sensitive FMA functions than other types of cloud edge technology. The virtual private cloud extends from a cloud region ("FMA regional datacenter") to a private cloud edge ("FMA headend"), simplifying FMA OSS operations. Traditional cable HA capabilities can be achieved by the cloud infrastructure and services, including network redundancy, multiple availability zones, load balancing across containers and virtual machines, and database, cache, storage, and file system redundancies. Cloud-native services can not only implement FMA functions but also bring them to modern OSS operations as illustrated through the streaming telemetry use case.

It is time to implement FMA in the cloud by applying the FMA cloudification approach and leveraging the cloud infrastructure and services.

1. Introduction

New global initiatives support the electrification of the planet, and the demands for power will continue to rise and stress the already-strained global electric power grid. Electric power directly affects costs for cable broadband, many industries and consumers, and is a root cause of soaring inflation. In response to increasing costs and power outages, federal and state legislatures and regulators, utilities, and energy managers are rapidly reorganizing energy mixes, focusing on the resiliency, sustainability and affordability of electricity generation, transmission, distribution, and storage.

Because utilities are increasingly dependent on the Internet to manage the delivery of electricity, cable broadband providers have a unique opportunity to provide innovative new services to the electric grid and commercial microgrids. These new services can save billions of dollars in fuels and other costs. In Texas, generation fuel savings of \$1 billion dollars a year are possible by time-shifting demand for electricity which would also extend the life and carrying capacity of the end-to-end, generation-to-load power grid.

As societies depend more on non-carbon-based electricity and less on fossil fuels, new broadband standards create valuable opportunities to reduce unnecessary power generation, delivery costs, and outages. Two new standards by American National Standards Institute (ANSI) and the Society of Cable Telecommunications Engineers (SCTE) could ensure seamless integration of broadband-enabled electricity services by all types of users across the globe thereby allowing for rapid, efficient, and effective adoption in transportation, buildings, industry, and agriculture.

The two new standards leverage the decades of investment in broadband networks to manage and monitor the grid and enable its transformation more efficiently. The ANSI/SCTE 267 *grid management* standard improves the efficiency and capacity of generation, transmission, distribution, and storage of electricity by orchestrating electricity demand relative to optimized supply. The ability to continuously manage demand at scale is needed to mitigate the increasing grid operational challenges of distributed energy resources such as fixed and mobile batteries and other flexible electric loads, especially as dispatchable thermal generation is retired and replaced with variable renewable energy. In addition, the ANSI/SCTE 271 *grid monitoring* standard provides a quantum leap in detecting, predicting, and proactively addressing conditions relevant to distribution grid faults, safety, reliability, congestion, and the hosting of renewables and electric vehicles.

Broadband providers may partner with utilities to distribute ANSI/SCTE 267 signals to electricity consumers to optimize electrical load on the grid and may deploy ANSI/SCTE 271 sensors throughout the outside plant to provide utilities with extremely fine-grained telemetry on grid performance. These control and measurement tools can profoundly influence the reliability and affordability of power used by both cable companies themselves and their customers.

2. Why Evolve The Grid

To understand cable broadband's role in services and standards, we first examine the evolving grid. A confluence of factors creates unprecedented challenges in grid operations and business models. One factor is the rising costs of electricity in global markets. For example, at the time of drafting this paper, the Northeast U.S. wholesale prices are forecast to exceed \$100 per megawatt hour (MWh) between June and August 2022, up from an average of about \$50/MWh last summer. Figure 1 shows forecast increases in wholesale electricity prices across the U.S. from the Summer of 2021 to 2022.¹

¹ U.S. Energy Information Agency, Short-Term Energy Outlook (6/16/22), *EIA expects significant increases in wholesale electricity prices this summer.* <https://www.eia.gov/todayinenergy/detail.php?id=52798>

Summer average wholesale electricity prices at selected price hubs (Jun–Aug, 2021–2022)
dollars per megawatt hour

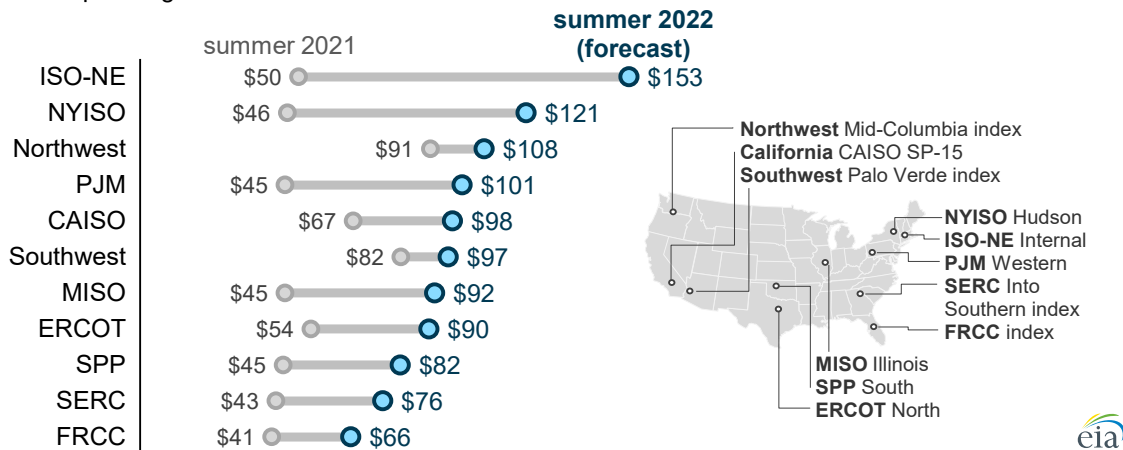

Figure 1 – U.S. Summer 2021-2022 Average Wholesale Electricity Prices.

While there are various reasons for rising wholesale electricity prices, the cost of generator fuel is a primary driver. Across the U.S., the price of natural gas delivered to electric generators is expected to average \$8.81/Million British thermal units (MMBtu) this summer, up 125% from \$3.93/MMBtu last summer.² Price increases in Europe and elsewhere are expected to be much higher.

In the past, when natural gas prices have risen, power providers with natural gas plants have substituted coal-fired generation. More recently however, many coal power plants are less likely to be used because of continued coal capacity retirements³ and lower-than-average stocks at coal plants.⁴ Other industry conditions that can contribute to higher wholesale electricity prices include fuel and water scarcities. For example, restricted contribution of hydropower this summer will likely lead the State of California to generate more electricity from natural gas and to import electricity from neighboring states.

Another factor creating unprecedented challenges in operating the grid is increased outages resulting from declining reliability of near end-of-life grid components, infrastructure frailty in severe storms, and lack of anticipated generation resources. Higher electricity demand coupled with potential supply reductions are raising concerns around the world. For example, the U.S. Midcontinent System Operator (MISO) has predicted outages this summer based on the anticipated shortfall of supply resources to meet normal and extreme demand shown in Figure 2.⁵

² Note the difference in abbreviating a million-watt hours (MWh) which is based on the International System of Units (SI) versus a million British thermal units (MMBtu) which is based on the Imperial System of Units.

³ U.S. Energy Information Agency, Short-Term Energy Outlook (1/1/22), *Coal will account for 85% of U.S. electric generating capacity retirements in 2022*. <https://www.eia.gov/todayinenergy/detail.php?id=50838>

⁴ U.S. Energy Information Agency, Short-Term Energy Outlook (12/7/21), *In September, the U.S. was at its lowest coal stockpiles since 1978*. <https://www.eia.gov/todayinenergy/detail.php?id=50558>

⁵ CleanTechnica (6/5/22), *Potential Electricity Reliability Concern for Central U.S.A.*, <https://cleantechnica.com/2022/06/05/potential-electricity-reliability-concern-for-central-u-s-a/>, U.S. Energy Information Agency, *Today in Energy* (6/3/22), <https://www.eia.gov/todayinenergy/detail.php?id=52618>, NERC (5/22), *2022 Summer Reliability Assessment*, https://www.nerc.com/pa/RAPA/ra/Reliability%20Assessments%20DL/NERC_SRA_2022.pdf, MISO (4/28/22), *MISO projects risk of insufficient firm generation resources to cover peak load in summer months*. <https://www.misoenergy.org/about/media-center/miso-projects-risk-of-insufficient-firm-generation-resources-to-cover-peak-load-in-summer-months/>

Midcontinent Independent System Operator (MISO) summer reliability projections (2022)
gigawatts (GW)

Figure 2 – MISO summer 2022 Reliability Projections.

To ensure reliability, MISO and other “balancing authorities” plan to always have more supply available than demand. As shown in Figure 2, in MISO’s summer 2022 reliability projections, of the 143.2 GW of anticipated resources (at left), a reduced capacity of only 114.9 GW of generation may be available to meet between 118.2 GW and 125.2 GW of demand (at right). A shortfall will result in rotating blackout outages, most likely during a heat wave, which will likely cause loss of life and property. To anticipate electricity demand, balancing authorities produce a range of forecasts for average demand and extreme environmental conditions that used to occur only once in 10, 50, or 100 years, but are occurring more frequently. Planned and unplanned maintenance (aka forced outages) of power plants reduces available capacity as does derating generation capacity for factors such as drought, low-wind conditions, or fuel supply limitations .

Yet another factor creating unprecedented challenges in operating the grid are low and declining end-to-end, generation to load efficiencies. Efficiencies are so low that most of the fuel energy used in generating electricity, propelling transportation, and powering buildings and industry is rejected as waste heat as shown in Figure 3.⁶

⁶ Lawrence Livermore National Laboratory (6/16/22), *Energy, Water, and Carbon Informatics*, https://flowcharts.llnl.gov/sites/flowcharts/files/2022-04/Energy_2021_United-States_0.png

Figure 3 – 2021 Estimated U.S. Energy Consumption.

Figure 3 depicts the sources of energy (at left), how they are used, and how much is rejected (at right). Line widths are proportional to quantities of energy flows and all numbers can be roughly interpreted as a percent of total U.S. energy in each flow or sub flow. Complex interrelationships are depicted, such as the fine orange line (at lower right) denoting 0.02% of all energy consumed in the U.S. was used to charge electric vehicles.

In Figure 3, the most important takeaways are the costly inefficiencies (in light gray) that result in unnecessarily rejected energy as waste heat and greenhouse gases from: 1) electricity generation, where almost 2/3 of energy is rejected, 2) transportation, where almost 4/5 of energy is rejected, and 3) industry, where more than 1/2 of energy is rejected. Comparing the totals in light and dark gray at right, the U.S. (like most other developed nations) wastes about 2/3 of all energy used, primarily due to poor inefficiencies in electricity generation and transportation.

An alarming result of not significantly improving energy efficiencies over the last several decades is the emission of carbon continues to be colossal and will not be reduced until we have non-carbon-based electrons propelling transportation and replacing direct fossil fuel use (e.g., propane, heating oil, gasoline) in other applications.

Despite renewables and natural gas being added to the electricity generation mix and the retiring of coal powerplants, U.S. energy-related CO₂ emissions from all energy uses (electricity generation, transportation, and buildings) has not declined below 1975 levels as shown in Figure 4.⁷

⁷ U.S. Energy Information Agency, Today in Energy (5/13/22), *U.S. energy-related CO₂ emissions rose 6% in 2021*. <https://www.eia.gov/todayinenergy/detail.php?id=52380>

Figure 4 – U.S. Energy-related CO₂ Emissions.

In the U.S., the transportation and electric power sectors are the greatest contributors to energy-related CO₂ emissions, each responsible for roughly 1/3 of all greenhouse gas (GHG) emissions. In 2021, transportation emissions rose due to increased petroleum consumption as COVID-19-related restrictions eased. Likewise, electric power sector emissions rose due to increased electricity generation and the use of higher carbon intensity coal-based generation. In the U.S., electric power sector emissions from coal increased for the first time since 2014 (a global trend that is expected to continue for several years given natural gas supply constraints).

Exacerbating all the issues depicted in Figures 1-4 are declining energy efficiencies due to increases in extreme temperatures. On the supply side, as outdoor temperature rises, power plants, transformers, and powerlines become less efficient at moving electrons and rejecting heat. To make matters worse, on the demand side, air conditioners, the largest component of summer demand, also become less efficient as outdoor temperatures rise, causing air conditioners (AC) use more energy to keep buildings cool. This creates a death spiral: The hotter it gets, the more societies suffer by unsustainably declining efficiency, as more and more cooling energy is needed from less and less efficient power plants which are unable to meet demands for electricity. Thankfully, legislatures, regulators and grid operators are making efforts to deploy renewables and storage at utility-scale, community-scale, and premises-scale to help address spikes on the hot days due to AC loads and on cold days due to heating loads.⁸

3. Sustainability Financials

Inefficiencies undermine the sustainability of current grid operations and many other energy uses and business models, especially given the rising costs of energy. In 2019, U.S energy expenditures, the amount of money spent by consumers to purchase energy, was \$1.2 trillion.⁹ Considering more than just electricity, a disaggregation of energy expenses for all types of energy used over the last 50 years is shown in Figure 5.

⁸ Julie McNamara (7/9/2019), *How do power grids beat the summer heat*, The Equation, Union of Concerned Scientists, <https://blog.ucsusa.org/julie-mcnamara/how-do-power-grids-beat-the-summer-heat>

⁹ U.S. Energy Information Agency, Today in Energy (9/9/21), *In 2019, U.S. inflation-adjusted energy expenditures fell 5%*. <https://www.eia.gov/todayinenergy/detail.php?id=49476>

U.S. energy expenditures by source (1970–2019)
trillion real 2019 U.S. dollars

Figure 5 – U.S. Annual Energy Expenditures.

Referencing Figure 5, it is important to consider two significant yet uncharted imminent changes in trajectories: 1) cost increases attributable to the 2022 war in Ukraine have already doubled and could triple the costs of energy, and 2) the process of so-called beneficial electrification, e.g., the introduction of electric vehicles, will double or triple societies' consumption of electricity while decreasing the uses of petroleum, natural gas and coal over coming decades.¹⁰ The product of tripling electricity costs and tripling electricity consumption could yield a near 10x increase in residential, commercial, industrial and agricultural electricity bills, and could be unsustainable in terms of costs and GHG emissions.

4. Architectural History of Cable Networks and the Grid

Today's transformative path of the electric grid is similar to that of the historical evolution of the cable broadband network. Cable networks initially used centralized headends, proprietary systems, and one-way delivery of content. Over time, two-way upgrades and distributed headends and hubs enabled the development and deployment of new services, including telephony and high-speed data. As two-way services became highly penetrated and successful, the threat of network congestion and slowdowns gave rise to traffic engineering and the development of the massively scalable world-standard cable modem.¹¹ Tools to detect and mitigate network congestion were needed, were developed quickly, and continue to evolve.

¹⁰ Beneficial electrification (aka clean electrification, strategic electrification) is a term for replacing direct fossil fuel use (e.g., propane, heating oil, gasoline) with electricity in a way that reduces overall emissions and energy costs. There are many opportunities across the residential and commercial sectors. This can include switching to an electric vehicle or an electric heating system – but only if the end-user and the environment both benefit. Environmental and Energy Studies Institute (Jun 2022), *Beneficial Electrification, An Access Clean Energy Savings Program*. [https://www.eesi.org/electrification/be#:~:text=Beneficial%20electrification%20\(or%20strategic%20electrification,t he%20residential%20and%20commercial%20sectors](https://www.eesi.org/electrification/be#:~:text=Beneficial%20electrification%20(or%20strategic%20electrification,t he%20residential%20and%20commercial%20sectors) .

¹¹ Cable Television Laboratories, Inc. (CableLabs) led the effort to develop the world standard cable modem and certify interoperability. Consumers continue to benefit in the global telecommunications marketplace where vendors compete on price, functionality, and delivery schedules. An example of a powerful standard, interoperable cable modems are a thousand times faster than the proprietary cable modems they replaced and million times faster than dial-up modems.

As depicted in Figure 6, Many striking similarities arise when comparing the challenges of developing and deploying global broadband networks to the existing and anticipated challenges of developing standards-based scalable interoperable smart power grids.

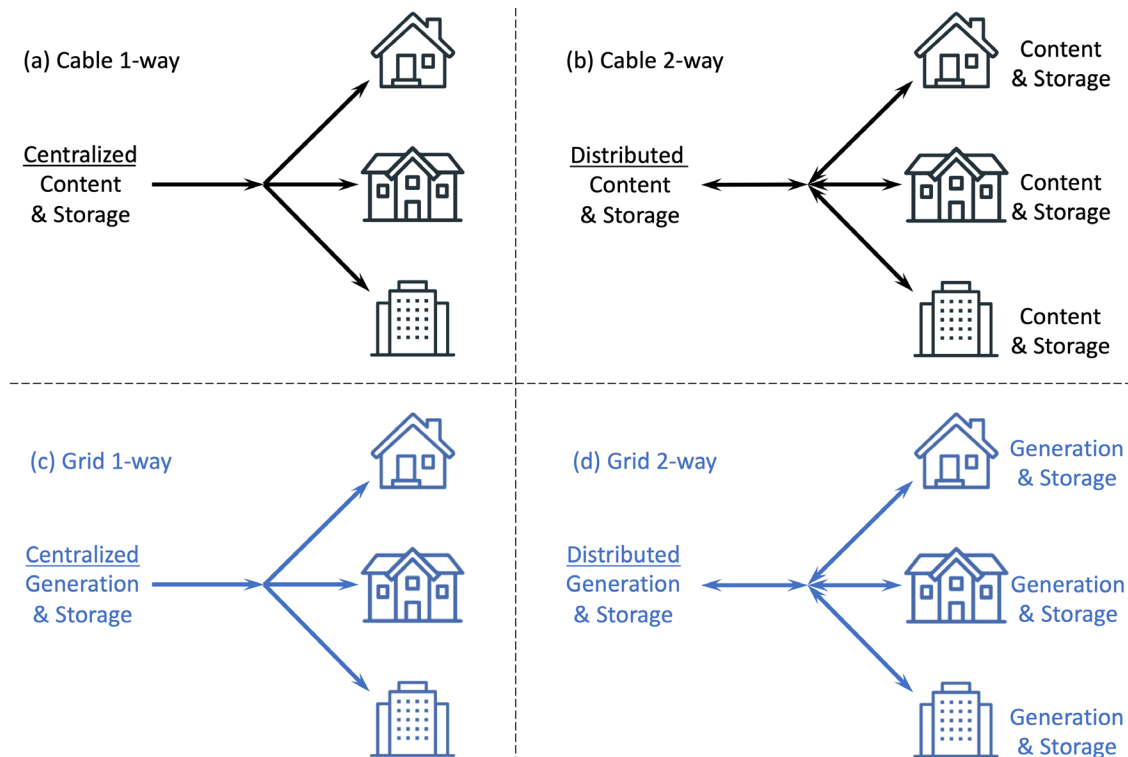

Figure 6 – Similarities in 1-way to 2-way upgrades of Cable and the Grid.

The top row of Figure 6 depicts (in black) the evolution of the cable distribution network from (a) 1-way to (b) 2-way. The bottom row depicts (in blue) a similar transition for the grid from (c) to (d). Cable's experience in transitioning to 2-way, identifying and managing congestion, can be helpful to the grid.

In the grid, the traditional model of central station generation is increasingly augmented by distributed energy resources (DERs) such as wind power, solar power, and other renewable energy technologies. DERs encompass more than electrical generators and include internet-connected batteries and electric loads that are smart in meeting user demands while time-shifting usage to operate now or later to reduce stress on the grid. DERs can choose to operate now, if there is abundant clean energy and no grid congestion issues or can operate later if there will be a more significant benefit to the grid. Some DERs, such as increasingly popular solar plus storage, create two-way flows of electrons that are managed by modulating (aka time-shifting or shaping) demands for electricity.

The process of influencing the timing of when electricity is delivered to the grid by DERs – or consumed from the grid by flexible loads such as batteries – is generally called Demand Side Management (DSM). DSM is facilitated by load shaping information provided by a power supplier in the form of a Demand Response (DR) signal.

Like in the early days of broadband, today's grid is operated with a mix of standards-based and proprietary solutions. Well-established standards include lamp sockets, wall plugs, voltages, and frequencies. Newer standards include managing DER behaviors in specific applications, such as solar

inverters, vehicle chargers and building controls.¹² The most significant challenges with DERs are orchestrating and aggregating their behavior to 1) maximize the resiliency, sustainability, and affordability of the grid, and 2) detect and mitigate congested electron flows that create heat, that shortens the lifespan of grid components and impacts outages and possible loss of property, life, or both.

5. The Symbiotic Future

As consumer-based generation “prosumer” trends increase, community-augmented electricity systems will likely become commonplace for providing resilient, sustainable, and affordable energy mixes. Community-level DER management will benefit from applying standards that rapidly modernize grid technologies to create efficient energy management orchestration synergies.

Modern telecommunications and broadband internet services work smoothly because each industry has adopted open, non-proprietary interoperability standards. Likewise, looking ahead for the next 10-20 years, the grid will perform more smoothly by favoring standards-based DSM solutions over propriety DSM solutions wherever possible. Demand response (DR) programs look to incentivize customers with the ability to inject power, add or shed load at a predictive time to reduce strains on the power grid. Demand response is a grid balancing option with limited deployment and represents untapped potential that has been modeled but not proven at scale. With a total available market of billions of DR devices in the U.S., and only 10 – 15 million deployed over the last 30-40 years, there is tremendous upside for global deployments of standards-based DERs to provide DR. To that end, the broadband industry has work to do in educating utilities, legislators, regulators, and power industry vendors about new scalable standards that accelerate the development of a sustainable and resilient smart grid.

Standards for *managing* demand and *monitoring* the power grid can be used to provide traffic engineering solutions that work remarkably well. Standards-based networked DERs can speed the deployment of renewables, batteries, and smart loads, guiding them to work in unison to shape load to raise the efficiency of the end-to-end generation, transmission, and distribution (G&T&D) infrastructure. By responding to changes in forecast daily grid needs and contingencies such as failures in G&T&D, networked DERs can manage load continuously to avoid costly peak generation and to move as many electrons as possible off-peak through would-be congested areas.

Combining grid monitoring sensor data with easy access to smart meter electricity interval usage data for consumers and authorized third parties will ensure that customer responses to DR signals are recognized and compensated. Compensation will be issued for DERs such as EVs, residential, commercial, industrial, and agricultural uses that follow load shaping signals. Load shaping will be based on forecasts of load and demand as well as observations from broadband-based sensors that monitor and quantify the impact of power anomalies on the grid. Anomalies are measured in terms of power quality issues such as oscillations and spikes in voltages, sustained over/under voltages, overloaded/overheated grid components, and other distribution system behaviors, faults, and their associated risks.

¹² Much work has gone into developing interconnection and interoperability standards that define how to assemble, configure, and connect devices to form a smart modern grid. Nonetheless, a major challenge with standards to date is that they are limited to development within specific technology domains, such as vehicle charging or air conditioning. As such, existing standards lack a complete vision for how distributed energy resources need to interact with G&T&D to deliver resilient and sustainable end-to-end grid services. While some standards are mature, technically robust, and meet the needs within a specific domain, in aggregate, they do not support optimum load shaping. The need for the ANSI/SCTE load shaping standard became apparent when assisting in the review of the U.S. Department of Energy, Grid Modernization Laboratory Consortium (Mar 2021), *Survey of Distributed Energy Resource Interconnection and Interoperability Standards*, <https://www.nrel.gov/docs/fy21osti/77497.pdf>

Combined analyses of customer meter data and grid sensor data will provide complementary insight into DER operations and their impact on the grid. In the near term, sensing and analysis will improve grid situational awareness and help determine and inventory the types, sizes, and locations of DERs operating on the grid today. Furthermore, sensing and analysis will identify normal and anomalous grid and DER operating states and behaviors. In the long term, sensing and analysis will be critical for asset and load capability forecasting. Having this more significant insight into grid operating states will ultimately enhance the availability and reliability of the broadband network.

6. What Broadband Offers The Grid

In 2021 the Society of Cable Telecommunications Engineers (SCTE) completed two synergistic American National Standards designed to reduce grid failures, contain electricity costs, and monetize demand response. The standards specify improved grid sensors and orchestration of electric loads via a simple information model. Separately and together, the standards improve electricity G&T&D, storage, and end-use while accelerating the adoption of electric vehicles (EVs) and resilient local power using batteries and other networked distributed energy resources.

6.1. ANSI/SCTE 267 Optimum Load Shaping for Electric Vehicle and Battery Charging

The SCTE 267 standard specifies end-to-end control of the electric power grid and commercial microgrids from generation to load, using one-way broadcast and two-way interactive signals. The standard defines how to create, transmit, and act upon a forecast optimum load shape (OLS) to manage the charging of EVs and facility batteries, as well as demands for electricity from flexible and discretionary smart electric loads.

An OLS provides grid control with a set of numbers, such as the target load for hours 1-24. The numbers in an OLS can, for example, forecast the cleanest, most efficient, and least cost electrical supply, so that all stakeholders: G&T&D entities, retail electricity providers, and consumers benefit.

Several topics are addressed in SCTE 267: 1) A generation-to-load OLS architecture is specified. 2) Based on inputs of forecast load and forecast generation from renewables, a method for producing a location-specific OLS is specified. 3) A method for managing the charging of electric vehicles is specified as an example of how any smart load can autonomously interpret and take local actions based on an OLS.

The OLS standard was created because existing siloed standards do not provide sufficient control to benefit the different needs of G&T&D. With OLS, stakeholders, including broadband providers, can reduce their electricity costs and carbon emissions by having their smart loads follow the lowest cost forms of supply. If not implemented, broadband providers will have less control over the rising cost of electric power.

Short-term benefits include creating and distributing both near and far-reaching OLS signals quickly and easily that allow intelligent devices that implement the standard to participate by shaping load. Benefits accrue in the short and long-term as more smart devices implement the standard resulting in more significant benefits for most stakeholders in the electricity value chain. The potential impact on the broadband industry is a reducing energy procurement costs and creating new revenue generating units based on managing the charging of cable customers' vehicles and batteries and flexible uses of electricity.

An OLS signal is created, transmitted, and acted upon, as shown in Figure 7. For example, an OLS Producer (typically an entity associated with an electricity supply or control system) ingests forecasts of

load, renewable generation, and costs. The Producer then uses 1-way and 2-way networks to distribute OLS signals to OLS Consumers (devices that manage the consumption of electricity).

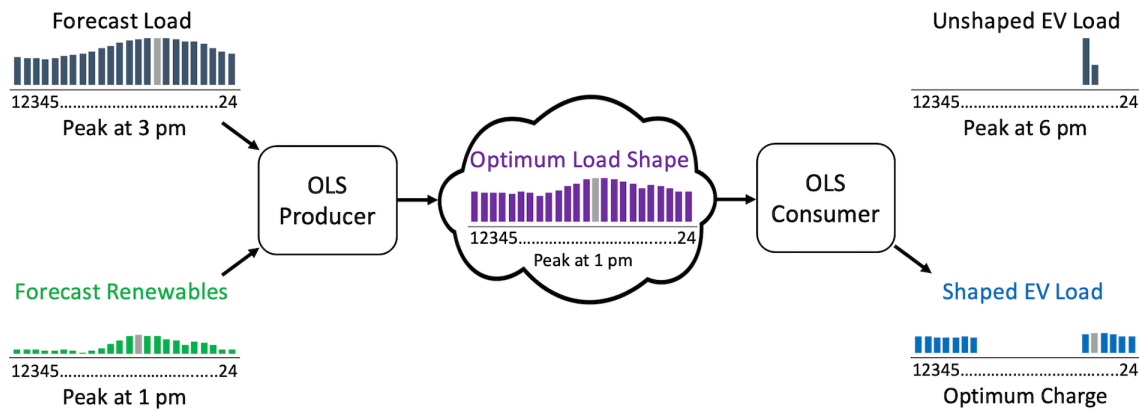

Figure 7 – Optimum load shaping system.¹³

An OLS Producer may employ various techniques to create an OLS signal. An algorithm may minimize costs and optimize the utilization of renewable generation. As depicted in Figure 7, the OLS Producer (at left) is a processor that obtains time-series signals such as load and renewable generation forecasts. The OLS Producer may: 1) subtract the forecast renewable generation from the forecast load to produce a net generation¹⁴ shape, 2) flatten net generation to maximize the efficiency of the mix of thermal generators, and 3) add the forecast renewable generation and the flattened net generation together to create the OLS signal. These steps and the resulting actions of OLS Consumers are described in detail in the SCTE 267 easy-read standard.

A single entity may be a Producer and a Consumer, for example, an entity that consumes an OLS signal from an upstream Producer such as a utility may produce localized OLS signals and share them with several downstream consumers. Continuing the example, a building energy controller may consume an OLS signal from a utility and send a modified OLS signal to water heaters, thermostats, and vehicle chargers to coordinate time-shifting of demand among appliances to reduce energy costs and optimize the performance of a home or business.

The ANSI/SCTE 267 standard makes possible the shaping of load across small and large geographic areas. For example, Figure 8 is based on the simulation of the serving of the Electric Reliability Council of Texas (ERCOT) and shows the hourly generation based on actual load (at top) and daily optimum load (at bottom) on 20–26 Aug 2005.¹⁵

¹³ Source: Society of Cable Telecommunications Energy (2021), *ANSI/SCTE 267: Optimum Load Shaping for Electric Vehicle and Battery Charging*, <https://www.scte.org/standards/library/catalog/>

¹⁴ In this context, net generation refers to the generation required from thermal power plants to meet demand for electricity after accounting for the contribution of renewables.

¹⁵ The primary author's generation-to-load simulation estimated the impact, in terms of production costs and CO2 emissions, attributable to the joint optimization of electric power generation and flexible end uses to support increasing penetrations of renewable energy. Newly conceived, evaluated, and foundational in developing the ANSI/SCTE 267 American National Standard was a transaction-less, yet continuous demand response system based on a day-ahead optimum load shape (OLS) designed to encourage Internet-connected devices to autonomously and voluntarily explore options to favor lowest cost generators – without requiring two-way communications, personally identifiable information, or customer opt-in. Boundary conditions used for model calibration included historical

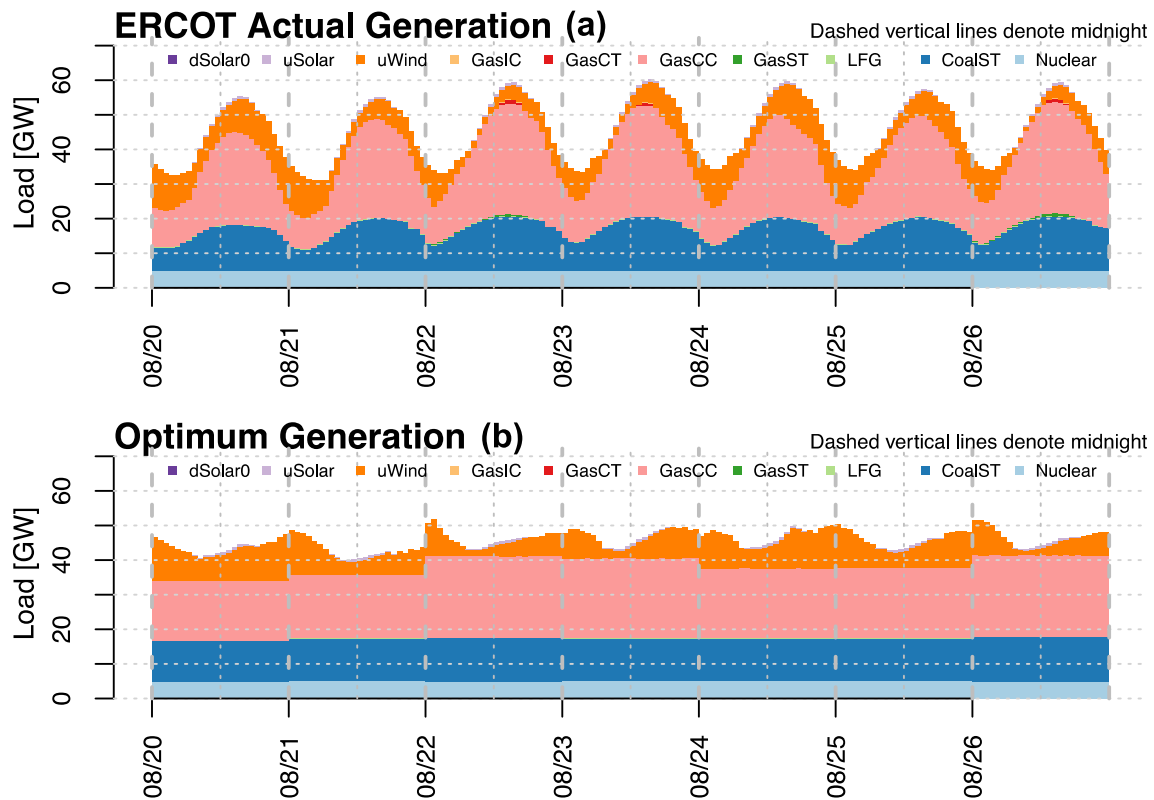

Figure 8 – ERCOT Hourly Generation Based on Actual and Daily Optimum Load.¹⁶

In Figure 8, production cost and CO₂ emissions were calculated for the unshaped actual historical hourly load (at top), and for the same load had it been optimally shaped over seven days. As expected, the minimum production cost was achieved when power plant output was constant, depicted as flat lines for thermal generation, as shown for each hour of 20–26 Aug 2005 as shown at the bottom of Figure 8. The week of 20–26 August is of interest as: (a) it was the hottest week of 2005 with over a TWh of energy delivered each day, and (b) many of the 600+ thermal generation power plants in Texas were active and could benefit from higher efficiencies that would result from higher capacity factors.¹⁷

The primary author's research, funded by the U.S. Department of Energy and conducted in-residence at National Renewable Energy Laboratory (NREL), shows that fixed and mobile batteries are the most

weather, residential building stock construction attributes, home appliance and device empirical operating schedules, prototypical power distribution feeder models, thermal generator heat rates, startup and ramping constraints, and fuel costs. Results of an hourly-based annual case study of Texas indicate a 1/3 reduction in production costs and a 1/5 reduction in CO₂ emissions are possible.

¹⁶ Robert Cruickshank, Ph.D. thesis, University of Colorado Boulder (Sep 2019), *Estimating the value of jointly optimized electric power generation and residential electrical use*.

https://scholar.colorado.edu/concern/graduate_thesis_or_dissertations/x059c851q

¹⁷ In generation, capacity factor is defined as the amount of energy actually produced divided by the maximum amount of energy that could have been produced at full output power. In transmission and distribution, capacity factor is defined as the actual amount of energy moved divided by the maximum amount of energy that could have been moved.

critical DERs to be networked first.¹⁸ The trend of increasing electric vehicle and in-building batteries is an opportunity to be addressed. To that end, e-Radio USA manufactures an SCTE 267-compatible EV charging adapter with various connectors that ensure backward and forward compatibility with all types of EVs as shown in Figure 9. Any kind of electric vehicle can plug into the EV Charging Adapter, which plugs into any EV charger. The adapter's green light indicator illuminates when the EV Adapter is receiving an authenticated FM, satellite, LTE or Wi-Fi signal and is working correctly. The EV charging adapter optimizes charging in response to grid signals, ensuring that wind, solar, and low-cost energy sources are maximized – and can be configure-less when used in broadcast applications. The vehicle owner can use the vehicle's standard control system to override the OLS signal if necessary to assure immediate charging.

Figure 9 – Electric Vehicle Charging Adapter.¹⁹

There are evolving accessibility and information security concerns to be considered and addressed to protect consumer privacy and grid security. To that end, the broadcast one-way delivery method for OLS signals may use multi-network authentication; thus, DERs do not add or shed load until each autonomously confirms the identical OLS signal is being received by multiple sources and/or networks. For example, a DER such as an EV charging adapter would verify that the same guidance signal is being received via FM radio, satellite, and/or the Internet. In all cases, the security of DERs, the data collected, security of software, and algorithm development processes must be addressed.

As part of DER participation, the bulk power system will benefit from a three-level battery hierarchy that manages the flow of electrons within and across transmission, distribution, and consumer networks. Transmission-scale and distribution-scale batteries provide increased system resiliency and pay for themselves with resiliency and with revenues from capacity, energy, and frequency response. While utilities and energy market participants are likely to directly control batteries located in transmission and distribution (T&D) networks, most batteries will be premises-based, consumer-owned, and can be voluntarily controlled by SCTE 267 OLS signals to the benefit of all three G&T&D realms.

¹⁸ Robert Cruickshank, Gregor Henze, Anthony Florita, Charles Corbin & Killian Stone (2021), *Estimating the value of jointly optimized electric power generation and end use: a study of ISO-scale load shaping applied to the residential building stock*, Journal of Building Performance Simulation, DOI: 10.1080/19401493.2021.1998222

¹⁹ Power Networks, LLC, Submission to Public Utility Commission of Texas (Jun 2022). Image courtesy of e-Radio and Xperi <https://drive.google.com/file/d/1CStDFzorzrME8Czf49TqVMsHj7fyu0SZ/view?usp=sharing>

SCTE 267 OLS signals are widely usable due to their ability to guide battery charge and discharge. OLS signals can guide a mobile or fixed battery to modulate charge/discharge over time. Figure 10 depicts battery charging and discharging wherein the charger voluntarily and autonomously uses the OLS signal (in blue) to inform charging and discharging profiles (in orange); a sinusoidal OLS signal illustrates the concept.

Figure 10 – Hourly Optimum: 1) Load Shape, 2) Charge/Discharge Shape.²⁰

In Figure 10, a battery charge controller receives an OLS signal (in blue) and then autonomously draws a horizontal line that divides the signal into charging and discharging intervals (in orange). The timing of charging/discharging is modified daily and hourly based on the forecasted availability of wind and solar power, actual grid contingencies, power system and user needs. When severe weather is expected, batteries can choose to enter “storm mode” and charge up to fully prepare for a potential grid outage.

Congestion detection and mitigation are increasingly crucial as beneficial electrification results in distribution networks connecting to more loads, particularly more numerous and higher capacity EV chargers. Once congestion is detected by location-aware DERs, it can be mitigated using a “local” OLS signal to raise the carrying capacity and extend the lifespan of a distribution network, as shown in Figure 11.

²⁰ Robert Cruickshank Associates (Dec 2021), Presentation to SCTE Microgrid working Group.

Figure 11 – A “Local” Load Shape to Mitigate Grid Congestion.²¹

Local load shaping is something broadband providers can be very good at and accomplish very quickly. Per SCTE 267, some DERs, like EVs, can choose to share their latitude and longitude when checking for load shapes. In Figure 11, mitigation of congestion (segments and locations shown in red at left) is achieved by modulating loads to utilize fully, but not overload, a distribution circuit using a local load shape for loads downstream of T&D congestion points. In the center of Figure 11, the flat purple shape guides DERs to adjust their load to raise the capacity factors of congested T&D network segments.

SCTE 267 and 271 were designed to work separately and together. For example, voltage sags sensed by an SCTE 271 sensor can indicate congested segments – which can deliver more energy when SCTE 267 local load shapes guide DERs to favor off peak electricity usage.

6.2. ANSI/SCTE 271 Power Sensing in Cable and Utility Networks

The SCTE 271 standard specifies provides precision, sampling rate, and configuration requirements if vendors measure and report voltage and current in hardware and software to enable advanced power sensing in cable and utility networks. Included are requirements for sensing and communicating power quality observations from both the 60/75/90 VAC quasi-square wave HFC network and the 120/240 VAC supply from the electric power grid. For systems that support remote communication of measurements, requirements for the control plane and communications security are specified. The specification does not require any particular measurements. Still, if supply voltage and current are measured, it specifies how those measurements are made to benefit the grid and broadband network operations.

The development of the SCTE 271 sensing standard was motivated by successes in the U.S. Department of Energy (DOE) Situational Awareness of Grid Anomalies (SAGA) project underway at the NREL and CableLabs since October 2019. Early in the SAGA project and while developing the Gridmetrics[®] Power Event Notification System (PENS), the NREL and CableLabs team recognized that the existing sensing capabilities specified in the ANSI/SCTE 25-3 standard were 1) out of date, and 2) could be updated to enrich grid and broadband Proactive Network Maintenance by finding congestion and loose seizure screws, high-impedance faults, and other voltage and current glitches and anomalies that could lead to grid and HFC service outages.

²¹ Source: R Cruickshank, A Silverstein, A von Meier (Jun 2022), The Society for Standards Professionals, Standards Engineering Journal, *Broadband standards to manage and monitor the grid*. <https://www.ses-standards.org>

For grid providers, a timeless and ever-important question is, “How many EVs and batteries can a distribution segment or transformer support before there is an increased risk of congestion and premature equipment failures and outages due to a thermal overload? For example, what would happen if many consumers in a community traded in their internal combustion engine vehicle for an EV? Would the community be unable to charge the new load profile with today’s “plug it in and take it” model? Furthermore, how could signaling and sensing comfortably help answer that question with a resounding YES? Both of the SCTE standards address these needs.

Today, congestion visibility in sensor-starved distribution networks can be achieved by deploying power quality sensors, such as SCTE 271-based sensors. Once detected, congestion can be mitigated using local OLS signals to avoid slowdowns/failures on the grid.

Many forms of grid measurement work together to ensure a resilient and sustainable power grid. As shown in Figure 12, Advanced Metering Infrastructure (AMI) provides kW demand and kWh consumption at customer meters, typically reported at 15-min resolution. Supervisory Control and Data Acquisition (SCADA) provides voltage or current magnitudes, reported at a resolution on the order of several seconds. Phasor Measurement Units (PMUs) provide voltage or current magnitudes and phase angles, frequency, and derivative quantities reported roughly every cycle (25-120 Hz). Point-on-Wave (POW) sensors, provide voltage or current magnitudes and phase angles, frequency and derivative quantities, and 256 to 1 million samples/sec of voltage or current waveform, reported for a short duration or on a continuous monitoring basis. SCTE 271-compliant sensors implement POW functionality to provide unprecedented visibility to grid issues.

Figure 12 – Time Scales for Electric Grid Monitoring and Control.²²

Referencing Figure 12, POW sensors provide the finest temporal resolution of power quality information to communications providers, utilities, and others. POW sensors stream data in real-time, enabling the rate of change of frequency and sine-wave goodness-of-fit to be calculated remotely from the measuring network element. This approach is favored by utility engineers and operations staff as it is robust in situations with high electrical noise and distortion, where traditional assumptions about sinusoidal waveforms are not met.

A key feature of SCTE271-compliant sensors is their ability to stream uncensored waveforms for cloud-based analysis aided by operations experts and machine learning. Utility engineers are reacting positively

²² International Council on Large Electric Systems (CIGRE) Webinar Academy, Alexandra von Meier (Oct 2020), *AI on the grid: Understanding PMU data*. <https://www.youtube.com/watch?v=qRAPYVtC2zM> and <https://iclesunc.memberclicks.net/assets/AI%20on%20the%20Grid%20%28Day%201%29.pdf>

to the availability of POW streaming waveforms that aid in detecting vegetation strikes and other grid failure signatures. By using human-in-the-loop machine learning, failure signatures can be rewound in time to improve early detection of grid and broadband network physical layer issues and provide a quantum leap beyond current best practices for identifying and predicting network issues.

SCTE271-compliant sensors do not over compress or distort data before backhauling to the cloud. With voltage and current precision of 0.02% per unit and sampling rates of 10,000 samples per second, SCTE-217 sensors preserve anomalies such as the voltage spike depicted in top panel of Figure 13.

Figure 13 – Analog Waveform, Utility Capture and Broadband Capture.²³

Figure 13 shows an actual analog wave form (at top), a phasor approximation commonly used in utility best practices (in middle), and a SCTE 271-based POW capture (at bottom). Note the glitch in the actual waveform is not observed by utility best practices that assume the underlying alternating current signal is a perfect sine wave –but is accurately observed by POW measurement.

7. Conclusion and Next Steps

Around the world, the aging and frail bulk power grid is weakened by a confluence of factors that include inefficiencies, fuel scarcities, unbridled demand, and increasingly severe and unpredictable weather.

²³ North American Synchrophasor Initiative (3/20/2020), Technical Report: High-Resolution, Time- Synchronized Grid Monitoring Devices, Alison Silverstein, Alison Silverstein Consulting, Dr. Jim Follum, PNNL

Temperature extremes add enormous demand while lowering the efficiency of generation, transmission, distribution, and end use. Costs are skyrocketing, and the impacts of outages are more cataclysmic due to our growing dependency on old and new electrically powered technologies. Moreover, there is a lack of consumer adoption of energy efficiency and automation.

The cable broadband industry has enormous opportunities to monetize critically essential capabilities for the evolving grid. New SCTE standards for managing and monitoring the grid enable relatively rapid transformational opportunities that improve resiliency and sustainability on a global scale. The power and broadband industries should build out SCTE 267 and 271 grid infrastructure to maintain business continuity, contain energy costs, and create new business opportunities.

Rising financial and environmental costs can be thoughtfully contained. New operations and business models can provide additional revenues from delivering load shaping signals and grid sensing as a service. Cable's established and evolving playbook in traffic engineering informs the roadmap for modernizing the grid. A symbiotic future of the grid and broadband networks is possible and beneficial.

Likely outcomes point the way for collaboration, such as: 1) renewables will continue to be added to the generation mix, 2) the retirement of dispatchable thermal generation and the rise of renewables will create a growing void in controls that balance electricity supply and demand., and 3) balancing supply and demand on the grid will be managed and monitored across multiple timescales. As opportunities continue to mature, the SCTE 267 standard should be pro-actively updated to support load shaping in seconds and minutes to complement the hourly and daily timescales already implemented.

1. Introduction

The goal of this project is to utilize artificial intelligence (AI) and machine learning (ML) techniques to gain insights into the drivers of support calls. These insights are used to determine areas of improvements to both processes and products to enhance our customer experience.

In this paper, we discuss the end-to-end automated pipeline to go from call center data to actionable insights utilizing machine learning techniques such as Automatic Speech Recognition (ASR) and Natural Language Processing (NLP). Discussion of the pipeline architecture, use cases of automated call disposition, and call topic trend analysis are also included. Broadly, the pipeline converts recorded call audio conversations to text transcripts using automatic speech recognition, then uses those transcripts to train classification models to predict call disposition. Unsupervised topic modeling extracts new trends and topics from the call-volume data over time to identify new or emerging call drivers. These call drivers subsequently drive new feature development and product roadmaps.

Please note: Charter has a longstanding commitment to protecting the privacy and security of its customers. To provide our customers with technical support and high quality customer service as well as to determine areas of improvement, customers are informed that communications between customer service agents and customers may be recorded when authorized by the customer for quality and training purposes.

2. Technical Approach

2.1. Call disposition Flow Overview

Current call dispositions are collected through a manual process in a call tracking tool, where call center agents select a call disposition and enter notes into the system. If a call is transferred to another agent, it is split into call segments where each agent selects a disposition for their corresponding segment. Dispositions are predefined, and selected via drop-down menu.

While this approach enables quick selection and consistent responses, there are some limitations. Selection of disposition is subjective and can vary from agent to agent. Only one disposition can be selected per call, even when multiple issues are discussed. Changes to the disposition response list requires both a software update and agent training, and cannot be applied retroactively. Furthermore, due to the nature of a manual dispositioning process, some call segments are missing a recorded disposition in the tracking tool.

These limitations can be addressed through a machine learning approach. Using an automated machine learning approach enables scalable, consistent, and reliable call disposition labeling. Nuances in how an individual agent labels a given call segment are removed, as all call segments are systematically evaluated. Furthermore, assignment of multiple labels to a single call can bring to light underlying factors affecting multiple call reasons.

2.2. Machine Learning Pipeline Overall Architecture Review

We have developed a pipeline for data processing and modeling, in combination with cloud AI services such as cloud transcribe and cloud NLP services for an end-to-end call disposition architecture. Additional call insights are gained through the implementation of our topic modeling framework. The pipeline is implemented in Python 3 through boto3 (Amazon Web Services 2015). See Figure 1.

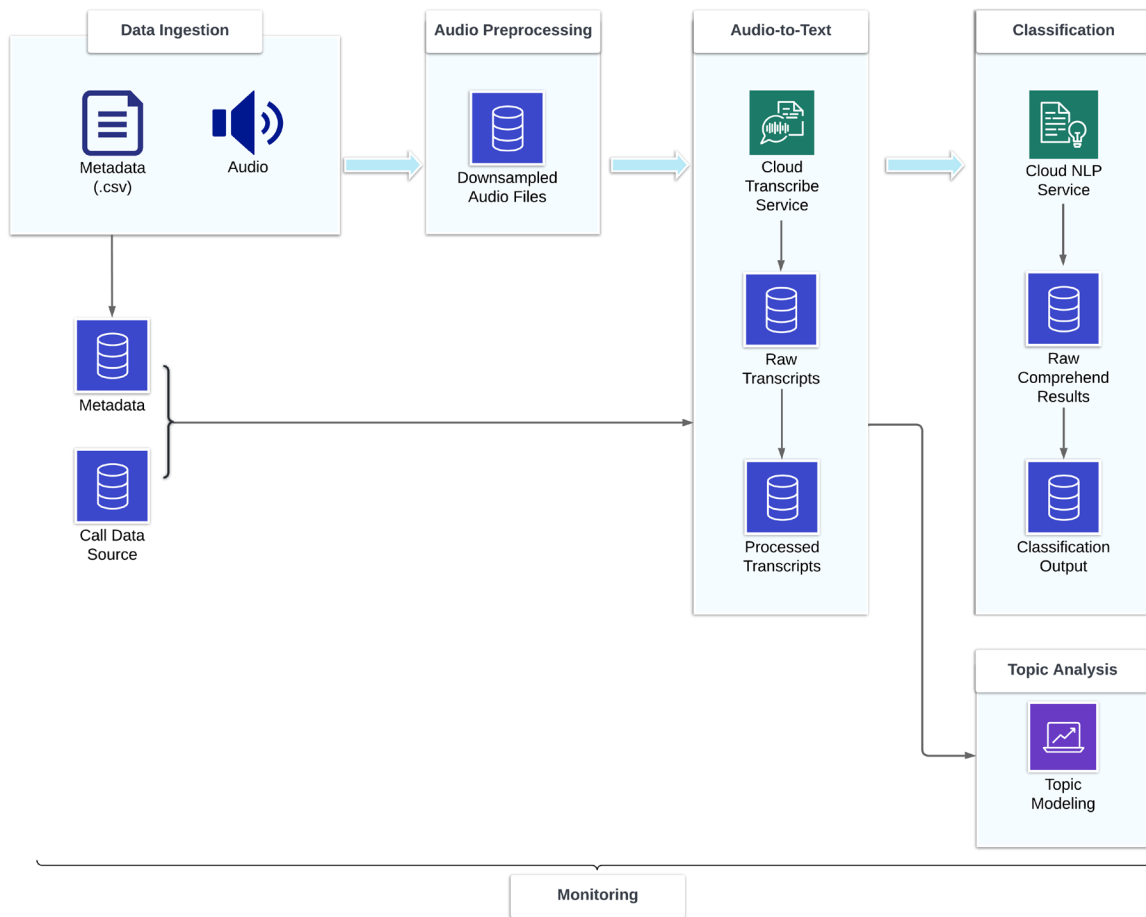

Figure 1 – ML Pipeline Architecture Overview

2.3. Data Ingestion

Every morning, call audio recordings and associated metadata from the previous day are ingested into the data science cloud storage.

2.4. Audio Preprocessing

To prepare the audio data for the cloud transcribe service for the best transcript output, we preprocess audio recordings after the audio files are ingested. In this step, we downsample the audio to a sampling rate of 8,000 Hz, and convert the audio files into .wav format through a parallel batch process. The downsampling and conversion are implemented through the open-source library librosa (McFee, et al. 2022). This pipeline is also batch parallelized and implemented through joblib (Joblib developers 2020).

2.5. Convert audio into text transcripts

There are multiple automatic speech recognition services available on the market to convert audio to text transcripts. In our pipeline, we utilize a cloud transcribe service to convert downsampled audio files into text transcripts. We harness built-in features such as custom vocabulary to improve the transcript quality, channel identification to add data dimensionality for analysis, and transcript redaction for data privacy and compliance. We experimented with different settings and decided on the configuration for production

based on the best word error rate (WER) evaluation metric. We describe these features and the WER evaluation in the next sections.

2.5.1. Custom vocabulary

Using custom vocabulary can help to improve transcribe accuracy for domain specific words and phrases. We worked with subject matter experts (SME) to identify technical vocabulary words and phrases commonly used in call center conversations for our use case. With sound-alike and phonetic annotations, we created a custom vocabulary for the cloud transcribe process to ensure Spectrum specific terms are represented correctly in the final transcripts.

2.5.2. Channel identification

Since the audio recordings contain two audio channels, we are able to generate transcripts for the full conversation, as well as separated transcripts by each audio channel. The transcripts by channel could be used in further analysis, such as associating topics in different channels to call issues and resolutions (Pratik K. Biswas 2021).

2.5.3. Redacting transcripts

We enabled redaction in the cloud transcribe service, where Personally Identifiable Information (PII) such as name and address are removed from the transcript output.

2.5.4. Word Error Rate (WER)

Speech-to-text is quite challenging for call center audio recordings. The audio quality is usually low, and there could be background noise such as a TV playing, dogs barking, or the customer asking questions. There are at least two people on the call, sometimes talking at the same time, and the speaking style is conversational and usually loosely structured. Thus, it is crucial that we measure the quality of the speech-to-text translations.

The most common metric for speech recognition accuracy is called word error rate (WER) (Seyfarth and Zhao 2020). WER counts the number of incorrect words identified during recognition, and divides the sum by the total number of words provided in the human-labeled transcript (N). $WER = (I + D + S)/N$, where I stands for Insertion Error: words incorrectly added in the transcript; D stands for Deletion Error: words undetected (deleted) in the transcript; S stands for Substitution Error: words substituted between reference and hypothesis. The lower the WER, the more accurate the system.

We randomly selected 15 transcripts and labeled them to evaluate WER. The WER ranged between 5% and 43%, with an average WER of 19%. By comparison, a benchmark analysis of nearly 3,000 call center conversations across five domains transcribed with automatic speech recognition (ASR) tools versus transcribed by two professional annotators found WER for call center conversations within the telecommunications domain to be between 17.62% and 23.31% (Szymański, et al. 2020).

2.6. Classification

2.6.1. Identify call disposition categories

The data science team worked with SMEs to identify eight high-level categories to train a classification model to predict call dispositions.

2.6.2. Multi-label classification approach

In the multi-label classification, individual classes represent different categories, but these categories are somewhat related and not mutually exclusive. As a result, each document has at least one class assigned to it, but can have more. In call center calls, a conversation can discuss multiple topics, justifying the use of multi-label classification.

We implemented the multi-label classification model through a cloud NLP service. For each input transcript, the model returns three labels with the highest predicted scores. Note, in some cases, even the highest predicted score is low if the model is not confident in the classification of any of the eight categories. Therefore, we applied category-specific score thresholds to the predicted labels, and only keep labels where the score is higher than the threshold as the final predicted label(s).

2.6.3. Create labels through LabelStudio

To train a classification model, it requires us to provide the cloud NLP service with examples of call transcripts with their appropriate classification labels. In order to do this, the data science team worked with SMEs to understand what to look for in calls in order to provide example labels. This team listened to approximately 1,000 calls in order to provide examples of about 100 calls for each category.

To support labeling the call data, we set up a cloud instance to run Label Studio (Tkachenko, et al. 2020), an open source annotation tool. Label Studio allowed us to create a custom interface that includes both audio and text media for annotation. The annotator was required to label each document with at least one label and optionally up to three labels. Each document was labeled at least twice, and, if there was no consensus, a third time. An example of the annotation layout can be seen in Figure 2. We consider the call categories labeled in Label Studio through this process as the “ground truth” data.

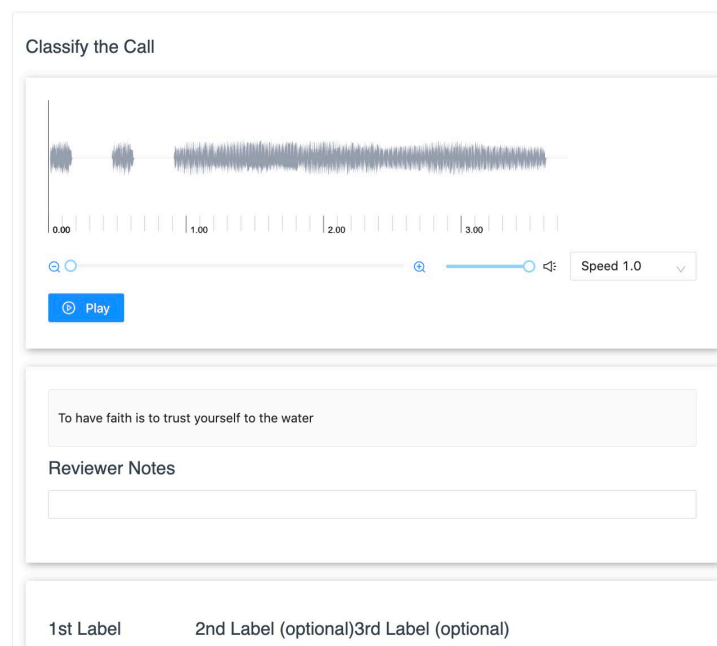

Figure 2 – Label Studio call labeling interface

2.6.4. Train Comprehend classification model and model evaluation

Once we obtained approximately 100 example calls for each category, we split our transcripts into 675 files for training and 191 files for validation. We experimented with various transcribe and comprehend configurations in the pipeline to determine precision and recall scores, and combined them into a single representative micro F1 score. A micro F1 score balances precision and recall across individual categories and provides a single quality metric for multi-label binary problems. The best performing comprehend model has a micro F1 score of 60% on both the training and validation set. Finally, we evaluated the fit of our model based on a random selection of 90 transcripts of previously unseen data, and examined the model's eight categorical predictions compared to the manually-curated call dispositions supplied by our call center agents.

We found the classification model trained with the cloud NLP service obtained a micro F1 score of about 59% on the evaluation set across the categories, with some categories performing better or worse than others. For example, one category obtained an F1 score of about 84%, while another category obtained an F1 score of about 25%. We also found the classification model performed very similarly to agent-based dispositions (58%) against labeled ground truth data, with similar performance across categories. See Figure 3. Future work will focus on improving the comprehend model with additional labeled data and refining the classification categories.

Figure 3 – Agent vs. ML classification F1 score performance

2.6.5. Inference

After training the classification model, we ran the model on a month of call transcripts from one month to understand which of these eight categories are driving the majority of calls. Recall that calls can be classified in multiple categories. We found the majority of calls for our use case, 40%, came from requiring support in one specific area. We also see a large portion of these calls, 27%, fall into the “Other” category. In the next section, we show how utilizing topic modeling can give us more granular

insights into the call drivers in the Other category, and will break down the top category into actionable subcategories.

2.7. Topic Modeling

When we shared the ML disposition results with stakeholders, they immediately wanted to know if we could find out more granular call reasons and if we could identify improvements to features and workflows to provide improved product experience. To answer these questions, we applied topic modeling to further analyze the call transcripts.

Topic modeling is an unsupervised method for discovering topics in a large collection of documents. Topics can then be used to find high-level summaries of these documents, search for documents of interest, and group similar documents together. In practice, we implemented the open-source library Top2Vec (Angelov 2020) for our analysis. Some benefits of the Top2Vec algorithm include automatic identification of the number of topic clusters and the ability to identify topic hierarchies.

The topic modeling process includes the following steps: text preprocessing such as normalization, training the topic model, interpreting topics, and visualizing and analyzing trends.

2.7.1. Text normalization

Text normalization is the process of transforming text into a single canonical form, so it is “cleaner” or less random. We found this step necessary to obtain more interpretable topics. As mentioned earlier, the audio-to-text task is challenging for call center audio files. Even after significant efforts to optimize AWS Transcribe, there are still consistent words or phrases incorrectly represented in the transcripts. Additionally, there are text formats in the transcripts that interfere with the topic model’s tokenization process. For example, “DVR” is often displayed as “D. V. R.” in the transcript. Since we also use “.” as a text delimiter, it would have been split into three separate letters “D”, “V”, “R”, and the individual letters lose the meaning compared to “DVR” as a whole. Through normalization, we are able to fix consistent transcribe errors, and normalize words and phrases so they will be represented correctly for topic modeling.

In order to handle the text normalization task on a large volume of call transcripts, we needed a process that is optimized and parallelizable. We chose HuggingFace’s tokenization pipeline (Wolf, et al. 2019) to normalize the data, and trained a Byte-Pair Encoding (BPE) Tokenizer on call transcripts to generate cleaned input documents for the Top2Vec model. We chose this tokenization pipeline because it is an efficient and optimized implementation, allowing us to use all cores on the data science cluster and process the text in parallel, which significantly reduced the processing time.

2.7.2. Training the Topic Model

The Top2Vec algorithm includes the following steps: the first step is to create a joint embedding of document and word vectors. Once documents and words are embedded in a vector space, the goal of the algorithm is to find dense clusters of documents, then identify which words attracted those documents together. Each dense area is a topic and the words that attracted the documents to the dense area are the topic words (Angelov 2020).

For experiments, we tested multiple embedding models, including Doc2Vec (Rehurek 2022), and pretrained embedding models such as universal-sentence-encoder (Cer, et al. 2018) and all-MiniLM-L6-v2 (Reimers and Gurevych 2019). We have found using Doc2Vec to generate the document and word embedding vectors produced the most interpretable topics. This is because call transcripts contain many

Spectrum-specific terms, and the Doc2Vec embedding is trained from scratch using all the transcripts as part of the topic modeling process. Therefore, the Doc2Vec embedding is able to represent Spectrum-specific terms well. While pretrained embedding models, even though they are trained on massive language datasets using complex neural networks, since they have never “seen” Spectrum call data before, they require additional fine tuning to perform well with our call data.

2.7.3. Topic interpretation

We trained the Top2Vec model on a month of call data. Because topic modeling produces unlabeled clusters of call transcripts, we supplemented the model by labeling each topic cluster with the most frequent keywords and bigrams. This provided some contextual meaning to each of the clusters.

2.8. Productionalization and Monitoring

Given the number of moving parts in our pipeline, we have established a monitoring framework to automatically measure data availability, reliability, and operational performance against our baseline. This enables us to identify and correct any arising issues early. Our monitoring framework has been integrated into the pipeline so every execution produces an associated monitoring report.

2.8.1. Data Ingestion

Each day, we receive call audio recordings in a cloud storage repository. Additionally, we receive a daily manifest file listing each audio file expected and its associated metadata, such as unique call identifier, agent information, and source of call. As an initial step to our pipeline, we validate the files received match the files listed in the manifest. Independently, we validate the manifest file contains the calls we expect to receive based on a separate internal call data source. By utilizing automated data validation, we are able to quickly identify and address discrepancies when these numbers deviate from one another. As a result of this monitoring, we are able to quickly identify and resolve this issues that come up during normal course of business.

2.8.2. Audio Preprocessing

We downsample and convert audio files to WAV format for ingestion into a cloud transcribe service. We monitor the number of audio files that failed to convert, the total count of files successfully converted, and the minimum, maximum, average, standard deviation, and percent quartiles for both call lengths and file sizes following downsampling. This enables us to capture any issues in file transfer or conversion in our hybrid environment, and to provide insights into the size and length of the audio files received.

Monitoring became crucial in identifying an underlying issue in our downsampling process. We were finding roughly 100 files were being produced with a zero-length audio file. Interestingly, the files producing the zero length audios were different from run to run. Through troubleshooting, we identified that the pydub python library (Robert, Webbie and others 2018) would intermittently fail to downsample a given file when run as a parallel process. In the end, this was overcome by our transition to the librosa python library.

2.8.3. Convert audio into text transcripts

As files are transcribed, we capture the total number of audio files that fail as well as the individual errors and corresponding number of files per failure reason. Capturing the reasons associated with the failures enables us to see if there are underlying errors requiring remediation. The most common error observed

stems from the file being less than .5 milliseconds, the minimum audio duration required for transcribe. Because we cannot process these files, they are logged and removed, and the pipeline continues execution.

After transcription, we parse the individual files based on their audio channels, join to their associated metadata, and combine into a single dictionary in preparation for classification. In addition to monitoring the total number of processed transcripts, we further monitor the individual word count statistics produced. For example, we monitor the mean word count across the transcribed files; when the word count drops substantially, we are able to identify if the current run has failed to appropriately transcribe the calls.

2.8.4. Classification

At the completion of classification, we validate the output file has been created and its location documented. Summary results are logged indicating the distribution of audio files across our defined classification labels. Insights are delivered to our stakeholders for actionable business intelligence.

2.8.5. Configuration Details

Finally, to ensure we have repeatable results, we log the configuration metrics, including run time, file locations, custom vocabulary file, and any process-specific parameters utilized in the run.

2.9. How AI/ML Insights Drive Product Roadmaps

With quantitative metrics in hand, our stakeholders are empowered with empirical evidence to better guide and prioritize their roadmaps. Broadly, we were able to utilize topic modeling to identify call drivers and use those call drivers to identify areas where improvements would increase efficiency. As such, these topic modeling results are driving current and future product roadmaps and supporting continual product improvement.

3. Future work

Future work is focused on improving the accuracy and efficiency of our pipeline. Using audio transcripts for call disposition is just the beginning. We want to enrich our call disposition data with additional data sources which can open up our analysis to understanding patterns, and will enable us to better understand the broader picture. Improvements to our visualization dashboard will better highlight topic insights derived from the model.

We also plan to experiment using the same tokenization pipeline on call transcripts to train a transformer-based model, such as BERT (Devlin, et al. 2018). As a result of the training process, BERT learns contextual embeddings for words. We can then use the custom trained model to produce embeddings for topic modeling. These BERT embeddings should contain more contextual information and might be able to improve the topic model.

As an unsupervised learning method, topic modeling is great in clustering semantically-similar documents together to show trends; however, it still requires human input for topic interpretation and requires effort to measure output accuracy. Conversely, supervised classification modeling, is easy to set up, but requires high-quality labels for meaningful training and evaluation. As such, we plan to augment our topic modeling process with a human-in-the-loop to create new training labels for the classification model.

4. Conclusion

We have discussed an automated end-to-end pipeline from call center data to actionable insights. In our pipeline, we developed a flow to ingest audio data, performed audio downsampling, converted audio to text, ran a classification model on high-level dispositions, and performed topic modeling for more granular insights. This pipeline is monitored at each step with measurable metrics for quality control.

While the manual call tracking tool collects high-level call dispositions, the machine learning and natural language processing approach is fast, reliable, and scalable. Machine learning elevates us from statistical metrics to deriving deep analytical insights and identifying new trends. These insights help shape product roadmaps and drive new feature development.

5. Acknowledgements

We would like to extend our special thanks to Jonathan Stribley, Sean O'Donnell, and Keara O'Brien for their partnership in these endeavors; the Call Center Technology team for their partnership in data ingestion, Sandeep Kumar Sarikonda, Pablo Lopez, and the Data Science Machine Learning Operations team for their assistance in setting up and maintaining the pipeline environment; the Data Platform team for establishing the development and production environment; Steven Naumann and the Data Engineering team for their assistance and insights with the internal call data; Laurie Porter for listening to hundreds of calls and helping us to understand the business process so we can establish a labeling guideline; Rohan Khataavkar and Aaron Osher for their help in labeling call dispositions; Cody Zeigler and Pierre Dumas from the cloud service team for their expertise and partnership in the proof of concept (POC) of the pipeline and productionalization; Mike Baldino for his support and leadership; and last, but not least, Marjorie Sedillo and Brock Bose for their support, expertise, and guidance in the development of the pipeline and model, as well as their editorial feedback on our manuscript.

1. Introduction

Efficient network planning requires accurate forecasting of customer behaviors in the near and long term. The goal is to anticipate the location and magnitude of capacity augments months, and even years, into the future using forecasted monthly bits per second demand (Mbps). This prevents outages, increases reliability and prepares the network to handle faster speeds. However, no longer does a blanket growth rate apply to every neighborhood. Network architecture is transitioning to run fiber deeper into the network and make Service Groups (SGs) smaller, decreasing households passed while increasing speeds. This adds further challenges as smaller SGs are more sensitive to individual household patterns and faster speeds create more usage spikes. As an example, single releases of popular games downloading to a console are enough to create network congestion as are increasingly frequent live sports streaming events.

In the existing analog node world, an office park could hang off the same SG as a housing complex. The difference between day versus night peak, and weekday versus weekend, are washed away due to the size of the SG and augment decisions could be made by the macro trend to consume more traffic at faster speeds. Now, in the digital node world, SGs are smaller. An office park may have a dedicated SG and a residential community may have its own dedicated SG. If we sum their traffic at the headend level, we will certainly see the macro trend, but now the individual SGs have their own driving forces. The office park is driven by weekday, daytime peaks with seasonal dips for vacations and holidays, not to mention pandemics. The residential component is driven by nighttime and weekend peaks that spike heavily in work-from-home situations or when popular games have new releases (and homework lay forgotten). In fact, popular gaming releases can more than double the number of SGs that peak on a single day. With the popularity of gaming and the increase of sporting events dedicated to streaming, these spikes are anticipated to become more frequent. As such, the trends of these SGs cannot be accurately predicted using a headend or national level CAGR (Compound Annual Growth Rate)

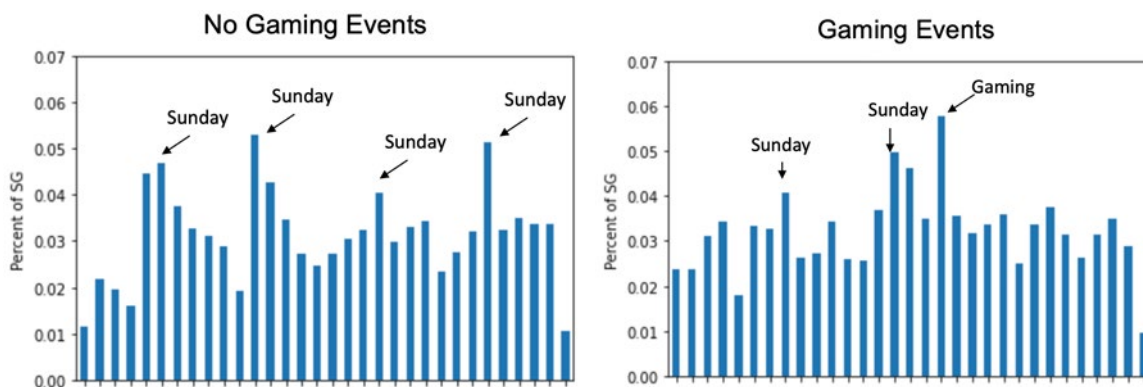

Figure 1 - Gaming is changing when SGs peak

The share of SGs experiencing their monthly peak on a given day is predictable when there are not large gaming download events.

At Comcast we are enhancing our forecast efforts to predict traffic deeper into the network. A small team within the CONNECT organization has worked for over one and a half years to develop a machine learning (ML) solution that produces individual patterns for SGs and Bonding Groups (BGs). The resulting Neural Network uses the growth patterns of SGs and BGs to accurately predict monthly 98th

percentile bps regardless of age or technology across the entire network representing hundreds of thousands of individual time series allowing for targeted network planning months and years in advance .

2. Current State

For more than 10 years, Comcast has been developing a comprehensive process to provide network traffic forecasting. Models are developed at the national, regional, and site level. Our access network component model is built to take the site-level aggregate and apply it to each active SG on the network. The model forecasts when SG augments will be required to maintain healthy SG utilization.

At the national level, there are macro level growth analysis models which look at different contributors, drivers, and industry trends. We also evaluate various assumptions and insights across Comcast product categories.

At the regional and site levels, time series focused Machine Learning (ML) has been developed to predict DOCSIS 3.0 (D3.0) and DOCSIS 3.1 (D3.1) traffic growth. We also apply reconciliation and a quality control process to reconcile the bottom-up (site level) model outputs with top-down (national level, regional level) models to ensure consistent forecasting output throughout. A Unified Demand Model (UDM) is the last step in the process to integrate bottom-up and top-down, reconciliation, quality control model outputs, products, device assumptions, and facility information. The output of the UDM model for access network is site level D3.0 and D3.1 traffic.

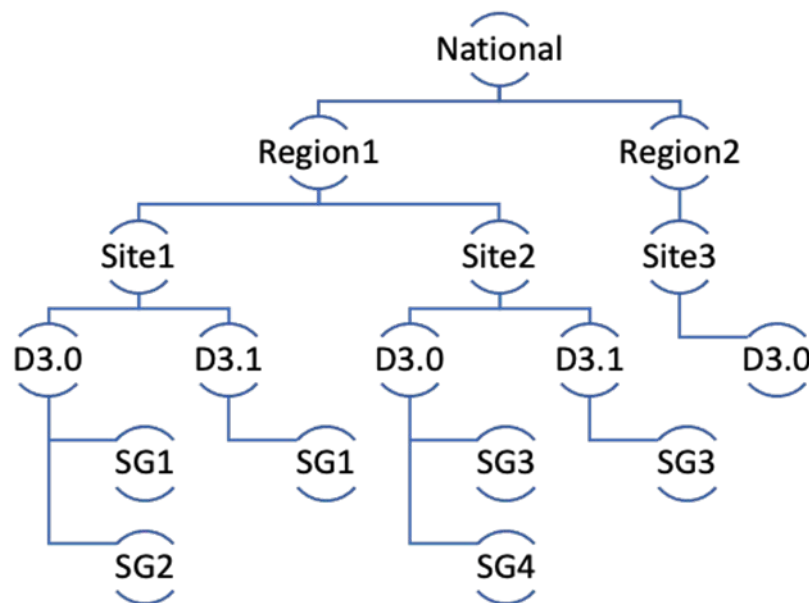

Figure 2 - Forecasting layers

National, Regional and Site level models are reconciled, then product, device and facility assumptions are added through the UDM to produce D3.1 and D3.0 traffic forecasts .

The next layer is SG. However, due to the number of the SGs, the scale and volatility of the data, we were not able to generate SG level forecast from the ML models which were used in site-level forecasting. At the SG level, our traffic growth process applies ratio-based site-level utilization to the individual SG (e.g., SG-01's last known actual bps utilization was 30% of the site-level aggregate, so in the next forecast period we will add 30% of the incremental bps site-level traffic to SG-01). We then look at the number of DOCSIS QAMs currently configured on each SG. If the number is less than the current year's target, we will add D3.0 or D3.1 channels to ensure the SGs will have the targeted capacity for that time period. QAM configurations will also be adjusted based on the amount of D3.0 versus D3.1 traffic. If an augment needs to occur in the model, a new SG is created; traffic is split among old and new SGs, and the traffic growth process continues. The ratio-based traffic growth process applies to upstream SGs as well.

n98th Mbps Aggregate		
	Site Actual	Site Forecast Month 1
Site A	5000	6000

	Service Group Actual	Percent of Actual	Service Group Forecast Month 1
SG-01	1500	30%	1800
SG-02	2000	40%	2400
SG-03	1500	30%	1800
Total	5000		6000

Figure 3 - SG traffic allocation

n98th Mbps Aggregate		
	Site Actual	Site Forecast Month 1
Site A	5,000	6,000

	Service Group Actual	%'age of Actual Mbps	Service Group Forecast Month 1
SG-01	1,500	30%	1,800

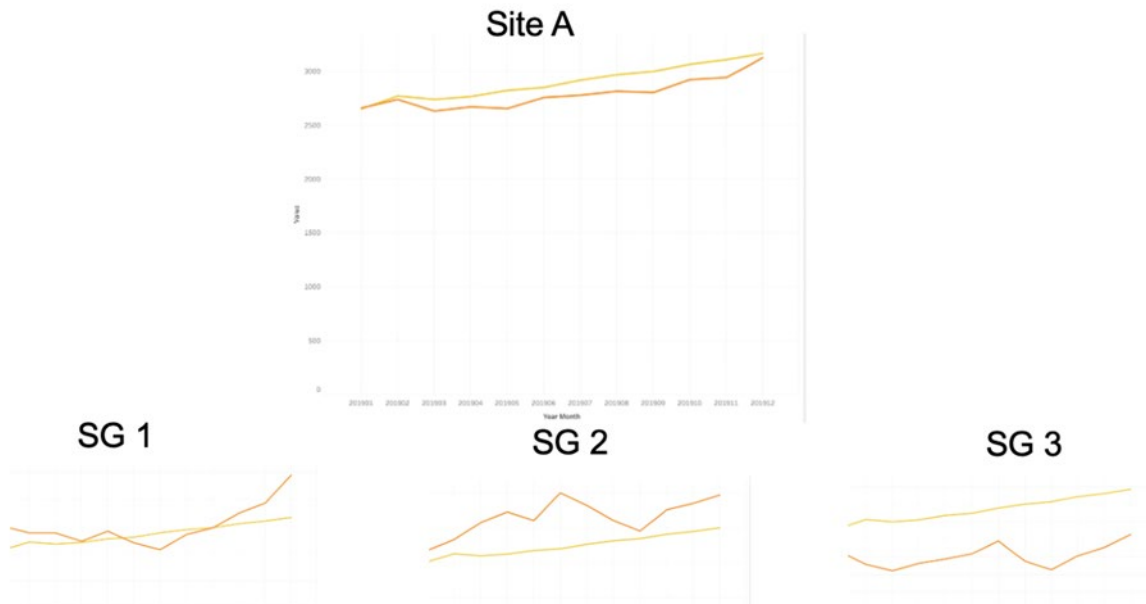

Figure 4 - Site to SG example

The site level forecast is very accurate, but when applied to the SGs underneath it the pattern no longer holds. This is because each individual SG has its own growth drivers and the smaller sample size leads to higher variance in the pattern.

This network simulation method has effectively helped with our long-range planning and budget needs for the next calendar year. The challenge comes as we get closer to

and into those budget years – how do we help our partners in the field find the right SGs to augment six to twelve months out? Our site-level-aggregate forecasts are only run at certain times of the year which

leads to stale data. Customers churn, and release events for gaming and streaming video occur, leading to site-level forecasts that do not translate to in-year planning for the individual SGs. As we focus on proactive network augments, how can we direct construction teams to the right areas before utilization exceeds capacity and impacts customers?

3. Model Evolution

There is currently a time-series solution at both the regional and site (headend) levels. These solutions use ARIMA (Autoregressive integrated moving average) and Exponential Smoothing models to produce results for each unique region and site. So, the first step in the SG modeling effort is to see if there is an application of what we are already familiar with at the SG level. Using R on Spark and later Databricks we built a solution that produces unique ARIMA and Exponential Smoothing Models for each SG. This model produces results for all SG regardless of age and the sMAPE (Symmetric mean absolute percentage error) for the DS traffic was improved.

Figure 5 - Time Series model results

This demonstrated improvement in the forecasting process, but the model still did not produce a scalable solution because: (1) the sMAPE nationally was not improved, (2) the model behaved very poorly for SGs with inconsistent trends, and (3) it took 28 hours to run on Spark. So, our first pass was not our final answer, but we did learn how to handle the massive data sets and gained an appreciation for variance in the observed data.

Figure 6 - Time Series model issues with irregular patterns

The next step was to explore more advanced machine learning models. Based on the deficiencies mentioned above, we needed a solution that could scale, handle high variance, and run in less than a day. We experimented with multiple options of ensemble methods and Neural Networks and landed on a Sequential Neural Network. We trained the neural network on 2 years of raw bps data per SG. The results included improvement in the sMAPE for downstream (DS), D3.1 and upstream (US) demand.

Average sMAPE by Month by Model

Figure 7 - sMAPE of NN on bps

Figure 8 - NN on bps example output

However, once again certain inconsistent trends, like SGs being collapsed and seasonal patterns did not perform well. Furthermore, the model could only be run on SGs with perfect data. This meant that we could not produce forecasts for SGs with data issues or seasonality, nor provide guidance on newer SGs including traffic over RPDs (Remote PHY Devices) on the new vCMTS locations that only have a few months of observed data.

Figure 9 - Where NN on bps does not forecast well.

Collapsing sites and seasonal locations did not produce valid models.

To produce a model that meets our needs we need improved accuracy, fast runtime, and solutions for all SGs regardless of age. The discussion then veered to isolating problematic SGs since they were the gap in the Neural Network solution. The largest class of problematic SGs is seasonal locations. That is, SGs serving a geography that is primarily a vacation area such as shore and mountain locations. Identifying an appropriate model for these SGs first requires identifying them at scale. We currently identify site level seasonality through a mix of time series analysis and exception lists developed over years of site level modeling. However, seasonal sites can have non-seasonal SGs, and we need to be able to capture that in an automated way.

We know a seasonal site has a ‘look’ when you are scanning visually - you can see the peaks and valleys. This pattern can be described as a monthly growth rate with high positive growth in the season ramp-up followed by large negative growth as the season ends. Using this approach, we can put all the SGs on the

same scale - size will not be visible. We can identify similar growth patterns and find seasonal locations. We can also more universally describe all SG growth regardless of size and pattern. This highlights customer behavior as opposed to size driven by engineering decisions. We can increase forecast accuracy by feeding all SG data into the model as a monthly growth rate. Since the scale of the input is the same, the neural network can focus on learning a pattern, not both size and pattern.

4. The Model

Zooming back out to the national view we can create monthly growth rates from the monthly 98th traffic for each SG/BG. To accurately predict seasonal trends, it is ideal to have 24 monthly growth rates. Additionally, we will need a target growth rate for our first prediction month. This means that we need 26 months of data to produce 25 growth rates. Many of our SGs have missing data so we can fill in those gaps with 1s. We also have the issue of hyper-growth or data driving high monthly increases. Although it is impractical to perfectly clean a huge data set, we can cap monthly growth and decline to anywhere between 15%-50%. These options seek to balance variance vs natural seasonality. The most recent month is used as the target and the previous 24 months are the features. We then train that on a sequential neural network with 4 layers. Twenty-four months of data predicts 1 month. To reach a full year, we must modify the model input to include recent forecasts as features in the trained model.

P_month1: X includes Growth Rate 1 - 24

P_month2: X includes Growth Rate 2-24, P_month1

P_month3: X includes Growth Rate 3-24, P_month1, P_month2

These growth rates are then restated as bps by referencing the most recent month's bps and multiplying by the following month's predicted growth rate.

Once the result is stated as bps, sMAPE is used to guide model tuning and showed that breaking out the model by geography (North, South, East, West) and direction (downstream, upstream, OFDM) produced the most accurate result. Hyperparameter tuning used sMAPE and Loss to select layer count, optimization functions and epoch count to optimize the model.

The resulting model predicts 12 months of traffic for each SG and BG regardless of age.

Figure 10 - NN on growth rate results

To determine if this is a superior model to our previous SG model iterations or the legacy solution, we once again look at the sMAPE which shows that the NN produces the lowest error of any model for both the US and DS. So, this NN solution produces a more accurate model for all SG/BG regardless of age and can be run in a few hours. We can now move to the step of implementing these results in network planning models to inform future budgeting.

Figure 11. sMAPE graph comparing all models.

Lower is better for sMAPE. Across the time forecasted the NN using growth rate (green) outperforms all other models.

5. Future State

We now have a working time series model. Our immediate next step is to insert this model into the network planning process and facilitate decision-making from its output. We will have to slightly re-factor the network planning models as well as set up a quality control process. The quality control process will have multiple visualizations in 2 groups. The first group will be based on model accuracy to

show how close we are in aggregate and compare model options to target the lowest error rate. The second group will highlight SGs with high variance and questionable forecasts.

Once we have a working model, we will continue to improve the neural network. We are striving to get more accurate with seasonal sites by incorporating Holt Winters seasonality in those specific locations. We are also looking at options to add other data into the model including geography, node type, customer mix, device type, and SG age. We will measure these additions by the level that sMAPE and MAPE improve when compared with the historical time series.

Additional improvements to the algorithm have already been identified. Currently, we are producing a point estimate for each SG for each month. In the future we can produce a range of values based on the probability of scenarios. Additionally, we can use this information to inform probabilistic risk of needing a split for each SG within a period. Being able to define algorithms and probabilities at this level also allows us to build scenarios using optimization modeling techniques. Improved forecast accuracy, probability scenarios and split risk can be extended to build cost functions for needing a split. We can then enter the next frontier of establishing the cost of NOT splitting by adding customer experience metrics like speed tests, latency, and packet loss. At which point we will have a set of ML driven functions defining risk of split/non-split which can be solved using a Linear Program.

6. Conclusion

Growth in internet demand is currently driven by residential gaming, streaming video, and business applications. To ensure the highest customer experience we need to forecast network traffic to ensure we maintain sufficient capacity to meet user demand. In the past national, regional and site level forecasts were sufficient and development cycles were dedicated to them. Now, in the digital node world we need more accurate and granular forecasting to the neighborhood level, using ML to predict trends at the SG level.

Our team has developed an ML solution that has demonstrated improvement in time series accuracy. Additionally, it can handle new SGs regardless of size because it relies on monthly growth rates instead of bps to predict demand. Currently we are working closely with our internal partners to add this level of detail to the network planning process. This includes visualizing results to both aid model selection and highlight SGs that need further analysis.

A working model that aids financial budgeting and long-range planning decisions will mark the completion of our first phase. Next, we need to enhance the accuracy of our forecasting models using seasonal models and include additional data about the SG's behavior. This will allow us to explore other modeling techniques to cluster based on device, geography, or customer behavior. A further goal is to incorporate optimization modeling techniques that build on our ML models to maximize both the customer experience and financial performance.

We are in the beginning phases of an evolution in forecasting and network planning. Our combination of ML, time series analysis and collaboration will ensure our success at accurately predicting network demand so that all games can continue to be streamed and homework can (eventually) be done.

1. Introduction

As the industry gives monitoring and optimizing latency more attention, there is an increasing interest in understanding the value created by that network investment. Gamers are often mentioned as a key user segment that would value such investment because of the improvements to their user experience when playing games online.

Using a dataset from Network Next that includes 10-second latency data for every session of a multiplayer, competitive game during the first 2 months after its launch, we estimate that a one standard deviation improvement in 99th percentile (abbreviated as “99%ile” for the remainder of the paper) latency results in an 8% increase in the number of unique days of game play on average (approximately 0.4 extra unique days).

In addition, when a 7ms ceiling is applied to users’ queuing delay, to estimate the impact of Low Latency DOCSIS[®] technology, we find that some cable operators could see up to a 50ms improvement in 99%ile latency, while the improvement for other operators is smaller due to variation in queuing delay across cable operators. However, the user experience of gamers on all cable broadband networks are likely to benefit from the greater consistency in observed latency.

Lastly, the Network Next data allows analysis of Wi-Fi performance by gaming platform (PS4, Xbox One, Switch, Windows) on a per operator basis. Wi-Fi connections are used by 68% of the players of this game. Given that Wi-Fi is one of the largest sources of latency on the network, any complete solution to improving latency must address home Wi-Fi networks.

One potential technology to improve Wi-Fi latency is Wi-Fi Multimedia (WMM) tagging. For this game, the Nintendo Switch uses WMM. We find that for the Nintendo Switch, Wi-Fi latency is 46% lower than that of a PlayStation 4 (PS4), a console that does not use WMM. We also find there is substantial variation in Wi-Fi performance across operators.

2. Data Source & Methodology

2.1. Data Source

For the first two months following the launch of a game in the summer of 2021, Network Next provided CableLabs latency observations for each 10-seconds of activity. Each observation included the minimum latency observed during that 10-second window, jitter (defined as the standard deviation from the minimum latency observed during that 10-second window), and packet loss. Each 10-second observation is a summary of 100 pings.

The metadata include the user ID, a session ID, a postal code for the user and for the server, a timestamp, the gaming platform, whether the session was over the wired or wireless interface on the device, and the ISP name. The global data set includes 6.4 million players of the game, playing 260 million sessions, and 9.8 billion valid 10-second observations. When filtered down to the top 14 operators in the lower 48 states of the U.S., the data set includes 1.6 million players of this game who played for at least an hour.

2.2. Data Limitations

The Network Next data set comes with two notable limitations. First, the relationship between engagement and latency that we observe are not externally valid for other games or applications. This is because the sample only contains data on a single game, which limits how generalizable our results are,

and it has a unique relationship between latency and engagement, which is discussed in Section 3.2. In short, maximum engagement for this game peaks where there are more players (i.e., the latency experienced by *most* players), not at the *minimum* latency observed; this relationship creates an upside down “U” shape that is shown below. Network Next says they have verified this result but say it is unique to this game based on their experience studying other games. Other games tend to have flat engagement out to approximately 100ms of latency, and then it decreases. However, more generally, we hypothesize that the relationship between lower latency and engagement are related to a game’s characteristics. For example, players of real-time puzzle games may value latency improvements differently than those who play fighting games.

Second, some believe (Broadband Internet Technical Advisory Group, 2022) that online gaming is sensitive to the 99th percentile packet latency. This sample only provides minimum latency and standard deviation every 10 seconds. By comparison, we try to estimate the relationship between the measured minimum latency in the Network Next data to packet latency percentile, using empirical data collected at CableLabs, but this relationship is imprecise. Also, as shown in Table 1, the relationship between Network Next and actual latency measurement quantiles includes a couple of step functions that could easily move around based on network conditions, adding uncertainty to the meaning of the lower quantiles.

2.3. Analysis Methodology

We considered four different variables to proxy for game engagement:

1. Total game time played
2. Unique active days
3. Time between first and last session
4. Average time per Unique Active Day

Each of these four variables correlate well with latency, but unique active days was chosen because it had the strongest correlations, consistent region-to-region, and closely relates to how Network Next tracks retention. Using unique active days also mutes the effect of differences in free time between gamers. Finally, we propose, without empirical evidence or market research to confirm, that choosing to play a game again on a different day likely speaks better to a gamer’s enjoyment from playing more so than a longer playing session on a single day.

Based on modelling against lab data and input from Network Next, we find *latency + jitter* for each 10-second observation (summary of 100 pings) is the best stand-in for actual latency. For each user, the primary input variable used is their quantiles of 10-second (*latency + jitter*) observations.

As discussed above, the Network Next measurement system is based on 10-second windows, where 100 “ping” packets are sent and summarized in terms of minimum measured round-trip time and the root mean square deviation from that minimum. For the round-trip time (*rtt*) of the 100 pings in each 10-second observation:

$$latency_{NN} = \min(rtt)$$

$$jitter_{NN} = \sqrt{\sum \frac{(rtt - \min(rtt))^2}{100}}$$

To estimate the relationship between a Network Next's $latency_{NN} + jitter_{NN}$ measurements (i.e., individual summaries of a 10-second window ping) and the raw latency distribution over a period of observation, we measured raw per-packet latency for a cable modem connection carrying a mix of traffic for 700 seconds and calculated the $latency_{NN} + jitter_{NN}$ on 10-second windows. We then compare percentiles of the $latency_{NN} + jitter_{NN}$ distribution to percentiles of the raw latency distribution. The results are summarized in Table 1 below. For example, we find that the 99th percentile $latency_{NN} + jitter_{NN}$ value is roughly equivalent to the 96th percentile raw latency value.

Table 1 - Distributional Comparison of $latency_{NN} + jitter_{NN}$ to Raw Latency, Duration: 700 Seconds

Network Next Quantile	4.0%	14.0%	30.0%	45.0%	56.0%	75.0%	90.0%	95.0%	99.0%
Est. CL Latency Measurement WG Quantile	25.0%	52.3%	57.1%	78.1%	90.1%	94.0%	95.4%	95.7%	96.1%

Regression analysis is used in Section 3 to estimate correlations between latency and game engagement. As described earlier in the first part of Section 2.2 and more completely below in Section 3.2, this game has a unique upside down “U” shape in the relationship between latency and engagement. The upward slope approaching the peak (i.e., the portion of the curve that describes how the lowest latencies in the sample relate to engagement) is filtered out, so only data from the peak and after is used in the regressions. More exactly, mean engagement is calculated for gamers (minimum 10 gamers) by operator and state and the maximum value is found (L_{pe}). User data between L_{pe} and $3*L_{pe}$ are used in the regressions. All regressions include operator fixed effects to account for any time invariant operator-specific variance in the data.

To determine wired queuing delay, the mean routing delay (r) was determined for each user connection to a given server from a given location over a given ISP. R is estimated by the mean of the 10-second minimum latency for each combination of user, game server, and ISP. Then queuing delay for each 10-second observation was calculated as $latency + jitter - r$. Reported quantiles in Section 4 are of this distribution.

Cleanly isolating Wi-Fi delay was difficult. For a single user, differentiating jitter due to wired queuing from jitter due to Wi-Fi queuing is impossible. Therefore, we matched pairs of wired and wireless users from the same postal code connecting to the same server from the same ISP at the same time using the same gaming platform. As there were only two wired Switch players in the entire data set, Switch wireless gamers were matched with Windows wired (Dowle & Srinivasan, 2021) gamers. This resulted in a set of 42,252 user pairs with at least an hour of overlapping activity. The latency ($latency + jitter$) of the wired user was subtracted from the latency of the wireless user to get an estimate of latency from Wi-Fi for the wireless user. After that, quantiles of Wi-Fi latency ($latency + jitter$) were calculated on a per-wireless-user basis.

An exponential regression of ISP and gaming platform dummy variables was performed to see the effects of different ISPs, gaming platforms, and the interactions between the two on Wi-Fi latency.

3. Interaction of Latency and Game Engagement

In this section, the focus is on latency and game engagement. In particular, how different latency percentiles compare to each other and whether the relationships with engagement are significant. Overviews of latency and its relationship with game engagement are first, followed by the regression analysis.

3.1. Latency Overview

Figure 1 shows the cumulative distribution of latency per user measured at different quantiles (note the x-axis is log scale). While quantiles 75% or below are generally under 70ms, latency grows quickly at higher quantiles, especially the 99%ile.

Per-User Latency by Measurement Quantile, Cumulative Distributions

Figure 1 – Per-User Latency by Measurement Quantile

3.2. Relationship Between Active Unique Days & Latency

As shown in Figure 2, the game used in this study has a unique response curve between latency and unique active days playing the game. The peak unique number of active days is wherever most players are and is near the average latency for each operator, causing occasional double peaks or at least visible “shoulders”. The shoulders in the 56%ile, 75%ile, 95%ile, and 99%ile curves are caused by the presence of an operator whose mass of latency is at that point. The plot uses a logarithmic x-axis to emphasize the slope of each curve.

According to Network Next, other games have flat engagement to about 100ms and then it falls off. However, in this game, those with better-than-average 95%ile latency play significantly fewer days than

those with average latency. While the cause remains unknown, Network Next is working with the game developer to test several hypotheses.

As you can see from the plot, the steepest falloff is in the 56%ile and the 75%ile, and this will be reflected in the regressions. However, given the step-function nature of the correlations found in Table 1 this could be an artifact of the measurement system instead of actual engagement. Nevertheless, all measurement quantiles seen here have a significant correlation to gamer engagement both above and below the peak engagement.

Latency vs. Unique Active Days

Gamers with less than 200 ms median latency + jitter

Figure 2 – Latency vs. Unique Active Days by Measurement Quantile

Following the regression analysis methodology outlined above, we estimated three different regressions to better understand different parts of the latency-engagement relationship. In all of the regressions, unique number of active days is the y-variable. Our x-variable includes three different latency calculations. The first is latency in 10ms increments, the second is median latency, and the third is user z-scores. The results of these three regressions are summarized below in Figure 3, where each panel is a different regression. Each dot represents a estimate coefficient in the regression on the latency variable. Note that the negative correlations in Figure 3 are inversely related to engagement: the more negative a coefficient is, the more engagement there is. The primary findings of these regressions is the following.

1. The positive slope in the top panel is misleading. While we do find that improvements in lower latency quantiles is larger, the next two regressions add perspective. That is, 99%tile latency does matter. However, the key result is intuitive. Median latency, for example, is experienced much more frequently by a gamer than 99%tile latency.
2. When engagement is measured relatively for each user, where their median value for each percentile is used, we find the reduction in engagement from worse latency measurements across

percentiles flat until the 99%tile. This suggests the importance of higher percentiles is more important than the first panel suggests.

3. Finally, a z-score is a useful way to summarize how extreme a value is relative to a mean using the distributions standard deviation. In the third panel, the results suggest that extremely large latencies at all percentiles similarly impact engagement, even out to the 99%tile.

Based on these results, we will focus on 99%ile measurements for the remainder of the paper.

Change in Unique Active Days ...

Correcting for Operator-level Effects

Figure 3 – Correlation of Latency by Quantile to Unique Active Days

4. Wired Latency

This section begins by quantifying the latency distribution of wired gamers and separating that latency into routing latency and 99%ile queuing latency. Next, improvements to 99%ile queuing latency are

examined and with estimates of what improvements to wired latency might be expected from a full-scale deployment of Low Latency DOCSIS technologies.

4.1. Overall Wired Latency

This section uses PS4, Xbox, and Windows players with a wired connection to their home gateway.

Total 99%ile latency L is separated into a routing delay (R) and a queuing delay (Q).

$$R_{99\%ile} + Q_{99\%ile} = L_{99\%ile}$$

The 99%ile queuing delay (Q) is the 99%ile latency (L) minus an estimate of routing delay (R).

$$Q_{99\%ile} = Quantile_{99\%}(L - R)$$

As depicted in Figure 4, with one exception, cable and telco latencies were generally comparable during May & June of 2021. 99%ile latency generally ranges from 30 to 200ms for cable operators with a somewhat wider range for most telcos.

99%ile Wired Latency by Operator, Cumulative Distributions

Figure 4 – 99%ile Wired Latency by Operator

Figure 5 is a map of latency within the lower 48 states of the U.S. It shows 99%ile wired latency by location. The sample is biased away from dense urban centers to avoid overplotting, so it is not representative. The line from each user to a game server represents the game server most often used by that gamer while each gamer's icon is colored according to his or her latency.

Two things stand out on this map:

1. Some gamers primarily use a server other than their nearest one. In fact, outside of a few states such as Illinois, Michigan, Georgia, and Florida this seems to be the norm rather than the exception. This result suggests that game matching algorithms are using more criteria than just the closest server location (at least, sometimes as shown by this game). *(Note: Lines that appear to go from one server location to another such as from Chicago to Omaha are an illusion and are virtually passing through “Chicagoland” from users in Northern New England.)*
2. The worst latency performers are generally telco customers in rural locations (likely DSL) such as the Mississippi Delta, east Texas, eastern Arizona, and central Nevada.

99%ile Latency per Wired User

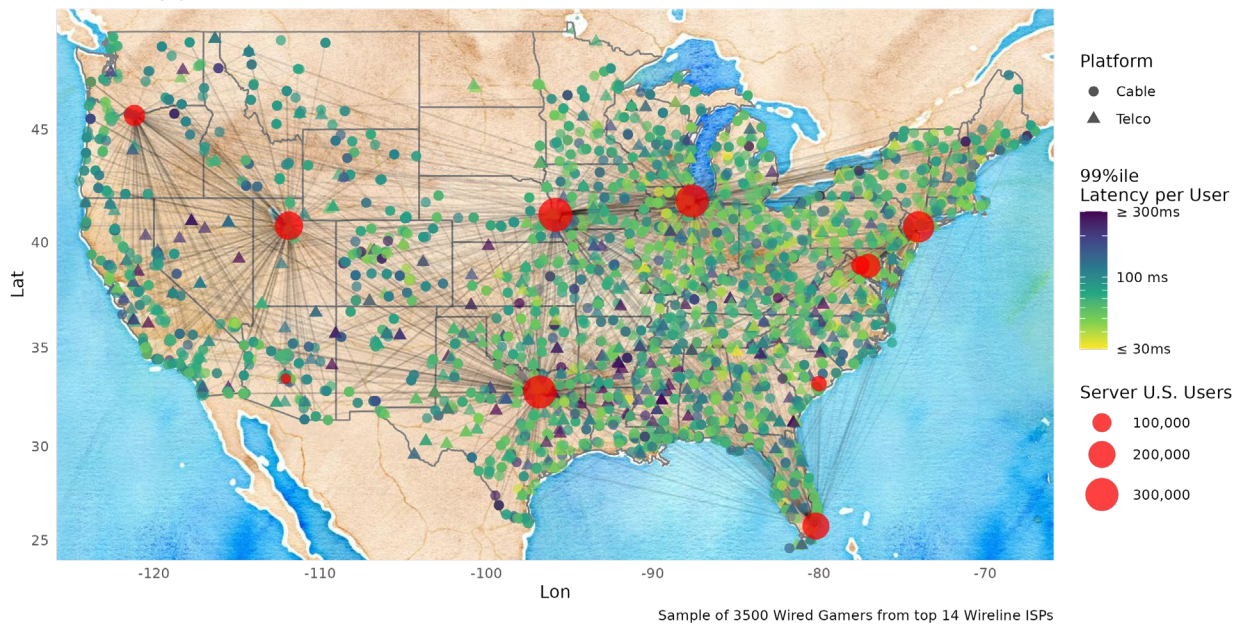

Figure 5 – 99%ile Wired Latency U.S. Map

4.2. Routing Delay

This section is presented to help readers compare the size and shape of routing delay distributions to the wired queuing delay distribution in Figure 8, the Low Latency DOCSIS counterfactual in Figure 10, and the Wi-Fi queuing delay in Figure 12 & Figure 13.

In general, routing delay ranges from 10 to 100ms in the lower 48 states of the U.S., and as the map in Figure 5 implies, is primarily determined by geographic proximity to the relevant game server for that operator’s user population.

Routing Delay by Operator, Cumulative Distributions

Figure 6 – Routing Delay by Operator

4.3. Queueing Delay

While routing structures are unique to each cable operator, the access network and the queueing delays that happen there are more a function of DOCSIS technology. Therefore, queueing delay and the potential impact of Low Latency DOCSIS technology as a way to improve queueing delays is of high interest. This section will examine how much of an impact wired network queueing delays (assumed to be primarily access network queueing delays) typically have and then the impact Low Latency DOCSIS could have on them.

To give an idea of the relative scale of routing and queueing delay for different operators: For cable operators, 25% of gamers in the study had at least 45% of their total 99%ile latency come from transient, assumably queueing-based delays. For telcos, the top 25% starts at 34% of 99%ile latency coming from queueing. That is, for these gamers, queueing delay is a larger share of overall latency on cable networks compared to telco. The results are summarized on a per operator basis in Figure 7.

% of 99%ile Latency due to Queuing Top 10 Operators by Wired Gamer Count

Figure 7 - % of Latency due to Queueing

Figure 8 shows the cumulative distributions of queuing delay for each of the top 10 U.S. wireline Internet service providers and provides some guidance on what Low Latency DOCSIS[®] (LLD) should be able to provide. The queuing delay experienced by users typically ranges from 2ms to more than 200ms. In general, the best telco customers experience less than 3ms queuing delay while the best cable customers experience less than 11ms. However, with one exception, all the telcos fall behind the cable curves in the top quartile. The 6 largest cable broadband operators fall into three distinct groups with a singular queuing delay leader, a close pack of three in the middle, and then two others.

99%ile Queuing Latency by Operator, Cumulative Distributions

Figure 8 – Queuing Delay Dist. by Operator

The expectation of Low Latency DOCSIS is that it should make cable operators queuing delay much more competitive to telcos. Without the Proactive Grant Service (PGS), LLD should be able to deliver queuing delays reliably 7ms or below. With PGS, that falls to 2ms but at the cost of allocating some upstream bandwidth to the proactive grants. This is reflected in the annotations in Figure 8.

Taking that a step further, Figure 9 is a *simplistic* imagining of what might happen if the top 6 cable broadband providers in the U.S. enabled LLD across their entire installed base. Suddenly the queuing delay cumulative distributions would appear as they do in Figure 9, resulting in an average 38% improvement in 99%ile latency for cable broadband customers.

Low Latency DOCSIS Counterfactual

99%ile Queuing Latency by Operator, Cumulative Distributions

Figure 9 – Queuing Delay Dist – LLD Counterfactual

Finally, Figure 10 estimates what the overall 99%ile latency curves would look like for the top 6 cable operators if LLD were fully enabled on each of their networks. As you can see, the results vary wildly with the current queuing delay leader (top left) making relatively modest gains but the 99%ile queuing delay of other operators improving by 50ms or more for a significant fraction of their customers. However, the improved consistency in latency from lower jitter is understated by this figure. On today's network, latency + jitter can exceed 100ms with too much regularity to support the requirements of future real-time applications and user experiences.

Cable Low Latency DOCSIS Counterfactual

Est. 99%ile Cumulative Latency Distributions w/ LLD by Operator

Figure 10 – Est. 99%ile Latency w/ Full LLD Deployment

5. Wi-Fi Queueing Delays

5.1. Wi-Fi Share

For this game, 68% of players connect via Wi-Fi and 32% on wired. A full breakout of gaming platforms can be found below in Figure 11. Xbox One is the most popular Wi-Fi platform, followed by the PS4, then the Switch, and last is Windows. Wi-Fi delays can be larger than all wired delays combined. Therefore, improving Wi-Fi must be considered in any end-to-end network latency plans.

Share of Game Players by Platform & Connection

Figure 11 – Wi-Fi Share

5.2. Wi-Fi Delay

For the 42,252 Wi-Fi gamers where we could find a wired match with at least one hour of overlap, their 99%ile Wi-Fi delay ranges all the way from 4ms to near 300ms. Most operators are grouped together, but two telco operators stand out for the worst 45% of their matched gamers. Each operator in this plot has at least 400 matched gamers.

Wi-Fi Delay by Operator, Cumulative Distributions

Figure 12 – Wi-Fi Delay by Operator

5.3. Performance by Operator & Gaming Platform + WMM Packet Marking

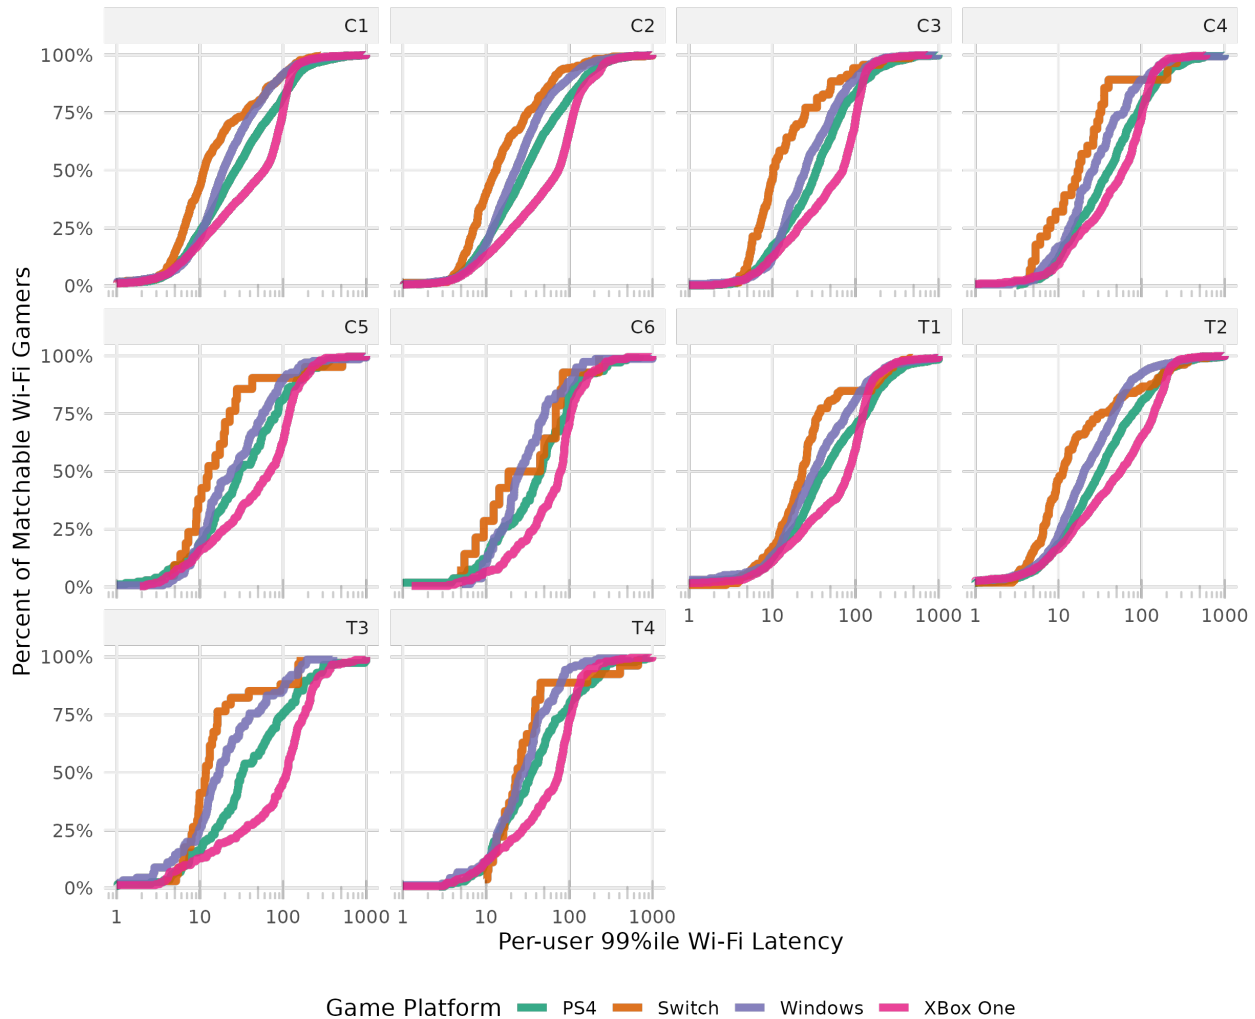

One unique feature of this data set is that Network Next's Wi-Fi stack included WMM packet marking on the Nintendo Switch and Windows Wi-Fi clients while the network stacks on the Xbox One and the PS4 did not. Figure 13 provides insights into the impact of this and other differences in the Wi-Fi implementation on different devices on 99thile Wi-Fi latency performance. This gives us a chance to compare the performance of each of these network stacks as they interact with the home gateways used by customers of different Internet service providers.

In general, the Nintendo Switch has the best Wi-Fi performance, followed by MS Windows clients, followed by PS4 clients, with Xbox having the worst performance.

Other things to note:

- For T1, T2, and C4, it appears that there are a few gateways that have noticeably worse performance with the Switch than other gateways used by customers of the same operator. (Step function in the middle of the figure.)
- In general cable operators are outperforming the telcos in Wi-Fi delay, but not by much.

Wi-Fi Delay by Operator & Game Platform, Cumulative Distributions Switch & Windows use WMM Packet Marking; Consoles Do Not

Top 10 U.S. Wireline Broadband Operators by Matchable Gamer Count

Figure 13 – Wi-Fi Performance by Operator and Gaming Platform

Finally, referring to Table 2, we run a dummy variable regression of the top 10 ISPs interacting with the four gaming platforms against log of latency. The base case in this dummy variable regression is ISP C1 + PS4.

While the other measurement quantiles are presented in Table 2, the 99thile alone will be discussed:

- The geometric mean intercept is 28ms, and each ISP except C5 results in a statistically significant increase of latency over C1 (who is the Wi-Fi latency leader) ranging from a small 11% increase for C2 to a 61% increase for T1.
- The Nintendo Switch has 46% lower latency than the PS4 and Windows Wi-Fi has a 23% improvement, meaning that WMM packet marking has a significant and large effect on Wi-Fi latency compared to the unmarked PS4 packets (and even more so compared to the Xbox One). We note, however, that WMM works well on packets like those studied in this sample (i.e.,

gaming), but may not be sufficient for other types of traffic (e.g., real-time video). Therefore, other technologies like L4S AQM implemented over Wi-Fi are things to be considered.

- The Xbox One Wi-Fi implementation results in a 34% worse latency over the PS4
- ISP C2 has a unique issue with the Xbox One (it does quite well otherwise), seeing a 21% increase in latency compared to other operators serving the Xbox One. ISP T3 seems to have a similar problem.

Table 2 - Regression of Wi-Fi log(latency) vs. ISP & Gaming Platform

	4%ile	14%ile	30%ile	45%ile	56%ile	75%ile	90%ile	95%ile	99%ile	Max

6. Conclusion

There are several opportunities for cable operators to make more enjoyable gaming experiences for their customers by reducing latency.

The first priority is to be able to understand how to measure latency in a way that correlates well to a gamer's enjoyment of this game, and the takeaway is that all of the measurement quantiles up to and including the 99%ile are well correlated to users' engagement in this game with an across-the-board one standard deviation improvement in latency likely resulting in between 0.4 and 1 (7% - 18%) more unique active days played of this game.

The second priority and biggest opportunity for differentiation compared to telcos is Wi-Fi. While there is hope of substantial improvements with Wi-Fi 6E, which will feature new (greenfield) 6 GHz channels where all the clients and base stations will include major latency-improving features such as OFDMA. However, the state of the game console cycle combined with the fact that the honeymoon period where the 6 GHz channels are unpopulated will come to an end leads us to emphasize that improvements here will require full ecosystem collaboration. For most cable operators, broader WMM adoption could result in halving the Wi-Fi lag for the Xbox One and the PS4.

Low Latency DOCSIS will have a significant effect on wired queuing delays measured at the 99%ile with some operators able to save many of their customers up to 50ms 99%ile round trip time.

Finally, routing latency should not be neglected. While it is beyond the scope of this research, there are indications in the data that one telco has been able to achieve results in routing latency vs. distance-to-server over and above the other ISPs, and there is therefore a real opportunity to bring this number down.

Acknowledgements

We would like to thank Greg White of CableLabs for his immense assistance modelling the 10-second summarization technique used by Network Next on lab latency data he has and using that model to help us adjust the quantile range we were looking at. This paper would be far harder to understand without his help.

We would also like to thank Glenn Fielder, Tapan Desai, and Andrew Baumbach of Network Next for sharing several of their current hypotheses and their excellent support of this data set.

Appendices

Appendix 1 – Regression of Unique Active Days vs. Latency & Operator

Table 3 includes a summary of the full regression coefficients and significance levels for each measurement quantile. (The regression is run separately at each measurement quantile.) The highest r^2 occurs at the 75%ile, but the strongest effect for improvement (such as by deployment of Low Latency DOCSIS[®]) occurs in the 99%ile measurements, so that is what is discussed here.

The inclusion of operator effects (that some operators have more engaged gamers than others) was necessary to get a clean correlation for the main variable.

Notably:

- The average player on operator C1 plays 5.1 unique active days of this game.
- For every standard deviation of increase in 99%ile latency, a gamer plays 0.4 unique days less.
- ISPs C7 and T6 both have significantly higher engagement than the base case operator (C1), while T3, T5, and possibly C2 and T4 have lower base case engagement.

Table 3 - Regression Output of Unique Active Days per user vs. Z-score of Latency & Operator by Measurement Quantile

1. Introduction

Depth-based media is an emerging market for users and enterprise that has recently witnessed a sharp uptick in growth and investment. With the rising demand for remote communication in virtual spaces, automation in transportation, maintenance, supply chain, and visualization techniques in healthcare, defense and simulation industry, startups and large companies are competing in this nascent market with the launch of fixed and wearable display units. A host of ecosystems are making efforts to integrate and co-ordinate accelerating development efforts among software professionals and industry experts. Despite growing support, challenges to content generation and transmission include developing an interchange format to support compatibility and an evolved network infrastructure to satisfy bandwidth and latency requirements to reliably and securely deliver immersive content.

The Immersive Digital Experiences Alliance (IDEA) was formed in 2019 to solve the twin problem of *media compatibility* and *media-aware transmission* over a 10G network. IDEA² developed 3D Streaming and Intelligent Buffering with the overall objective of enabling optimal immersive content delivery at minimal bandwidth consumption, while preserving viewing experience on multiple classes of immersive display units. The main benefit in bandwidth savings comes through offloading rendering from the core network and moving to the client-side.

The network architecture is robust enough to deliver assets of varying quality to the wide range of available compute resources on fixed and wearable units. The key assumption behind adaptive streaming being that display on a small screen requires fewer details, and therefore lower quality assets would reasonably allow for a satisfactory user experience on mobile and AR glasses. Larger displays however require greater amount of detail for objects closer to the viewer, which is captured and represented in higher-quality assets.

The present work briefly introduces media format interchange and proceed to explain the media-aware network enabled by 3D Streaming and Intelligent Buffering. Section 2 presents current bandwidth challenges to immersive media streaming to a host of different immersive platforms of varying screen sizes. Section 3 explains the 3D Streaming network architecture and Intelligent Buffering over a 10G network, along with a heuristic implementation of asset scheduling contained within the client-side logic. Section 4 evaluates bandwidth usage savings of queue-forming traffic flows of vectorized asset streaming over non-queue forming streaming of rendered frames. Latency measurements on the client-side demonstrate asset scheduling effectiveness in gaining maximum concurrency while fetching assets from remote asset servers. The conclusive sections describe algorithmic improvements made to asset scheduling and integration of current 10G capabilities into the existing network architecture.

2. Challenges to Wider Adoption of Immersive Media

2.1. Immersive Media offers Depth-Based Perception

Immersive media refers broadly to a variety of media that involves depth-based perception and accurately accounting for parallax differences at multiple depth levels. Immersive video allows the viewer to perceive the distance to depicted objects, with the viewer's own eyes as if the objects are physically present in the real world. *Parallax* is one of the main drivers of real-world perception: With viewer perspective shifting, objects nearer to a viewer appear to move relatively faster than objects in the background. VR and AR might be the most well-known examples of immersive media today. In contrast, an image on a computer monitor does not qualify as immersive media because the viewer can only

² IDEA Webinar on 3D Streaming, May 4th, 2022 [1]

perceive a flat image on the screen from any perspective and location. The present form of 3D movies also does not qualify as immersive media as parallax is not correctly accounted for by a pair of 3D glasses that stereoscopically superimpose a pair of rendered frames to create an illusion of depth perception.

While immersive media could reasonably be considered an emerging technology, there is a growing support on a host of platforms available in the market today. VR headsets are perhaps the longest running example of an immersive display available today, beginning with the high-profile founding of OculusVR in 2012 [2]. Augmented reality (AR) and mixed reality (MR) are also supported by several products on consumer and enterprise markets today [3], [4]. Together, VR, AR, and MR are collectively known as extended reality (XR).

Volumetric displays, supporting depth-based video, have recently emerged as a new class of display with form factors of a television or a desktop monitor. Volumetric displays are divided into two categories: *eye-tracking displays*, which track a single viewer's eye movements to create the illusion of depth on a 2D screen, and *light field displays*, which send different images out at different angles to produce perceivable depth for multiple viewers at once. Although few volumetric displays have reached the public to date, there are a number of companies already working in this space [5]–[10].

Immersive content generation occurs via digital content creation (DCC), through live captures from the real-world events using advanced camera technologies or using a combination of the two approaches. Digital content creation is the most common approach today, because for the most part it is straightforward to extend existing digital workflows to support immersive displays. Immersive display manufacturers publish free-to-use plugins that integrate with popular graphics toolsets and game engines. In contrast, live capture methods have lagged behind in technological development and adoption for immersive content generation and streaming, although this has been an area of significant innovation in both industry and academia over recent years. Depending on the use case, application requirements, and access to compute and network resources, live capture approaches extend from 2D photo conversion pipelines to depth cameras built into the latest smartphones to high-precision specialized camera systems: Neural Radiance Fields (NeRF) uses a neural representation to achieve exceptionally high fidelity from a sparse set of 2D input images [11]. For a deeper dive, refer to the IDEA white paper [12] on live capture methods and representations.

2.2. Growing industry demand

Over recent years, interest in immersive media has risen significantly. Some have argued that prior to the pandemic, AR and VR reached the “trough of disillusionment” along the Gartner Hype Cycle, which occurs after a product reaches peak inflated expectations and fails to deliver on the hype [13]–[15]. Then during the pandemic, people became acutely aware of the limitations of video conferencing as opposed to face-to-face exchanges. The reasons are numerous – lack of copresence, removal of spontaneous, random encounters, and perhaps worst of all, the newly dubbed “Zoom fatigue” that people experience after extended periods of time spent on video calls [16]–[18]. AR and VR witnessed a significant growth throughout the pandemic, at least in part because of the increased time spent working from home and the prospect of overcoming the limitations of video conferencing [19].

Then the concept of the metaverse came into mainstream attention with Facebook's rebranding to Meta at Facebook Connect 2021³, while showcasing their progress on building a new platform for rich, immersive social experiences online. Google's Project Starline also investigated immersive media technologies for enhanced telepresence, bringing live 3D video to the video call format [16]. NVIDIA announced its

³ CEO Mark Zuckerberg's letter to Meta employees [20]

launch of Omniverse platform that allows real-time collaboration on digital twins, architecture, education, and facilities maintenance [21]. Looking Glass Factory recently secured the CIA's venture capital funding to provide immersive displays for intelligence and defense applications [22]. Hollywood movies are increasingly being produced using game engines [23].

Industry giants and startups continue to expand upon XR development – creating applications, utility tools and supporting hardware to allow immersive content generation, streaming and consumption. Display manufacturers, game engine developers, network operators, chip manufacturers and application developers continue to invest capital and participate in evolving ecosystems surrounding immersive technologies. We believe this trend will continue to dominate as demand for immersive content finds an increasing use in improving learning and productivity while enhancing entertainment experiences.

2.3. Rasterized transmission will require prohibitive bandwidths

Newer displays and media pose several challenges that need to be considered to enable the ideal vision of an immersive future. First, the massive variety of methods for capture, encoding, and display of immersive media leads to a “many-to-many” problem when developing workflows and processes related to immersive media. Each method, format, and display has its own advantages and drawbacks, and conversion between representations runs the risk of significant information loss. Even today, conversion among existing 3D scene description formats can lead to problems like missing materials, untranslatable logic, and subtly altered rendering behaviors. This gets worse as the number of features and formats continues to grow.

Bandwidth requirements for immersive displays are expected to grow at an unprecedented rate. State-of-the-art VR headsets today reach resolutions above 4K [24], but light field displays are anticipated to be orders of magnitude higher resolutions than anything available today. To provide a 3D effect without eye tracking, light field displays attempt to mimic the behavior of rays of light bouncing off a real, physical subject. While a pixel on a 2D display unit encodes a single color at 24 bits in total, a *holographic pixel* would need color encoding for each ray emanating from angles discretized in the azimuthal and altitudinal directions. A holographic pixel supporting 90 different angles horizontally (azimuthal) and 90 different angles vertically (altitudinal) could enable viewers to experience a few inches of depth [25], but would require a total of 8100 color encodings. A holographic still image on a UHD-4K display (3840×2160) using these 90×90 holographic pixels would require 67 gigabytes of uncompressed data. While compression reduces data requirements, their application on compressing immersive media for light field displays is in early prototyping phases, and public data and literature remains scarce.

3. Vectorized Content Delivery over Scalable Networks

3.1. 3D Streaming of Interchangeable Media Format

IDEA has published a suite of royalty-free specifications establishing a baseline for interchange of immersive media, known as the Immersive Technologies Media Format (ITMF). The format was initially intended to be used for interchange amongst industry-standard digital content creation (DCC) tools, i.e. for the packaging and creation of 3D synthetic, computer generated, and natural media, including audio and visual media. As a baseline format primarily for use with DCC tools, assets described by ITMF are agnostic to the specific type of device on which they may be presented. For example, visual media will be display-agnostic, so that a subsequent rendering step in a media- and application-aware distribution system can reformat the visual media to match the capabilities of the client display.

While streaming rendered frames require massive bandwidths, real-time streaming of immersive content followed by rendering 3D assets on the client within display units could mitigate the challenges associated with the delivery of immersive media. Local rendering of 3D assets on a game engine runtime has the advantage of asset reuse over multiple scenes, thereby eliminating bandwidth redundancy that comes with streaming rasterized frames. We present **3D Streaming** — a system architecture supporting real-time streaming of immersive content to clients by transmitting ITMF scene graphs and associated assets to clients. In addition to reducing light field display bandwidth requirements, 3D Streaming simplifies content distribution to heterogeneous immersive display units. This system also generalizes to other scene graph formats – Universal Scene Description (USD), Graphics Language Transmission Format (glTF) – accommodating diverse application-level requirements and use cases.

The general framework of 3D Streaming finds its form in a network architecture that could be scaled on-prem, in cloud or the edge, dictated by network flows in streaming 3D assets depending on the use case. The key components described here would be considered essential to the overall implementation.

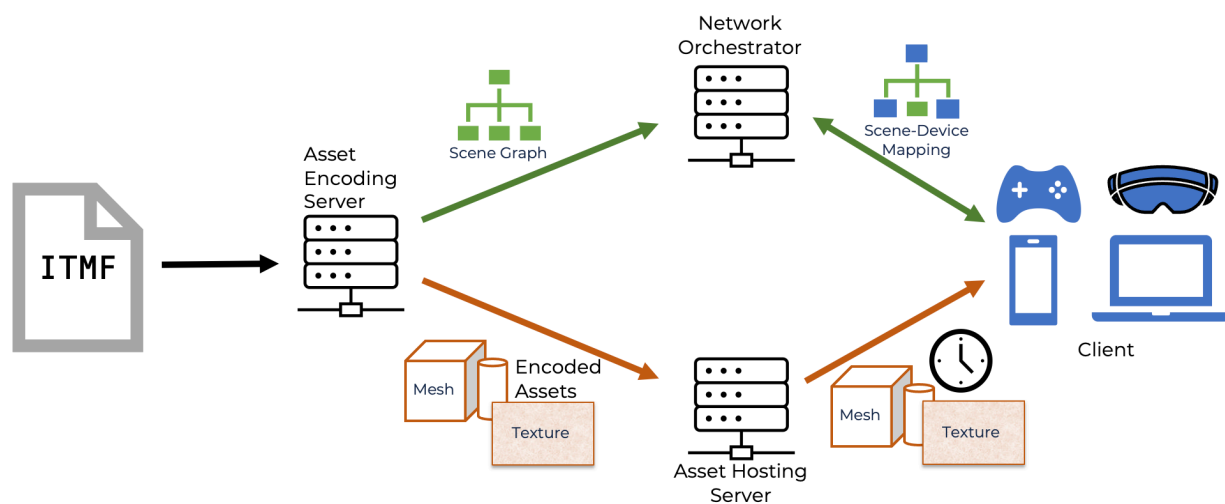

Figure 1 - 3D Streaming Architecture built with an Asset Delivery Pipeline

3.2. System Architecture

Figure 1 describes the architecture of the 3D Streaming demonstrated in IDEA's May 2022 webinar [1]. The end-to-end pipeline of conveying an ITMF scene to an immersive display unit consists of the Asset Encoding Server (AES), the Network Orchestrator (NO), and the Asset Hosting Server (AHS). Initially an ITMF container is ingested by the Asset Encoding Server (AES), which extracts various files from the ITMF container, namely (1) the *assets* (meshes, textures) that spawn in scenes, and (2) the *scene graphs* (XML, JSON) describing the layout and properties of the assets and the scenes (lighting, animation).

The AES pushes the scene graphs to the Network Orchestrator (NO), which is mainly responsible for mapping client requirements to the *asset quality*, and control plane operations related to individual streams. Asset quality (AQ) is defined as an abstraction of mesh compression, texture compression and levels-of-detail (LODs). The AQ-client mapping allows for a real-time adaptive asset streaming to heterogeneous platforms (clients) of widely ranging compute requirements and operating under dynamic network conditions (latency, jitter).

The assets are pushed to the Asset Hosting Server (AHS)⁴, defined as an abstraction layer of content delivery network (CDN) hosted on-prem, in public/private cloud and on edge resources. The AHS distributes assets of varying asset quality (AQ) to meet the compute and network requirements of the application (Section 3.3.2). Alternate encodings and/or levels of detail (LODs), i.e., AQ, may be generated by the AES and included in the distribution to the AHS to support performance and hardware constraints on the client.

When a client initiates a 3D Stream, it establishes a connection with the NO, which ensures that any constraints known up front are applied to the scene, such as support for specific asset encodings or display-specific content. The modified scene information is then sent to the client. The client reads the scene information, sends data plane asset requests to the AHS, and finally the client renders the scene in real time on a game engine (Unreal, Unity) runtime. The client makes several asset fetch calls to the AHS at different times during an interactive session (multiplayer gaming, XR application), and a non-interactive session (live streaming, playback) to buffer immersive content on an immersive display unit. Therefore, this *scene awareness* allows for buffering content time-to-time, distributing large downloads over multiple smaller downloads over time, as and when the required assets are relevant to the scene.

3.3. Intelligent Buffering over the 10G Network

Intelligent Buffering refers to the use of network and scene awareness to fetch 3D assets from the AHS such that fetch times and the impact of adverse network traffic conditions are minimized while ensuring best possible QoE for the client. *Network awareness* refers to the consideration of latency and bandwidth and *scene awareness* refers to the consideration of 3D scene properties like asset placement and timing. Together, network and scene awareness enable cloud orchestration for scalable, adaptive streaming of 3D assets of different levels of detail and compression. We consider two different facets of intelligent buffering that can be controlled at runtime to support QoE: (1) Queueing asset fetches according to the time they appear in the scene; (2) selecting asset LODs when prioritization is not sufficient.

Intelligent Buffering

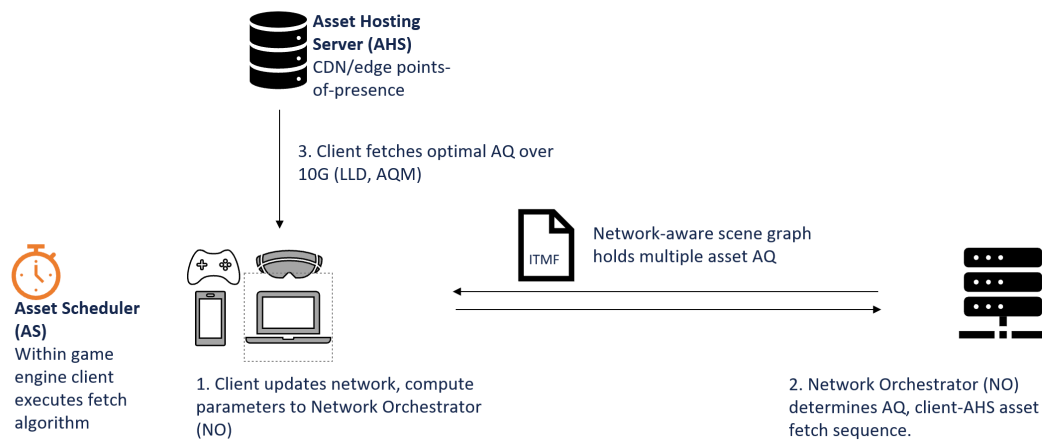

Figure 2 - Intelligent Buffering over the 10G Network

⁴ In prior webinars, this was called the “Asset Server”.

As noted in Section 3.1, the main advantage of 3D Streaming comes in the form of asset reuse over multiple scenes, therefore mitigating redundant content streaming requirements over several rasterized frames. For example, assets representing natural background objects (forest, rocks, foliage) remain largely static in a scene, and could be fetched once from the AHS and reused on multiple scenes. The uncompressed rendered assets (highest AQ) preserve the content quality under favorable network and compute conditions, much like adaptive bitrate streaming can deliver the highest quality of video content available, and adaptively adjusts frame bitrate as network conditions degrade during video streaming.

The client-AHS connection forms the main network bottleneck of 3D Streaming due to larger bandwidths (compared with client-NO, AES-NO connection) and rendering latency requirements on the client. In most cases, the scene graph is significantly smaller than the assets that fill the scene. During a 3D Stream, it is essential that the client fetches and renders all of the necessary assets on its memory to allow for compute and rendering latencies to display when needed. Failure to display assets during a scene playback would result in loss of necessary details or may temporarily pause the playback while the assets are transferred and loaded (akin to “buffering” on video streams). Such issues arise due to adverse impacts of network congestion, packet loss, and poor memory management.

This critical queue-forming traffic can be optimized by leveraging maturing 10G capabilities of Low-Latency DOCSIS[®] (LLD) technology with Active Queue Management (AQM) being incorporated into the working design of Intelligent Buffering. While traditional video streaming is download-heavy, immersive traffic would require the increased upstream capability of DOCSIS 4.0 networks to enable live capture and streaming. Mobility considerations include Low-Latency Wi-Fi and Low Latency Mobile Xhaul over converged networks.

The following sections describe intelligent buffering using its runtime variables and metrics, along with an overview of asset selection processes and algorithms as key enabling tools to optimize asset delivery to multiple clients on heterogenous platforms.

3.3.1. Variables and Metrics

In our initial intelligent buffering system, we incorporated the following variables and metrics available at runtime to support effective scheduling decisions. A list of assets from the 3D scene carries the following information:

- Asset type (mesh, texture, animation),
- URLs for multiple AQs of each asset,
- Asset file size associated at each AQ,
- Start and end times of asset visibility in a scene.

While the first three metrics constitute asset metadata available on the AHS and the scene graph, asset visibility time range is not explicitly described in typical scene graph representations. Rather it may be computed in a preprocessing step on the client. Content that is also generated in real-time, such as that from a source game engine, could be instrumented to log and transmit asset visibility, but this is not yet implemented.

From the network connection, the round-trip time (RTT) and download throughput is measured for every asset fetch call from the client to the AHS to determine current network conditions that dictate AQ selection for next fetch call or subsequent fetch calls over a time window.

3.3.2. Asset Quality Selection

The asset quality selection algorithms determine fetch sequencing and AQ. In traditional 2D video streaming, a high bitrate video is typically encoded on the server with multiple bit rates, enabling clients to perform adaptive bitrate: switching between encodings to maximize the content visual quality without experiencing interruptions like buffering. The analog to this in 3D Streaming is asset selection: the AHS provides multiple AQs for data intensive assets like textures and meshes. This way, the intelligent buffering algorithm may react to network conditions to provide similar assurances to those applied by adaptive bitrate.

Most common asset types, especially those that tend to have large file sizes, have existing facilities for lossless and lossy compression. For example, textures are often ingested into game engines using widely used formats like PNG or JPEG. However, the engine may convert image files to specialized, lossy texture compression formats like DXT1 which reduce game package size with minimal or zero impact on decode latency [26], [27]. With respect to meshes, games often include multiple AQs of the same mesh because different amounts of detail are needed when an object is close or far from the camera. In practice, mesh AQs may be generated either automatically or manually based on how much control is needed [28].

3.3.3. Basic Heuristic Example

Here, we demonstrate a simple heuristic approach for network-aware intelligent buffering to illustrate its fundamental application. If a designated latency threshold is met, say, over 45 milliseconds, a “high latency” mode is triggered which means subsequent asset fetches are made using smaller asset variants. In practice, there are many directions that could be taken to improve performance (see Section 5.2 for further discussion).

Consider a client that initiates a 3D Stream of an ITMF file containing a list of N assets. For each asset, a high detail and low detail variant are hosted on the AHS. Once the client receives the scene information, the client sorts the asset list according to time of first appearance. The first asset’s larger variant is fetched, and round-trip time (RTT) is measured. If this time exceeds 45 milliseconds, the high latency mode is toggled so that the next asset fetched uses its smaller variant. Fetch the next asset, measure RTT, and update high latency mode if needed. Repeat this process until all assets have been fetched. Rendering can begin as soon as all assets that appear at the very start of the scene have arrived, at which point rendering and streaming may continue in parallel.

While simple, this approach is primarily intended to illuminate the problem space that is occupied by intelligent buffering. The overwhelming majority of the logic occurs on the client, which facilitates low-cost, high throughput server deployments while achieving the objective of maximal QoE for clients. As previously mentioned, the AHS requires no more than static file hosting, so that component may be deployed on a traditional CDN.

4. Analysis

This section presents early analysis of intelligent buffering, including a description of key network performance metrics and a qualitative comparison to traditional video streaming. Measurements were taken on 3D Streams of small sample scenes.

4.1. Performance Metrics

Figure 3 - Timing of Asset Transmissions in a 3D Stream

Figure 4 - Measured Latency and Bandwidth of Assets in a 3D Stream

Figure 3 shows a waterfall chart of the asset transmissions that occurred over time during a stream. Assets 0 and 1 were transferred first for the scene to begin rendering, then Assets 2-4 were transferred afterwards. This demonstrates that asset transmissions in a 3D Stream need not occur synchronously: much like a web browser, the client can utilize multiple connections at once to provide a smoother experience where possible. Our goal with intelligent buffering is to develop an approach that minimizes the horizontal length of this plot (total time elapsed transmitting assets).

Figure 4 shows, for each asset transmitted in a stream, the latency and average bandwidth measured from the HTTP response. The vertical dashed line represents the latency threshold from our heuristic example in Section 3.3.3: assets whose latency surpasses 45 milliseconds, Asset 4 in this case, trigger “high latency mode”. Moving beyond the basic heuristic example, bandwidth measurements are a key metric for understanding network conditions to enhance QoE.

4.2. Compared to Conventional 2D Streaming

Figure 5 - Measured Latency and Bandwidth of 3D and 2D Streaming

3D Streaming can be considered a complementary solution to traditional video streaming for media delivery: While 3D Streaming does not completely replace the use cases enabled by video streaming, it performs better in various contexts. At a high level, the biggest differences between 3D and video streaming are the use of 3D rendering on the client and the patterns of network transfer. 3D Streaming requires sufficient client resources to perform the real-time render, but this is increasingly common today due to widespread consumer use of graphics processing units (GPUs).

The difference in network behavior is illustrated by Figure 5. This plot shows bytes transferred each second on a 3D Stream and a video stream. In this case, both streams coincidentally transfer about 40 megabytes of data in total. However, the 3D Stream transmits most of that data in one short burst up front, while the video stream transmits small amounts of data steadily over time. This is because the 3D Stream transmits all assets as soon as possible, while the video stream must consistently transmit video frames over the full duration of the content playback.

With the rise of heterogeneous immersive displays, we anticipate that content creators will increasingly need to develop media that supports many different types of displays at once, such as VR headsets, volumetric displays, and 2D displays. Ideally, that media should be tailored as best as possible for each display type. This would be challenging with traditional video: a different version of the content would need to be produced for every single display type, and it would be hard to accommodate the specific advantages of different displays, such as VR's higher degrees of freedom, without a focused, manual effort. Real-time rendering simplifies this process because the display-specific experience can be generated at runtime, often via a specialized plugin or API provided by the display manufacturer. The streaming application may also support custom enhancements like interactivity, which are much more complex to execute in a video streaming context.

As mentioned earlier, immersive displays are leading to increases in effective video resolutions at unprecedented rates, particularly light field displays which increase by an order of magnitude for each degree of freedom introduced. While today's display resolutions are generally well supported by modern network infrastructure and video codecs, it is unclear how long today's systems will remain effective. 3D Streaming is unaffected by this problem because the size of the scene is not correlated with the resolution of the display like a video is. Furthermore, rising adoption of 10G facilitates the delivery of larger scenes faster and more reliably.

As long as the client has sufficient storage, assets only need to be transmitted to the client once each. This means that reuse of assets over time is rewarded with less network chatter. In Figure 5, this is apparent because all the assets were transmitted at the beginning, then nothing else needed to be transmitted for the remaining playback time, keeping the network silent for the rest of the trace. Asset reuse is also useful for scenes that have repetitive content, such as trees, bushes, or buildings in a cityscape. This is already a commonly practiced technique in game development, as it allows the use of *GPU instancing*, which is a performance optimization that renders multiple copies of an object in a scene at one time [29].

5. Discussion

5.1. Related Work

Several online video games and geographic applications have developed systems for the real-time delivery of 3D content over the network [30]–[33]. Similarly, efforts in cloud and distributed rendering have implemented related functionality such as real-time collaboration on shared 3D scenes or scene delivery over the network [34], [35]. All these systems excel at their respective use cases, but do not generalize beyond that. In contrast, 3D Streaming is a general-purpose system for 3D content delivery over the network. In the future, it should be possible to build new networked 3D applications, whether games or content creation tools or otherwise, by leveraging the architecture presented here.

Petrangeli et al. [36] presented a system for streaming AR objects in real time with a mechanism for heuristically adapting LODs according to network condition and scene placement, significantly reducing startup latency and data requirements compared to predownloaded AR scenes. In the context of our work, their approach would be an effective drop-in solution for network and scene awareness in intelligent buffering, likely to be included in future analyses of intelligent buffering methodology. Our architecture also generalizes to broader use cases, including heterogeneous immersive display units with support for tailored experiences.

5.2. Future Work

Enhanced network awareness. We intend to develop a robust analysis of intelligent buffering algorithms. Petrangeli et al.’s work on AR streaming [36] provides one option to analyze, but there may be ways that we can incorporate enhanced network and scene awareness for further improvements.

Device awareness. Another factor to consider in optimizing the QoE of a 3D Stream is the client hardware. We refer to the usage of client hardware conditions and specifications for ensuring the best possible QoE as *device awareness*.

One example of device awareness is to consider the client as a cache comprised of three layers: its GPU memory, CPU memory and storage. In situations where the scene is particularly large or the client is resource-limited, such as embedded or mobile devices, it is possible that the entire scene would not fit on the client at one time. When an asset is delivered to the client over the network, we would store it on an available layer, beginning with GPU memory, falling back to the next when out of space. Coupled with an eviction algorithm that takes into consideration the available space in each layer, along with network and scene conditions, to intelligently free up space, this approach would allow for lower latency, local retrievals of previously seen assets into the scene. Another opportunity for device awareness is to factor in the client’s screen resolution into our asset quality selection algorithm. Lower asset quality is less likely to harm QoE on lower resolution displays.

Real-world capture support. We are interested in exploring the deployment of methods for viewing real-world 3D data on the client. Many real-world capture encodings can be embedded into a 3D scene graph [12], [37], and some of them, including NeRF, can render in real time [38]. As real-world 3D capture becomes more accessible, this will likely become a core use case for immersive displays. Embedding these captures into scene graphs will also enable new forms of mixed content: for example, one could imagine a virtual gallery filled with 3D scans of real art.

6. Conclusion

The current paper explores recent progress made on the development of a network architecture for scalable, vectorized content distribution to multiple platforms, rendered on client-side game engines. An end-to-end testing of a content delivery pipeline demonstrates significant bandwidth savings, while preserving content quality during transmission and allowing for asset reuse over multiple scenes. The architecture leverages modularity and scalability to allow for high availability of content over core network and cloud deployment. By streaming content over a 10G network, queue-forming traffic of immersive content can be delivered over reasonable times.

A key challenge for the present architecture lies in compute requirement on the client-side, especially with the growing demand for lighter wearable XR platforms to improve user experience. Future testing of the asset scheduler will determine algorithmic effectiveness in improving AQ adaptability, while *tail-end latency* ranges are expected to be curtailed primarily by deploying 10G capabilities on the existing platform without the need for making significant hardware changes.

As newer versions of game engines feature photorealism with even greater detail, vectorized content streaming could be the preferred choice of streaming immersive content. Although it may satisfy the demands of latency-sensitive applications like gaming, live event streaming (sports, concerts) will deliver live-captures (large bandwidths) but driven by latency requirements. The current architecture presents a general framework that can be adapted for live-capture and streaming by using low-latency techniques, delivering traditional video frames and 3D assets on separate queues.

1. Introduction

Historically, Wi-Fi is a polite protocol. Users will take turns in the time dimension to access the radio interface, sending and receiving messages. As the number of devices in the home has grown, more efficient multiple-user technologies have been introduced. The objective is to utilize these advanced multiuser features to benefit broadband customers in a tangible way. Techniques to improve the speed of a single user can be readily observed by customers with a simple speed test. The benefits of multiple user technologies require several devices and applications working in tandem. Laser focus on how technology benefits customer experience rather than technology for technology's sake is key. A traffic model that accurately reflects the situation in customers' homes is critical in applying multiuser technology that improves customer experience.

For multiuser techniques such as Multiple User Multiple Input Multiple Output (MU-MIMO) and Orthogonal Frequency Division Multiple Access (OFDMA) to work, a confluence of devices and applications must meet. The customer's devices must have multiple-user capability. Not all devices can take advantage of multiuser technology. Sometimes, the probability of several devices using applications that need access to the Wi-Fi radio signal at the same time is low; when low probabilities multiply the overall probability gets exponentially lower. The trick is to weed out the low probability use cases and focus on the commonly occurring use cases. This paper identifies the commonly occurring use cases for multiuser Wi-Fi technology and describes the theory behind multiple user techniques of multiple antenna spatial streams, spectrum resource unit allocation, and spatial frequency reuse. The paper sorts out aspects that are mostly for show from the technologies that lead to better user experience.

2. Begin with the fundamentals

The cosine of 0 degrees is 1 while the sine of 0 degrees is 0. The cosine of 90 degrees is 0 while the sine of 90 degrees is 1. The sine and cosine wave functions are in quadrature, simply offset in phase by ninety degrees, $\frac{\pi}{2}$ radians. This property allows information to be sent on the amplitude of the cosine wave and sine wave at the same time. The trick is to read the amplitude of the cosine wave at the phase of 0 degrees when the sine wave is nulled out, and the amplitude of the sine wave at phase 90 degrees when the cosine wave is nulled out. Figure 1 shows a unit circle as an aid to visualize the quadrature property of sine and cosine waves. This is the familiar quadrature amplitude modulation (QAM). In the cable world we are so familiar with these signals that we give them a nickname, "QAMs". QAMs carry a multiplex of video streams in a 6 MHz channel width. Many QAMs are combined, each with different center frequency. This is frequency division multiplexing, FDM. Wi-Fi uses QAM and FDM as well, yet in a slightly different way.

OFDM, orthogonal frequency division multiple access, is a form of FDM with the restriction that the signals are orthogonal. The FDM used with DOCSIS and video QAMs contain each multiplexed signal within an assigned 6 MHz block of spectrum. The signals do not exceed their 6 MHz block. By contrast, the frequency multiplexed signals in OFDM are not contained in frequency at all, even though they do tend to die off further away from the center frequency. In fact, each signal goes on in frequency forever.

Figure 1 - Unit circle illustrating quadrature signals

A periodic signal can be represented by a Fourier series expansion, an infinite sum of sine and cosine waves with discrete frequencies that are multiples of the inverse of the period. A periodic signal in the frequency domain consists of uniformly repeating spectral lines. Periodic functions can be useful, such as clocks, but since they last forever in time, they do not make for high-speed information transfer.

Figure 2 Impulse response for sending high speed information in amplitude

A good signal for fast information transfer is a quick impulse function as shown in Figure 2. The impulse function, unlike the periodic function, is contained in a finite chunk of time. Being finite in time makes the impulse response go on forever in frequency. The frequency response of the time impulse function is determined by the Fourier transform shown in Equation (1).

$$F(\omega) = \int_{-\infty}^{+\infty} f(t)e^{-j\omega t} dt \quad (1)$$

$$e^{j\theta} = \cos(\theta) + j \sin(\theta) \quad (2)$$

The time domain impulse function as shown in Figure 2 is even and symmetric. Euler's formula shown in Equation (2) allows the exponential function of an imaginary argument to be broken up into real cosine and imaginary sine parts. The sine function is odd. When integrated with an even function the imaginary sine part of $e^{-j\omega t}$ will vanish leaving only the real cosine part of $e^{-j\omega t}$ to integrate. The cosine function is even and symmetric as is the impulse function. The integration can be performed only from 0 to $\tau/2$ and the result multiplied by 2.

$$F(\omega) = 2 \int_0^{\tau/2} \cos(\omega t) dt \quad (3)$$

The sine function has a slope of 1 at 0 degrees phase just as the cosine of 0 phase is 1. The sine function has a slope of 0, flat top, at phase 90 degrees just as the cosine function is 0 at 90 degrees. The derivative of the sine function is the cosine function. The anti-derivative or integral of the cosine function is the sine function. Knowing the integral of the cosine is the sine function allows the Fourier transform of an impulse response to be evaluated shown as a sinc() function in Equation (4).

$$F(\omega) = 2 \int_0^{\tau/2} \cos(\omega t) dt = 2 \frac{\sin(\omega t)}{\omega} \Big|_0^{\tau/2} = \frac{\sin\left(\frac{\omega\tau}{2}\right)}{\frac{\omega}{2}}$$

$$\omega = 2\pi f \quad \tau = \frac{1}{f_0}$$

$$F(\omega) = \frac{\sin\left(\frac{\pi f}{f_0}\right)}{\pi f} \quad (4)$$

At $f=0$ the Fourier transform of the impulse function goes to zero in both the numerator and denominator. L'Hôpital's rule is needed to determine that the Fourier transform of the impulse response is $1/f_0$ when f is zero. This is the peak amplitude of the frequency response. At any frequency that is a non-zero positive or negative integer of f_0 the frequency response of the impulse is zero. We can take advantage of these periodic nulls by frequency shifting other impulses by an integer multiple of f_0 .

Figure 3 plots the frequency domain response of the impulse determined in Equation (4). The frequency response of the impulse peaks at a frequency of zero and nulls whenever the frequency is a positive or negative integer multiple of f_0 .

Figure 3 - Impulse response in the frequency domain illustrates orthogonality

By multiplying the impulse by $e^{j\omega_0 t}$ the Fourier transform is shifted in frequency. The frequency shift property of the Fourier transform is derived in Equation (5). Multiplying the impulse by $e^{j\omega_0 t}$ is a form of QAM as revealed in Equation (2). The impulse multiplied by $e^{j\omega_0 t}$ can be thought of as a tone with a frequency of f_0 . In OFDM and OFDMA, tones are QAM modulated.

The Fourier transform of the impulse response has a peak at zero and periodically nulls every multiple of f_0 both positive and negative as shown in Figure 3. Another impulse can be shifted in frequency by f_0 and added. The two impulses will overlap in both the frequency and time domain. However, in the frequency domain the first impulse peaks at a null in the second impulse while the second impulse peaks at a null in the first impulse. The two impulses are said to be orthogonal. This is the “O” in OFDM. The information contained in the amplitude of the two impulses can be demodulated by taking the Fourier transform of the combined time domain waveform and sampling the result at 0 and f_0 . We can add as many orthogonal impulses as we wish and still demodulate with a Fourier transform and sampling every f_0 .

$$\int_{-\infty}^{\infty} (f(t)e^{j\omega_0 t})e^{j\omega t} dt = \int_{-\infty}^{\infty} f(t)e^{j(\omega-\omega_0)t} dt = F(\omega - \omega_0)$$

(5)

OFDM does this slightly differently, but the principle is the same. First, the frequency domain subcarriers are QAM modulated. An inverse fast Fourier transform (FFT) converts the signal to the time domain. The receiver demodulates the multiplexed subcarriers with an FFT and sampling. The impulse function and Fourier transform used to understand the principle of orthogonal signals in an OFDM symbol are continuous in both the time and frequency domain. They represent the waveforms after the transmitter digital to analog converter and before the receiver analog to digital converter. In the digital domain both time and frequency representations are finite and discrete. The discrete Fourier transform (DFT), is a version of the Fourier transform. The fast Fourier transform, is an efficient method of calculating the DFT. The DFT is shown in Equation (6).

$$X_k = \sum_{n=0}^{N-1} x_n \cdot e^{-j\frac{2\pi}{N}kn} \quad k = 0, 1, \dots, N-1$$

(6)

Table 1 kHz tones and ns

kHz	tones	ns
20,000		50
10,000	2	100
5,000	4	200
2,500	8	400
1,250	16	800
625	32	1600
312.5	64	3200

A 64-point FFT with a time sampling of 50 ns has a subcarrier spacing of 312.5 kHz covering 20 MHz in the frequency domain and 3.2 μ s in the time domain. Table 1 illustrates the relationship of channel width, tones, and time duration. A 6 Mbps signal used for beacons, probes, and other control and management frames uses a 64-point FFT with a 3.2 microsecond time duration in a 20 MHz channel width. Forty-eight of the subcarriers carry one half of a data bit. 800 ns guard interval is inserted to prevent inter symbol interference. The bit rate of a symbol, often referred to as PHY, can be calculated $(48*0.5)/(3.2+0.8) = 6$ Mbps.

The orthogonal subcarriers can be created all at once by an access point (AP) or station client wi-fi network adapter (STA), this is OFDM. Many stations can create orthogonal subcarriers that combine at the AP to form a complete OFDM symbol. This is called uplink (UL) OFDMA. The “A” stands for access since the resource that is being shared for multiple access is tones in the frequency domain of an OFDM symbol. OFDMA was introduced in 802.11ax along with a change in the subcarrier spacing. The subcarrier spacing for an IEEE 802.11ax high efficiency, he mode, signal is one fourth that of earlier modes. With a channel width of 160 MHz the FFT size of an he mode symbol is 2048. The subcarrier spacing is 78.125 kHz and the FFT duration is 12.8 μ s. The normal guard interval is 800 ns so that the symbol time is 13.6 μ s. The details of 802.11ax subcarriers, guard time, modulation, and coding are found in reference [1] and not repeated in this paper.

Multiple access can use the time and frequency domain. The space domain can also be used for multiple user access to the radio channel in several ways. Simply separating networks in space is one way. As the coverage falls off in one wireless network another wireless network can reuse the frequency and time resources. Spatial reuse employs transmit level control and coordinated transmissions that help multiple wireless networks to use shared time and frequency resources.

When multiple transmitters and receivers are used in a channel with strong reflections from scattering objects, multiple spatial streams can send information using the same time, spectrum, and space. With two transmitters and two receivers, two spatial streams can be sent. There are four paths from the two transmit antennas to the two receive antennas. This forms a 2x2 channel matrix. If the channel matrix can be inverted the receiver can calculate the two input signals by multiplying the output signal with the inverse of the estimated channel matrix.

Likewise, with four transmitters and four receivers four spatial streams can be sent. This poses a bit of a dilemma since most phone, tablet, and notebook wireless adapters are 2x2. A 4x4 AP can send four spatial streams and yet only two spatial streams to a 2x2 STA. This is a bit of a waste of the AP capability.

In general, this is not so bad. Four spatial streams at the highest PHY rates with 4x4 AP and 4x4 STA turn out to be quite rare. A 4x4 AP and a 2x2 STA turns out to be a performance sweet spot. The combination of two spatial streams and beamforming with a 4x4 AP to a 2x2 STA works at high PHY rate at good distance in residential multipath channels. Even so, MU-MIMO comes to the rescue by allowing a 4x4 AP to send four spatial streams to 2x2 STAs. We just need to have two or more 2x2 STAs with MU-MIMO capability.

3. Types of multiuser techniques in Wi-Fi 6e 802.11ax

The wireless access point for a residential broadband service connects many customer devices. Homes with broadband service may have multiple users with each user having several devices. A family of four active users, each with both a notebook computer and smart phone, along with two television sets and many home security and automation and health devices, provides a useful canonical example. There are three dimensions in which users can share access to the wireless network: space, time, and frequency.

In the time dimension each user gets a slice of time to use the wireless network. In the downlink from AP to STA all users receive the same signal and just need to know which time slice is meant for them. This is referred to as time division multiplexing (TDM). In the uplink from STA to AP the user must contend for a time slice or be assigned a time slice so that only one STA transmits to the AP at a time. This is referred to as time division multiple access (TDMA).

In the frequency domain each user is assigned a different portion of the channel width. The channel is broken up into tones and each tone is individually modulated with data. A discrete Fourier transform implemented with a fast Fourier transform that is a mathematical technique which makes modulating many tones over a channel-width very efficient. The 160 MHz channel width of a Wi-Fi 6 signal is created with a 2048-point FFT. The tones are spaced by 78.128 kHz with an FFT duration of 12.8 μ s. In the uplink from STA to AP, OFDMA allows multiple devices to transmit at the same time with each STA assigned different tones of the FFT symbol. In the downlink from AP to STA, OFDMA transmits a full FFT symbol by the AP that is received by all STAs with each STA assigned tones. Equation (7) shows the calculation of the subcarrier spacing and FFT duration for a 160 MHz channel width and 2048-point FFT forming a Wi-Fi 6/6e he mode 802.11ax OFDMA symbol.

$$B = 160 \times 10^6 \text{ Hz} \quad N_{FFT} = 2048 \quad \Delta f = \frac{B}{N_{FFT}} = 78.128 \times 10^3 \text{ Hz} \quad T_u = \frac{1}{\Delta f} = 12.8 \times 10^{-6} \text{ s} \quad (7)$$

It is important to realize that there is no theoretical difference between time division and frequency division multiplexing regarding channel capacity or throughput. Allowing users to take turns in time or allowing users to use the channel at the same time over portions of the channel width results in the same

efficiency. The details of the use case and the channel characteristics will determine if one technique has advantages over the other for a given situation. Accessing the channel in the time domain requires quite a bit of set up. To address the hidden node problem, a request to send signal is sent, followed by a clear to send reply, followed by the data transmission, and wrapped up with an acknowledgement. An interframe spacing is required between each of these bursts. A channel busy assessment, and potentially a backoff, is required before each transmission. The transmissions themselves have a preamble so that the payload data symbols can be demodulated. Even with a PHY rate of 2400 Mbps, there is a lot of set up that makes the channel usage inefficient for small amounts of data throughput. Here is where OFDMA may have an advantage over TDMA. In the case where many users have a small amount of data to transmit, rather than go through all the set up for each one at a time, efficiency is achieved by setting up all the devices to work at the same time on small chunks of the channel width, OFDMA.

The space dimension is a bit different as it depends heavily on the reflections due to scattering objects in the home. Multiple spatial streams of information can be sent at the same time and same frequency. This is possible when there is difference in the space dimension that allows the information streams to be sorted out. In the downlink direction when the STAs are in different physical locations, beamforming may be possible to create constructive interference to the desired station and destructive interference to the undesired station. With beamforming an information stream can be sent to one station with a null towards another station. Then a second information stream can be sent to the other station with a null to the first station.

The uplink space dimension multiple access is more of a true MU-MIMO. Here each station can send an information stream to the access point. The access point receives the signal from all the stations. Multiple inputs from the station's transmitters are received by the multiple antennas of the access point. The access point then makes a channel estimate and determines the many input signals by multiplying the channel inverse matrix by the receive vector. The key difference between uplink and downlink MU-MIMO is that the downlink requires a priori beamforming while uplink all processing can be performed after signal reception.

Five multiuser techniques in Wi-Fi 6e 802.11ax work together when many users are trying to access the wireless network. OFDMA and MU-MIMO work both in the downlink from AP to STA and the uplink from STA to AP. OFDMA and MU-MIMO work together. OFDMA and MU-MIMO are key building blocks of spatial reuse. Orthogonal frequency division multiple access, OFDMA, divides the OFDM symbol with many subcarriers over the channel width into resource units assigned to individual stations.

4. DL MU-MIMO

The maximum PHY rate with four spatial streams and 160 MHz channel width is 4800 Mbps. Each spatial stream with a 160 MHz channel width at MCS11 is 1200 Mbps. Four spatial streams require a minimum 4x4 AP and 4x4 STA. Four transmit antennas and four receive antennas are needed for four spatial streams. Most wireless adapters in phones, tablets, and notebook computers are 2x2, some with 80 MHz channel width and others with 160 MHz channel width. These 2x2 devices are limited to two spatial streams. Downlink (DL) MU-MIMO enables the 4x4 AP to fully utilize four spatial streams by sending information streams to many 2x2 wireless adapters at the same time. A 4x4 AP and two 2x2 STAs has the same multiple input multiple output structure as a 4x4 transmitter sending spatial streams to a 4x4 receiver. In both cases there are four transmit antennas and four receive antennas and 16 paths from antenna to antenna.

A critical difference between a 4x4 transmitter sending MIMO spatial streams to 4x4 receiver and DL MU-MIMO is that the stations do not receive all four signals. The receivers cannot make a channel

estimate and invert the four-by-four channel matrix and then multiply by the four-vector output to determine the four input signals. Instead, the stations provide beamforming feedback based upon channel sounding that the AP can use to send multiple spatial streams that add at one station and subtract at another.

In practice we find that with a 4x4 AP four spatial streams do not often happen while three spatial streams at the highest MCS rate are common at reasonable distances. With four vertically polarized half wave dipoles spaced 5/4 wavelength apart, the optimum DL MU-MIMO is in the azimuthal direction. With stations spaced in various adjacent rooms from the AP, three spatial streams at the highest MCS rate can be measured. Table 2 shows such an example. This is a DL MU-MIMO measurement with a 4x4 AP and two wireless adapters in notebook computers with 80 MHz channel width, 2x2 MIMO configuration, and 1200 Mbps maximum PHY rate. With a 1200 Mbps maximum PHY rate, a single device can download at most between 900-1000 Mbps. The maximum PHY rate of a single he spatial stream with 80 MHz channel width is 600 Mbps. Three spatial streams have a maximum PHY rate of 1800 Mbps. With 1800 Mbps PHY rate a TCP throughput of 1200 Mbps is possible. The measurement shown in Table 2 finds a total TCP throughput of 1285 Mbps. This is an important use case in delivering Gbps broadband service to customers. For example, if the broadband service has a peak speed of 1.2 Gbps then a single 2x2 80 MHz 802.11ax wireless adapter cannot by itself deliver the full broadband speed. However, several devices together can combine to exceed 1.2 Gbps Wi-Fi speed. This works well with two, three, and four DL MU-MIMO stations. We find that three DL MU-MIMO stations are the sweet spot, having slightly higher aggregate download speed than two or four stations.

The access point is 4x4 160 MHz 4800 Mbps PHY. The stations are 1200 Mbps PHY, 2x2, 80 MHz. The 80 MHz channel width 2x2 STAs used in the measurement of DL MU-MIMO in Table 2 provide beamforming feedback consisting of 10 angles every fourth subcarrier over the full 80 MHz. This powerful beamforming results in high PHY rate and throughput in both SU and MU operation. DL MU-MIMO shown in Table 2 is 5 GHz band with 80 MHz channel width devices.

Table 2 - DL MU-MIMO Measurement 1200 Mbps PHY Stations

STA	PHY Mbps	Data Mbps	bw MHz	mcs	Nss	mu-mimo
0	617.6	450.9	80	11	1	96.9%
1	1136.7	834.1	80	10.5	2	100.0%
sum		1285.0				

In Table 3 the stations are 2400 Mbps PHY, 2x2, 160 MHz, operating DL MU-MIMO in the 6 GHz band with 160 MHz channel width. Table 3 shows a measurement sample with two 160 MHz wireless adapters using DL MU-MIMO to download TCP at over 2 Gbps. Each device alone can download at around 1.6 to 1.8 Gbps TCP with a maximum of 1.92 Gbps. DL MU-MIMO increases the number of spatial streams to three, resulting in a capacity increase and an aggregate download for two devices over 2 Gbps, something not possible in single user, SU mode.

Table 3 - DL MU-MIMO Measurement Two 2400 Mbps PHY Stations

STA	PHY	Data	Channel width	MCS	Spatial streams	MU-MIMO
	Mbps	Mbps	MHz			
0	1310.0	755.8	160	11	1	90.9%
1	2401.0	1400.8	160	11	2	99.0%
sum		2156.6				

From Wireshark captures of the beamforming feedback from the 2x2 160 MHz 802.11ax stations used for the DL MU-MIMO measurement, only a single set of ten angles is reported. The beamforming for both SU and MU do not seem to work as well for these 160 MHz devices compared to 80 MHz devices with richer beamforming feedback over the full channel width. The PHY rates and throughput of the 160 MHz channel devices are still greater than the 80 MHz devices given the doubling in the number of data subcarriers. Yet, the 80 MHz channel width devices work better than the 160 MHz devices when normalized for spectrum use.

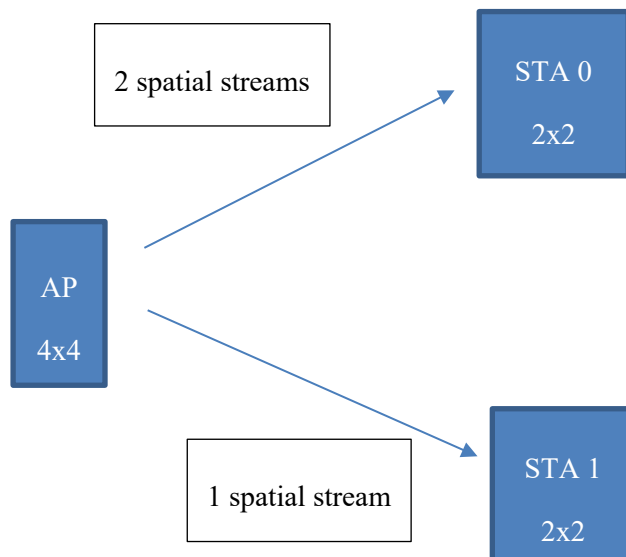

Figure 4 - DL MU-MIMO Example Block Diagram

Table 4 shows a sample measurement of DL MU-MIMO with three 160 MHz wireless adapters. In this sample, the devices were further away from the AP and the MCS rate dropped to between 8 and 9. As a result the sum of the data rates downloaded by the three devices was 1.5 Gbps, less than the maximum at the highest PHY rate, yet still an improvement over SU operation at these distances. DL MU-MIMO increases capacity of the wireless networks only when several devices have large files to download at the same time from Internet servers capable of Gbps downloads with all devices in high SNR conditions with good multipath reflections.

Table 4 – DL MU-MIMO Measurement Three 2400 Mbps PHY Stations

STA	PHY	Data	Channel width	MCS	Spatial streams	MU-MIMO
	Mbps	Mbps	MHz			
0	1696.8	782.4	157.5	8	2.0	97.7%
1	1246.3	595.3	157.9	8.7	1.3	69.2%
2	959.2	180.5	159.2	9.0	1.0	99.35
sum		1558.2				

DL MU-MIMO requires quite a bit of traffic demand from several capable devices at close range. Applications do not often generate enough traffic for DL MU-MIMO packets to be sent. An application downloading a large movie on a smart phone would seem to be ideal for MU-MIMO. However, when tried, the application downloaded the movie to the phone at 10 Mbps, not enough for DL-MU-MIMO.

5. UL MU-MIMO

Uplink multiuser multiple-input multiple-output allows several stations to transmit spatial streams at the same time. The access point collects the signals from each station and sorts out the spatial streams. UL MU-MIMO is pure MIMO whereby the receiver can process all the streams after reception rather than relying on a priori adaptive beamforming as in the case for DL MU-MIMO.

UL MU-MIMO has the advantage of significant spatial diversity and angle of arrival of spatial streams as the stations transmitting the streams can be in different locations relative to the access point.

Multiple stations can each transmit a spatial stream to the AP at the same time. The AP has multiple antennas and receivers. Each of the AP antennas receive a combination of all the signals from the stations. The spatial streams of independent information are all mixed together at each AP receiver. Without strong multipath in the channel and good channel estimation at the AP, the information streams from each station would be hopelessly jumbled. Each antenna of the stations to each antenna of the AP has an impulse response defined by the attenuation and delay of the direct path and various reflections from scattering objects.

The Fourier transform of the impulse response from antenna to antenna in the presence of multipath reflections reveals a frequency response that would need to be characterized in a single carrier system. OFDM comes to the rescue for UL MU-MIMO since each tone is narrow and can be considered as a flat frequency response. Thus, each antenna-to-antenna path is treated on a tone-by-tone basis and characterized by a single complex number per tone representing the Fourier transform of the impulse response. In practice the channel matrix is adequately characterized by the phase differences between the various paths.

UL MU-MIMO the AP estimates the channel matrix, inverts the channel matrix, and multiplies the inverted channel matrix by the received vector to determine the input signals from each of the stations. Thus, all the information streams from the stations can be decoded.

6. DL OFDMA

Downlink orthogonal frequency division multiple access divides the spectrum into tones and assigns resource units consisting of continuous tones to multiple stations. In general, with heavy traffic, DL OFDMA does not increase capacity. DL MU-MIMO increases channel capacity when stations are in a high signal to noise ratio (SNR), zone and enough traffic demand is there to fill the pipe. DL OFDMA is complementary in the sense that it helps when stations are in a low SNR zone with small amounts of data to transmit. Here SNR is defined as the average power of the transmitted signal at the receiver demodulator divided by the average noise and interference level from all sources expressed in dB. DL OFDMA does not improve the link budget in the same way as UL OFDMA. While stations in theory could take advantage of the lower noise floor of a smaller resource unit allocation, devices tend to demodulate the full downlink channel width and do not measure improved sensitivity due to DL OFDMA.

DL OFDMA is observed when devices are far enough away to forfeit DL MU-MIMO capacity increase and when traffic demand is low. One of the big advantages observed with DL OFDMA relates to the scheduler. With SU and many devices competing for wireless resources there is a tendency for one device to dominate the throughput. With several devices downloading at the same time one device may have very high throughput while the other devices are stuck at low throughput. DL OFDMA is much better at sharing the channel with each device downloading at close to the same throughput.

DL MU-MIMO takes a heavy traffic demand from multiple devices able to utilize DL MU-MIMO and a considerable amount of time. Typically, about 200 Mbps or more from several devices for over one minute is required to see DL MU-MIMO packets. By contrast, DL OFDMA packets make up a large proportion of traffic even with small amounts of traffic and the setup is very quick.

7. UL OFDMA

Uplink orthogonal division multiple access allows multiple stations to transmit at the same time with each using a different part of the channel width. UL OFDMA improves the link budget in the uplink. Each station can only transmit so much power. The maximum transmit level in the 2.4 GHz band for a typical wireless adapter in a notebook computer ranges from +17 to +21 dBm per chain with two chains in a 20 MHz channel width. Restrictions on out of band radiated emissions often results in different transmit power on some channel settings. 5 GHz band station transmit level typical ranges from 10 to 18 dBm per chain with two chains. The wireless adapter in the notebook computer used for 160 MHz channel width measurements in this paper is a type accepted with 5 dBi antenna gain in the 5 GHz band and transmit level of about +15 dBm per chain with two chains for a 160 MHz HE0 signal at 5570 MHz, +17 dBm per chain for an 80 MHz HE0 signal at 5530 MHz, +17 dBm per chain for a 40 MHz HE0 signal at 5510 MHz, and +18 dBm per chain for a 20 MHz HE0 signal at 5500 MHz. Note that the power spectral density and thus the received SNR, increases when the channel width decreases. The 160 MHz channel width case has 12 dB lower signal to noise ratio at the AP receiver than the 20 MHz channel width, 9 dB due to higher receiver noise level at 160 MHz compared to 20 MHz, and 3 dB due to the increase in transmit level at 20 MHz compared to 160 MHz. Therefore, the uplink channel width will drop to 20 MHz at the cell edge in the 5 GHz band. In the 6 GHz band for low power indoor operation the effective isotropic radiated power (EIRP) of the power spectral density is regulated and the behavior at cell edge is different. Figure 5 shows a measurement of the uplink dynamic range with PHY rate improving with the received signal strength indicator (RSSI).

Figure 5 - Dynamic Range in the uplink

Table 5 shows a sample of measurement results with two computers uploading at the same time in the 6 GHz band. Both the AP and the STA fall below the restrictions for low power indoor operation. The coverage is good throughout the home used for the measurement. Shown in Table 5 are cell edge conditions with stable connection and throughput, but connectivity will be lost at further distance between the AP and STA or more obstructions. Both stations are 2x2 wireless adapters in notebook computers with 160 MHz channel width capability and 2400 Mbps maximum PHY rate. The channel width remains at 160 MHz since under the regulatory limit of -1 dBm EIRP per MHz the uplink does not benefit from reduced channel width. UL OFDMA accounts for all the uplink packets with about 1000 tones allocated to each station. The PHY rate of each station is about 70 Mbps and the total upload rate was measured at 49 Mbps. Both stations sent two spatial streams at the lowest MCS rate of 0.

Table 5 – UL OFDMA Measurement Two 2400 Mbps PHY Stations 6 GHz band

STA	rssi	PHY	Data	Channel width	MCS	Spatial streams	ofdma	tones
	dBm	Mbps	Mbps	MHz				
0	-85	72.5	32.9	160	0	2	100%	1002.7
1	-85	73.5	16.0	159	0	2	100%	1014.3
sum			48.9					

Table 6 shows a sample measurement in the 5 GHz band with two 2x2 80 MHz stations having a maximum PHY rate of 1200 Mbps. Both stations are notebook computers using a common Unix based operating system. The sample measurement shown in Table 6 is the lowest observed UL OFDMA RSSI levels at the AP while making measurements of the two computers uploading data throughout a two-story residential home as well as outside the home with coverage up to 100 meters. Both stations have an uplink RSSI at the AP of -86 dBm. The channel width was 80 MHz with each station assigned about 484 tones with 100% UL OFDMA packets. The total throughput was 26.4 Mbps with PHY rates of 35 and 47 Mbps. Both stations transmitted two spatial streams at the lowest MCS level of 0.

Table 6 – UL OFDMA Measurement Two 1200 Mbps PHY Stations 5 GHz band

STA	rssi	PHY	Data	Channel width	MCS	Spatial streams	ofdma	tones
	dBm	Mbps	Mbps	MHz				
0	-86	35.2	12.7	80	0	2	100%	491
1	-86	47.4	13.7	79	0.3	2	100%	497
sum			26.4					

The 160 MHz stations in the 6 GHz band utilized UL OFDMA down to a receive level at the AP of -86 dBm. The 80 MHz stations in the 5 GHz band utilized UL OFDMA down to a receive level at the AP of -86 dBm. Is this good? Why were these the lowest observed levels? To answer these questions and better understand what is going on, let us review noise floor and Boltzmann constant. The thermal noise floor of the receiver is determined by Boltzmann constant and the noise figure of the low noise amplifier.

Ludwig Boltzmann developed statistical mechanics to understand the physics of steam engines. Boltzmann constant relates temperature to energy. Boltzmann constant applies equally well for determining the thermal noise in a receiver due to the vibrations of electrons. The thermal noise density is -174 dBm per Hz at room temperature of 300 Kelvin, equal to 25 degrees Celsius and 77 degrees Fahrenheit.

$$E = k_b T \quad (8)$$

$$k_b = 1.380649 \times 10^{-23} \quad (9)$$

$$N_0 = 10 \log_{10}(1000 \cdot 1.380649E - 23 \cdot 300) \quad (10)$$

$$N_0 = -174 \frac{\text{dBm}}{\text{Hz}} \quad (11)$$

The receiver noise floor referenced to the antenna input terminals depends upon the thermal noise density, the noise bandwidth, and the noise figure of the low noise amplifier. A 3 dB noise figure is a reasonable expectation for an AP allowing for a 1 dB noise figure low noise amplifier and 2 dB of losses through the switch, filters, and traces to the antenna.

$$N = N_0 + F + 10 \cdot \log_{10}(B) \quad (12)$$

$$B = 20 \text{ MHz}$$

$$N = -174 + 3 + 10 \cdot \log_{10}(20E6)$$

$$N = -98 \text{ dBm} \quad (13)$$

The receiver noise floor at room temperature with a 3 dB noise figure receiver in a 20 MHz channel width is -98 dBm.

Table 7 – Receiver noise floor and channel width for 3 dB noise figure at room temperature

B	N
MHz	dBm
20	-98
40	-95
80	-92
160	-89

In the 6 GHz band for low power indoor operation the AP is restricted to +5 dBm EIRP per MHz and the STA is restricted to -1 dBm EIRP per MHz. The AP can transmit +16 dBm per chain with four chains, 2.15 dBi half wave dipole antenna elements, 3 dB beamforming gain with two spatial streams.

Table 8 – EIRP regulation in the US for 6 GHz low power indoor access points

EIRP per MHz	5.00	dBm/MHz
channel width	160.00	MHz
channel width	22.04	dBMHz
EIRP	27.04	dBm
Antenna Gain	2.15	dBi
Beamforming Gain	3.00	dB
total transmit level	21.89	dBm
chains	4.00	
transmit level per chain	15.87	dBm per chain

The station EIRP per MHz in the 6 GHz band for low power indoor operation is -1 dBm per MHz. A 2x2 station with half wave dipole antenna element gain is limited to +16 dBm per chain transmit level for a 160 MHz channel width signal.

Table 9 – EIRP regulation in the US for 6 GHz low power indoor stations

EIRP per MHz	-1.00	dBm/MHz
channel width	160.00	MHz
channel width	22.04	dBMHz
EIRP	21.04	dBm
Antenna Gain	2.15	dBi
Beamforming Gain	0.00	dB
total transmit level	18.89	dBm
chains	2.00	
transmit level per chain	15.88	dBm per chain

Most stations transmit 6 to 9 dB lower than the levels shown in Table 9. The phones used to make the measurements of MU-MIMO and OFDMA in the 6 GHz band operate at +7.5 dBm per chain with two chains and antenna element gain of -6 dBi. The notebook computers used to measure MU-MIMO and OFDMA operate at +10 dBm per chain with two chains in the 6 GHz band with 160 MHz channel width.

The wavelength is calculated by dividing the speed of light by the frequency. In Equation 14, c is the speed of light, f is the frequency in Hz, and λ is the wavelength in meters. Table 10 shows the wavelength in mm for 2.4 GHz band channel 1, 5 GHz band channel 100, and 6 GHz band center frequency of a 160 MHz channel width signal having primary steering channel 69.

$$c = 299,792,458 \text{ m/s speed of light} \quad (14)$$

$$\lambda = \frac{c}{f} \quad (15)$$

Table 10 – Relationship between frequency and wavelength for 2.4, 5, 6 GHz bands

frequency	wavelength
MHz	mm
2412	124.3
5500	54.5
6345	47.2

The free space path loss at a reference distance is denoted A_0 measured in dB. The reference distance is denoted by d_0 measured in meters. A_0 is calculated as a function of d_0 and λ as shown in Equation (16).

$$A_0 = 20 \cdot \log_{10} \left(\frac{4\pi d_0}{\lambda} \right) \quad (16)$$

A log normal path loss model can be applied for distances beyond the reference distance. L is the log normal path loss in dB. A_0 is the free space path loss at the reference distance d_0 in meters. The distance between the AP and STA in meters is d . L_{floors} is the loss through floors and L_{walls} is the loss through walls. N_σ is a log normal probability distribution with standard deviation σ , typically around 3 dB. Equation 17 shows the IEEE 802.11 log normal path loss model for indoor residential channel.

$$L = A_0 + 35 \cdot \log_{10} \left(\frac{d}{d_0} \right) + L_{floors} + L_{walls} + N_\sigma \quad (17)$$

The Friis transmission equation was derived in 1945 at Bell Labs by Harald T. Friis. R is the received level in dBm, $EIRP$ is the effective isotropic radiated power equal to the transmitter power level plus the transmitter antenna gain, L is the log normal path loss in dB, G is the antenna gain of the receiver. A version of the Friis transmission equation is shown in Equation (18).

$$R = EIRP - L + G \quad (18)$$

Table 11 shows the distance d in meters for a 6 GHz band signal with channel width 160 MHz for each MCS level along with the PHY rate in Mbps and the maximum TCP throughput in the uplink for a low power indoor station at -1 dBm EIRP per MHz. This table does not include wall and floor loss or the log normal probability distribution factor. As can be seen the distance is quite far at 132 meters.

The wall and floor loss is a wild card. Often the wall and floor loss is not that much. Drywall attenuation may only be around 1 dB. Plaster with wire mesh can be 20 dB attenuation or more. Brick and concrete can have high attenuation. Even some glass sliding doors can have high attenuation. The indoor residential IEEE 802.11 path loss model uses a floor attenuation that is quite high at 20 dB for a single floor. This is much higher than often observed in practice. The wall attenuation used in the calculation references the IEEE 802.11 model of 5 dB per wall. Using these factors for the case of one floor and two walls the additional 30 dB attenuation reduces the coverage distance to 18 meters for the lowest MCS rate. Eighteen meter coverage is still not bad considering the high wall and floor attenuation.

An important point to notice is MCS 6 at a distance of 43 meters. The receive level in the uplink is -69 dBm. The PHY rate is 1297 Mbps and the TCP throughput is 1037 Mbps. This is the lowest level that will still deliver over 1 Gbps speed to the customer.

Table 11 – Distance, receive level for 160 MHz channel width uplink low power indoor station EIRP -1 dBm per MHz

MCS	Rx	PHY	TCP	d 6 GHz
	dBm	Mbps	Mbps	m
0	-86	144	115	132
1	-83	288	230	108
2	-81	432	345	95
3	-78	576	461	78
4	-74	864	691	60
5	-70	1152	922	46
6	-69	1297	1037	43
7	-68	1441	1152	40
8	-63	1729	1383	29
9	-61	1922	1538	25
10	-58	2161	1729	21
11	-56	2401	1920	18

8. Spatial Reuse

There are two different types of spatial reuse. PD uses power detection. SRP uses spatial reuse parameters contained within an OFDMA trigger.

Power detection spatial reuse lowers transmit level based upon neighbor's RSSI. The channel busy threshold for an 802.11 signal is -82 dBm. The energy detection threshold for a non-802.11 signal is -62 dBm. Oftentimes real devices deviate from the threshold levels called out in the IEEE 802.11 standards.

If the RSSI of a neighbor device, be it AP or STA, exceeds -82 dBm then the channel is determined to be busy. After an exponential time back-off the transmitter will be checking for channel busy once more, hoping for an opportunity to transmit when no non-802.11 signal exceeds -62 dBm and no 802.11 signal exceeds -82 dBm. Then the AP or STA will transmit.

Power detection spatial reuse allows the AP or STA to transmit even when an 802.11 neighbor signal exceeds -82 dBm. To reuse the time and frequency resources efficiently in two different locations the transmit power is reduced in proportion to the neighbor RSSI. If the neighbor RSSI is -72 dBm then the

transmit level is reduced by 10 dB. If the neighbor RSSI is -62 dBm then the transmit level is reduced by 20 dB.

In effect, power detection spatial reuse keeps the interference toward a neighbor wireless network no worse than full power with -82 dBm threshold while allowing for more transmit opportunities. The power detection method will work with any device, even devices without spatial reuse capability.

The SRP method is much more interesting, and powerful. SRP requires all participants to have spatial reuse capability. The UL OFDMA trigger of a neighbor contains the information needed to reuse time and frequency resources in different locations without interference. The path loss to the neighbor can be calculated by subtracting the measured RSSI from the neighbor transmit level read in the trigger. The trigger will advertise an acceptable level of interference to the UL OFDMA transmission. A transmit level can thereby be calculated that can work over top the neighbor UL OFDMA signal without interference.

9. Putting It All Together With Real Devices and Applications

Consider an illustrative use case with a phone, a notebook computer, and two television sets. All four of these devices have the same Wi-Fi capabilities, including multiple user. The four stations have a maximum PHY rate of 1200 Mbps. There are many different types of Wi-Fi clients. Some have 160 MHz channel width while others only operate at 80 MHz channel width. The devices tested for MU operation with a mix of traffic were 80 MHz channel width wireless adapters, which is very common. Each device has different application needs and different throughput capabilities. A mix of devices is shown in Figure 6.

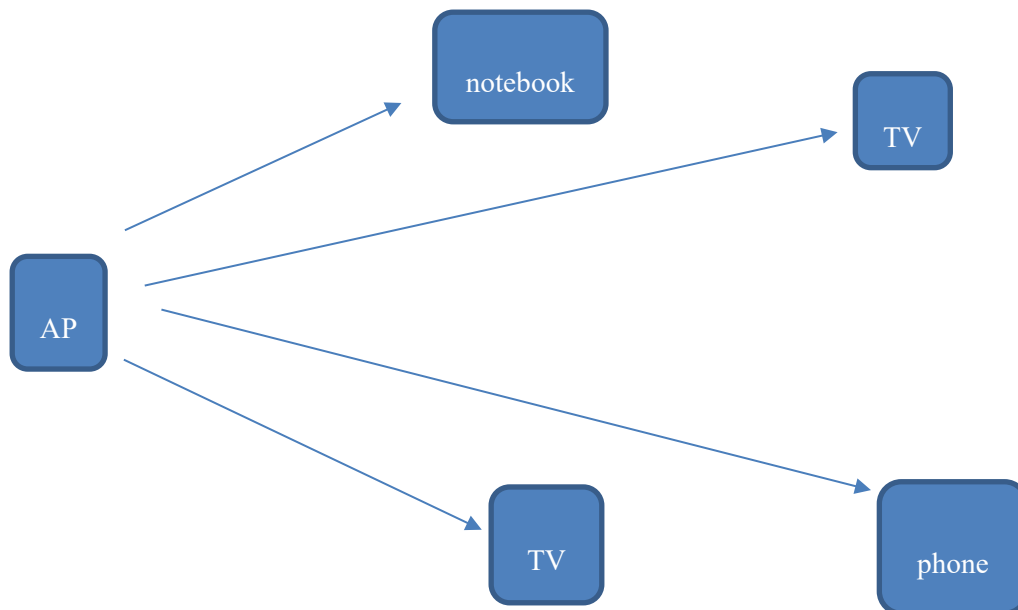

Figure 6 - Traffic mix

The measurement procedure begins with verifying broadband service from each of the devices used for the test. The cable modem wireless router used has four Ethernet LAN ports, three 1 Gbps speed and one 2.5 Gbps speed. A computer with a 2.5 Gbps USB-C network adapter is connected to the 2.5 Gbps Ethernet LAN port of the router. A speed test taken on the computer connected to the 2.5 Gbps Ethernet LAN port of the router measured 1.4 Gbps download. This verifies that this computer has a broadband connection at the full speed of the service.

Next, a computer with a 6 GHz band, 2x2 MIMO, 160 MHz channel width, 2400 Mbps PHY rate is connected to the 6 GHz band radio of the cable modem wireless gateway and a speed test is run at close range. The locations necessary for the highest PHY rate of 2400 Mbps are in the same room, and adjacent rooms on the same floor, or directly upstairs or downstairs of the AP. The speed test, although not as consistent as the DOCSIS to Ethernet speed, measured 1.3 Gbps download speed. This verifies the full broadband speed from DOCSIS WAN to 6 GHz radio.

While it is convenient and sometimes useful for testing purposes to measure from Ethernet LAN to Wi-Fi, it is imperative to include DOCSIS to Wi-Fi testing and verification since this accounts for almost all customer traffic. The phone and computer used in the mixed traffic MU testing measured download speed tests between 800 and 900 Mbps. The phone and computer wireless adapter were 2x2 MIMO, 80 MHz channel width, 1200 Mbps PHY. The set up shown in Figure 7.

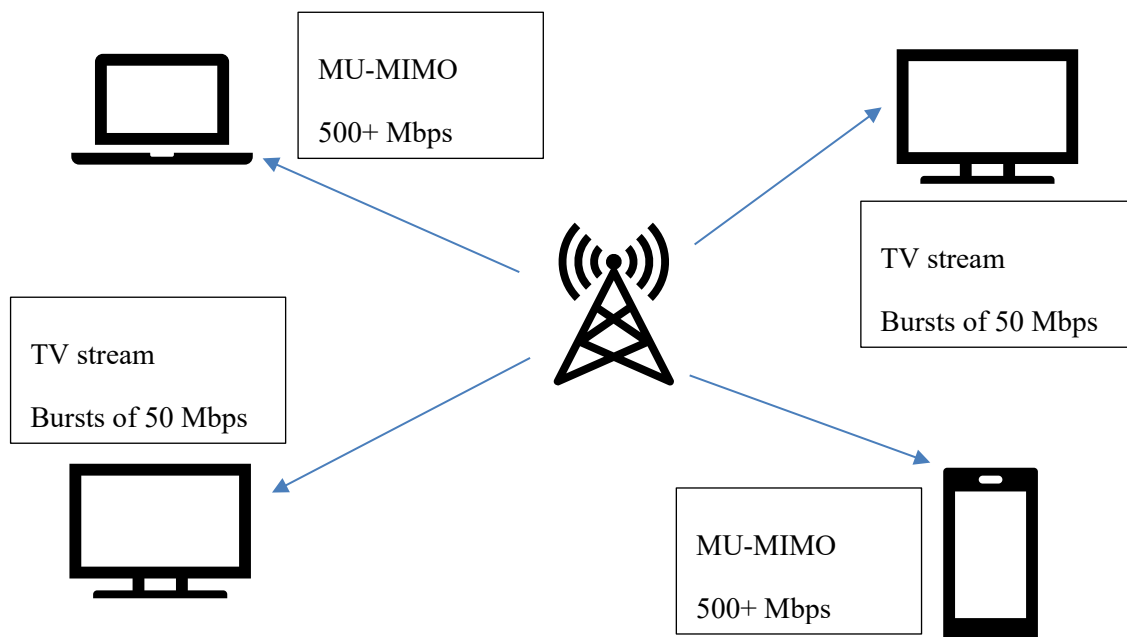

Figure 7 - DL MU-MIMO and UL OFDMA traffic mix

Generating traffic demand to form DL MU-MIMO required using iperf3 on the client phone and notebook computer with a server connected to the 2.5 Gbps Ethernet port of the cable modem wireless router. Traffic exceeding 1 Gbps was measured even though no individual station was capable on its own to download at 1 Gbps. Thus, DL MU-MIMO allowed the total of multiple devices working together to exceed that of any one device.

In addition to the download of large files to the computer and phone, two television sets with the same wireless adapters were used for streaming video. The statistics of the measured throughput listed in Table 12 and the graph of throughput for each device over time is shown in Figure 8. The television sets had bursty traffic with peaks of about 50 Mbps and average of 10 Mbps. The computer and phone had aggregate download speed that exceeded 1 Gbps employing DL MU-MIMO and UL OFDMA at the same time as the two video streams operating without impairment.

Table 12 - Statistics of Throughput with Four MU devices

Stat	phone	computer	TV1	TV2	Sum
average	455.9132	407.8673981	15.32821	8.530408	887.6392
std	126.2928	208.0782331	9.354155	14.13454	152.5777
max	917.4	785.2	49.7	64.5	1212

While these measurements focused on DL MU-MIMO, UL OFDMA was used for the lower bandwidth upload response. This is a good example of the various multiple user techniques working together for a better overall user experience.

Figure 8 - DL MU-MIMO and UL OFDMA Measured traffic mix

As seen in Figure 8 the sum of traffic often exceeds 1 Gbps and even peaks at 1.2 Gbps. This is a good example of MU techniques helping to deliver Gbps broadband service when devices work together. Alone, none of these devices can use the full broadband service. Yet working together, the customer receives the benefit of the full speed of the broadband service.

10. Conclusion
